PREFACE

I am delighted to convene our 8th International Conference on Urban Earthquake Engineering here in Tokyo on March 7th and 8th, 2011, once again welcoming numerous distinguished experts and guests from around the world. The conference has been held annually in Tokyo since fiscal year 2003 under the auspices of two major consecutive Center of Excellence (COE) programs, both headquartered at the Center for Urban Earthquake Engineering (CUEE) here at Tokyo Tech. These are the 21st Century COE program entitled "Evolution of Urban Earthquake Engineering" (FY 2003-2007) and the subsequent Global COE program entitled "International Urban Earthquake Engineering Center for Mitigating Seismic Mega Risk" launched in fiscal year 2008.

The current program aims not only to promote research to mitigate the seismic "mega" risk confronting vast and numerous modern cities in earthquake regions throughout the world, but also to produce next-generation practitioners and researchers whose task it will be to develop new strategies and practices for seismic risk reduction. Therefore, this 8CUEE once again seeks to promote our twin goals of intensive information dissemination and technology transfer, all in furthering the very active international network that is directed toward our young researchers in this field, through a sustained international collaborative effort.

The Eighth Conference offers a platform not only to share common interests and new information and technologies in the field of Urban Earthquake Engineering but also to share our collective research and educational outcomes, while expediting and strengthening the worldwide network for Earthquake Engineering. The Conference is to feature state-of-the-art technical presentations as well as an agenda of some 250 oral presentations on various themes relevant to Urban Earthquake Engineering, with participation comprising

scientists, engineers, researchers, and active planners of divers generations, including both younger researchers as well as graduate students. This conference also includes Special Sessions and Best Presentation Awards for Young Researchers. To facilitate conference participation of young researchers, postdoctoral fellows and PhD students, travel grants have been awarded this year again to some forty individuals studying or working at collaborating institutions.

This conference will be capped by two Special Lectures in honor of the retirement from Tokyo Tech of Professors Akira Wada and Tatsuo Ohmachi, both of whom have dedicated themselves and their professional activities to the progress of our discipline, not to mention the promotion of a robust faculty in the field of Earthquake Engineering at TiTech. We would like to express both our profound respect and heartfelt appreciation for their accomplishments and efforts. In closing, we hope that the Eighth Conference will prove a rich and stimulating opportunity for all participants, who inclusive of divers generations are dedicated to Urban Earthquake Engineering.

Kohji Tokimatsu
Global COE Program Leader and
Director of CUEE, Tokyo Tech

Table of contents

Paper ID Page

Keynote Lectures

08-076 Achieving Resiliency with Seismic Isolation 1
Stephen Mahin, Kenneth Ogorzalek, and Tracy Becker

02-142 Challenges in Estimating the In-situ Strength of Liquefied Soil 9
Ross W. Boulanger and I. M. Idriss

15-023 Seismic Behaviour of Large Dams During Recent Earthquakes and Current State of Seismic Design Criteria for Large Dams 15
Martin Wieland

15-098 Reflections on Evolution of Near-field Earthquake Engineering 21
Tatsuo Ohmachi

10-311 Wise Dynamic Testing for Enhanced Understanding of Structures 31
Akira Wada, Mineo Takayama, and Satoshi Yamada

Engineering Seismology

12-291 Earthquake Risk Assessment and Corresponding Contingency Plans of the Major Cities of Bangladesh 37
A. S. M. Maksud Kamal

01-229 Major Ground Motion Research Programs at the Pacific Earthquake Engineering Research Center (PEER) 47
Yousef Bozorgnia

01-069 Statistical Features of Short-period and Long-period Near-source Ground Motions 51
Masumi Yamada, Anna H. Olsen, and Thomas H. Heaton

01-112 Strong Motion Record Observed at Concepcion during the 2010 Chile Earthquake 61
Saburoh Midorikawa and Hiroyuki Miura

01-009 Correlation of Strong Ground Motion and Estimations of Seismic Hazard and Loss for Large Areas and Critical Elements of Network 65
Vladimir Sokolov and Friedemann Wenzel

01-206 Preliminary Study of New Attenuation Relationship for Response Spectra on Seismic Bedrock Including near Source Data 75
Hongjun Si, Saburoh Midorikawa, Hideaki Tsutsumi, Akemi Noda and Toshiyuki Masatsuki

01-223 On the Effective Earthquake Early Warning Systems for Both Distant and Near Events 79
Yutaka Nakamura

12-179 Evaluation of SRSND Simulator Againts Fragility Curves for Pisco Quake 89
Carlos Zavala, Zenón Aguilar, and Miguel Estrada

Paper ID		Page
14-181	Land Use Evaluation Using Satellite Imagery for Urban Inventories *Miguel Estrada, Hiroyuki Miura, Fumio Yamazaki, and Saburoh Midorikawa*	93
01-102	Evaluation of Building Damage Areas of the 2006 Central Java, Indonesia Earthquake Detected from Satellite Optical Images *Hiroyuki Miura, Saburoh Midorikawa, and Norman Kerle*	97
15-071	Building Damage and Tsunami Inundation GIS Datasets after the 2010 Chile Earthquake *Yoshihisa Maruyama, Fumio Yamazaki, Shizuko Matsuzaki, Hiroyuki Miura, and Miguel Estrada*	103
01-116	A New Data Logger with Large Dynamic-range to Observe from Microtremors to Strong Motions *Masayuki Araki, Hitoshi Morikawa, Takamori Ito, Masachika Tanigawa, and Keitaro Matsumoto*	109
18-280	Ground Motion and Tsunami Simulation for the Great 1707 Hoei, Japan, Earthquake *Takashi Furumura, Kentaro Imai, and Takuto Maeda*	115
01-083	Nonlinear Site Response of the 2008 Wenchuan, China Earthquake From Time-frequency Analysis *Kuo-Liang Wen, Jyun-Yan Huang , Xiaojun Li, Zhenghua Zhou, and Ruizhi Wen*	121
01-182	Estimation of Shallow 2D S-wave Velocity Profile from Waveform Inversion of Seismic Refraction Data *Hiroaki Yamanaka and Yasutomo Yamauchi*	127
01-028	Earthquake Input Motion to High-rise Building in the Western Part of Kobe City During the 1995 Hyogo- ken Nanbu Earthquake *Masayuki Nagano and Jianjing Zhao*	133
11-012	Sensitivity of Ground Response Analysis to Shear Wave Velocity Profile *Pulpong Pongvithayapanu*	143
01-208	Site Characterization in the Greater Bangkok by Microtremor Observations *Nakhorn Poovarodom and Nonthakorn Plalinyot*	151
14-156	Introduction of the Geological Database for TSMIP *Chun-Hsiang Kuo, Kuo-Liang Wen, Hung-Hao Hsieh, and Kai-Wen Kuo*	157
01-064	Effects of Water Layer on Seismogram Synthesis in Kanto Basin Area based on a Hybrid Boundary Element Method: Numerical Implementation *Zheng-HuaQian, Hiroaki Yamanaka, and Sohichi Hirose*	165
01-100	A Preliminary Study on Variability of Earthquake Ground Motions due to Random Inhomogeneity in Propagation Path *Yoshiyuki Sato and Saburoh Midorikawa*	171
01-021	Reevaluation of Deep Underground Structures in the Tokyo Metropolitan Area, Using Dominant Periods of H/V of Coda Waves Observed by MeSO-NET *Seiji Tsuno, Hiroaki Yamanaka, Shin'ichi Sakai, Naoshi Hirata, Keiji Kasahara, Hisanori Kimura, and Tamotsu Aketagawa*	179

Paper ID Page

07-106 Seismic Response Estimation of Nuclear Power Plant Model Based on Fault-structure System 183
Pher Errol B. Quinay, Tsuyoshi Ichimura, Muneo Hori, M.L.L. Wijerathne, and Akemi Nishida

01-139 Evaluation of Coseismic Displacements in the Near-field from Strong-motion Seismometers. Analysis of Four Recent Large Earthquakes 189
E. H. Javelaud, S. Inoue, A. Furukawa, and T. Ohmachi

01-202 Broadband Source Model for the 2009 L'Aquila, Italy, Earthquake 193
Natalia Poiata, Kazuki Koketsu, Alessandro Vuan, and Hiroe Miyake

01-052 The Possibility of Trap Wave and Site Effect in the Longitudinal Valley of Eastern Taiwan..... 199
Kuei-Mei Lin, Kuo-Liang Wen, Chun-Te Chen, and Jyun-Yan Huang

01-053 Analysis of the Site Effect in Chianan Plain from the 2010 Jiasian, Taiwan, Earthquake 205
Fei-Wen Cheng, Kuo-Liang Wen, Chun-Te Chen, and Jyun-Yan Huang

01-121 Estimation of Shallow S-wave Velocity Structure in Damascus City, Syria, Using Microtremor Exploration..... 211
Hussam Eldein Zaineh and Hiroaki Yamanaka

01-123 Surface Waves on an Exponentially Varying Transversely Isotropic Elastic Medium due to a Subsurface Point Load..... 219
Priza Kayestha, Takatsugu Konno, and Anil C. Wijeyewickrema

01-113 Determination of Shallow Shear-wave Velocity Profiles and Site Amplification in Metro Manila, Philippines Using Microtremor Array Observations..... 227
Rhommel Grutas and Hiroaki Yamanaka

01-148 Estimation of Surface-wave Group Velocity in the Kanto Basin using Seismic Interferometory of Long-term Microtremors..... 233
Kosuke Chimoto and Hiroaki Yamanaka

01-051 Coseismic Deformation of the 2008 Wenchuan, China Earthquake Calculated from Strong Motion Data..... 237
Jyun Yan Huang, Kuo Liang Wen , Chun Te Chen, and Sheng Chung Su

01-075 2D Finite Difference Modeling of Wave Propagation of the 2010 JiaSian, Taiwan, Earthquake..... 243
Chun-Te Chen and Kuo-Liang Wen

Geotechnical Earthquake Engineering

02-045 Seismic Performance of Earth Slopes 247
Ellen M. Rathje, George Antonakos, and Gokhan Saygili

02-097 Application of Discrete Element Method in Geogrid and Aggregate Interaction in a Reinforced Unpaved Roadway..... 255
Wen-Chao Huang

Paper ID Page

02-195 Finite Deformation Analysis of Earthquake Induced Damage to Breakwater during 1995 Hyogoken-nanbu Earthquake 261
Kyohei Ueda, Susumu Iai, and Tetsuo Tobita

02-082 Performance Based Seismic Design Method of Gravity Quay Walls..... 271
Heba Kamal, Mona Aid, and Amira Abdel Rahman

02-107 Centrifuge Model Tests on Dynamic Behavior of Quay Wall Backfilled with Granular Treated Soil..... 279
Yoshiyuki Morikawa, Hidenori Takahashi, Kimitoshi Hayano, and Youtao Okusa

02-313 Centrifuge Model Test of Fault Rupture Propagation in Alluvial Deposit 285
Jiro Takemura, Yukie Ishii, Yusuke Hara and Osamu Kusakabe

02-218 Basic Study for Simulation of Behavior of Soil due to Cyclic Loading using Particle Method..... 293
Tomohide Takeyama

02-115 Seismic Hazard for Maximum Shear Stresses in Soil Layers at Oakland International AirportI 299
Tadahiro Kishida

02-001 Ground Settlements and Earth Pressures around Embedded Foundations Subjected to Strong Ground Shaking 305
Kohji Tokimatsu, Shuji Tamura, Kazushi Tohyama, Hiroko Suzuki, and Hiroyuki Yoshida

02-192 Dynamic Soil-structure-interaction of Shallow Foundations on Dry Sand - A Centrifuge Based Study 311
S.K. Haigh, C.M. Heron, U. Cillingir, and S.P.G Madabhushi

02-128 Impulsive Vertical Acceleration Caused by Foundation Uplift during Earthquake..... 319
Shuji Tamura, Keisuke Adachi, and Kohji Tokimatsu

02-150 Effects of Sway-Rocking Motion on Pile Stresses during Large Shaking Table Tests..... 327
Hiroko Suzuki and Kohji Tokimats

02-006 Effects of Pile Rigidity on Response of Base-isolated Structure during Soil Liquefaction Based on Centrifuge Tests 333
Takenori Hida and Shuji Tamura

02-036 Comparative Study on Effect of Liquefiable Soil-structure Interaction by Shaking Table Test 341
Peizhen Li, Xiuqiang Li, and Xilin Lu

02-026 Dynamic Centrifuge Model Test of Pile-supported Building with Semi-rigid Pile Head Connections in Liquafiable Soil 349
Sadayuki Ishizaki, Kohji Tokimatsu, and Toshiaki Nagao

02-204 Seismic Response of Pile Foundation in Sloping Ground..... 355
Akihiro Takahashi and Takaho Yamazaki

Paper ID Page

02-353 Aging Effect on Liquefaction Strength and Cone Resistance of Fines-containing Sand Investigated in Triaxial Apparatus 359
Takaji Kokusho, Yohta Nagao, and Fumiki Ito

02-091 Estimating Shear Modulus vs Strain From Field Measurements 365
Daniel E. Torres, Giovanna Biscontin, and Jose M. Roesset

02-015 E-Defense Shaking Table Tests for Geotechnical Engineering Research Projects
- Summary of the First Phase and Introduction of Test Series in the Second Phase - 371
Yohsuke Kawamata, Kentaro Tabata, Manabu Nakayama, and Koichi Kajiwara

02-230 The Generalized Scaling Law for Liquefiable Sand Deposit
- Causes of Discrepancy at Low Centrifugal Accelerations - 379
Tetsuo Tobita and Susumu Iai

02-266 Blast-induced Liquefaction for Earthquake Studies 389
Michael Eller and Scott A. Ashford

02-094 Centrifuge Modeling on the Seismic Responses of Sandy Deposit with a Thin Silt Seam 395
Chung-Jung Lee, Yue-Chen Wei, Hon-Chen Lien, and Hui-Tsyr Chen

02-275 Performance-based Post-liquefaction Settlement Hazard Evaluation 401
Steven L. Kramer and Yi-Min Huang

02-037 Geotechnical Aspects of the 2010 Darfield (New Zealand) Earthquake 407
Rolando P Orense, Michael J Pender, Liam M Wotherspoon, and Misko Cubrinovski

15-188 Liquefaction-induced Damage in Christchurch City Caused by the 2010 Darfield Earthquake, New Zealand..... 417
Takashi Kiyota, Mitsu Okamura, Hirofumi Toyota, Misko Cubrinovski, and Rolando P. Orense

15-176 Strong Ground Motions and Site Effects of the 2010 Chile Earthquake 425
Toru Sekiguchi, Nelson Pulido, Gaku Shoji, Jorge Alba, and Fernando Lázares

03-065 Seismic Risk Performance of Urban Transportation Systems Considering Site Effects and Interaction With the Built Environment 433
Sotirios Argyroudis and Kyriazis Pitilakis

03-145 Pipeline Failure in Earthquakes: Should Active Fault Traces BE Considered a Serious Hazard to Buried Pipelines? 441
Francesca Draper, William Mahoney, Suresh Dash, and Subhamoy Bhattacharya

01-243 Estimation of Site Effects based on Recorded Data and the Ground Motion Attenuation Relationship 449
H. S. Kuyuk, K. Koketsu, H. Miyake, H. Si, Y. Fukushima, H. Ghasemi, and R. Ibrahim

02-025 Numerical Simulations of a Centrifuge Test to Study Void-redistribution and Shear-localization Effects 455
Ronnie Kamai and Ross W. Boulanger

Paper ID Page

02-120 Centrifuge Modeling on Uplift Behavior of Immersed Tunnel Embedded in Liquefied Soils 461
Yu-Chen Wei, Wen-Ya Chuang, Wen-Yi Hung, Huei-Tsyr Chen, and Chung-Jung Lee

02-265 Centrifuge Testing of Rocking Foundations on Saturated and Submerged Sand 467
Jacquelyn Allmond, Lijun Deng, and Bruce Kutter

02-132 Failure Mechanisms of Shallow Foundation under Combined Loadings 473
Michael Cocjin, Sakae Seki, and Osamu Kusakabe

02-141 Inclusion of Axial Load on Bending Response of Pile in Liquefiable Soils 483
Domenico Lombardi, Suresh R. Dash, and Subhamoy Bhattacharya

02-170 Simulation of Three-Dimensional Nonlinear Behavior of Soil-Pile-Structure in Large Shaking Table Tests 489
Youhao Zhou, Hiroyuki Yoshida, Hiroko Suzuki, Yasushi Nukui, and Kohji Tokimatsu

02-250 Seismic Analysis of Coupled Soil-pile-structure Interaction using Finite Elements 495
Mahmoud N. Hussien, Tetsuo Tobita, and Susumu Iai

02-197 The Effect of Loading Rate on Bearing Capacity of Pile Foundations 501
Koji Watanabe and Osamu Kusakabe

02-228 Effect of Arch Action on Pseudo-Static Response of Urban Mountain Tunnel at Relatively Shallow Depth in Soft Ground 509
Shuhei Shibayama, Akihiro Takahashi, and Osamu Kusakabe

02-302 Displacement of Tunnels in Liquefied Sand Deposits 517
Siau Chen Chian and Santana Phani Gopal Madabhushi

02-017 Stiffness and Poisson's Ratio Evaluation on Granular Materials by Elastic Wave Measurements on Laboratory Specimen 523
Laxmi Prasad Suwal, Reiko Kuwano, Junichi Koseki and Takeshi Sato

02-340 Effects of Initial Static Shear on Shear Strain Localization Characteristics of Sand in Undrained Cyclic Torsional Shear Tests 531
Gabriele Chiaro, Takashi Kiyota, and Junichi Koseki

02-205 Dynamic Characteristics of the Surface Soils in Lima, Peru 537
Diana Calderon, Toru Sekiguchi, Zenon Aguilar, Fernando Lazares, and Shoichi Nakai

02-169 Simulations of Strong Ground Motions Recorded at Three Stations in Kashiwazaki City during the 2007 Niigata-ken Chuetsu-oki Earthquake 543
Kota Katsumata, Kohji Tokimatsu, and Hiroshi Arai

03-022 Reliability Assessment of Tehran Province Gas Distribution Pipeline System during Liquefaction 551
Danesh Nourzadeh, Khosrow Bargi, and Shiro Takada

03-255 Seismic Performance of a System of Interdependent Lifeline and Infrastructure Components 557
Jacopo Selva, Kalliopi Kakderi, Maria Alexoudi, and Kyriazis Pitilakis

Paper ID Page

02-072 Study of Ground Response of Three Cities of Kathmandu Valley of Nepal Using Microtremor Observations 567
Youb Raj Paudyal, Ryuichi Yatabe, and Netra Prakash Bhandary

18-087 Numerical Study on Scour Problem Induced by Tsunami Flood 577
Tso-Ren Wu, Chung-Yue Wang, Meng-Zhi Chen, Ray Shyan Wu, and Yuan-Fan Tsai

03-038 The Seismic Mitigation Assessment of LNG Tank by 3D Numerical Simulation 583
Ruifu Zhang, Dagen Weng, and Weibo Ni

Structural Concrete

04-281 Behavior of FRP-Confined Capsule-shaped RC Columns under Lateral Loading 591
Kiang Hwee Tan, Tamali Bhowmik, and T. Balendra

07-158 Seismic Performance of a Coupled Wall with High Performance Fiber Reinforced Concrete 597
Chung-Chan Hung

04-099 Rapid Recovery Technique by Using Fiber Reinforced Composite for Damaged RC Column under Seismic Loading 601
Minoru Kunieda, Yasushi Umeda, Naoshi Ueda, and Hikaru Nakamura

04-251 Structural Behavior of Deep Beam with Deteriorated Anchorage of Main Reinforcement 607
Akira Hosoda, Hiroshi Kaneko, and Misato Yuzurio

04-270 Evaluation of Shear Resisting Mechanism of Partially Corroded RC Beams 615
Tomohiro Miki and Yasuhito Takeuchi

04-079 Evaluation Method for Load-carrying Capacity of Incompletely-grouted PC Girders with Broken Tendons 621
Ken Watanabe, Toshiya Tadokoro, and Yukihiro Tanimura

04-110 Deformability Models for Shear Critical Reinforced Concrete Members 629
Sung-Gul Hong

04-305 Effect of Crack Configuration, Axial Load, and Shear Reinforcement upon Hysteresis Characteristics of High-strength RC Columns 639
Yasuji Shinohara and Shizuo Hayashi

04-194 A Simplified Numerical Approach to Cumulated Damage Effects on Seismic Performance of Existing RC Frame Structures 649
Jiang Qian, Wei Huang, and Binbin Zhuang

04-007 Non-linear FE Analysis of Post-tensioned Precast Concrete Wall 653
Ohmura Tetsuya and Gregory G. Deierlein

04-226 Seismic Behavior of L-Shaped Core-Walls 657
Susumu Kono, Kohei Sakamoto, Kazuma Inada, and Masanobu Sakashita

04-119 Development of an Energy Dissipation Device for Prestressed Concrete Members 665
Yasushi Sanada, Yuta Sashima, and Hiroki Sugiura

Paper ID Page

08-217 Response of High Performance Fiber Reinforced Concrete Infill Panels Retrofitting Steel Moment-resisting Frames 671
Sarah L. Billington, Dimitrios G. Lignos, Joan V. Hanson, and Daniel Moreno-Luna

04-077 Damage Investigation of Reinforced Concrete Buildings at the 2010 Chile Earthquake..... 679
Taiki Saito, Susumu Kono, Koichi Kusunoki, Yousok Kim, Tomoya Matsui, Masanori Tani, Yo Hibino, Carlos Zavala, and Patricia Gibu

04-070 Seismic Fragility Analysis of RC Frame Structures 687
Huanjun Jiang, Junjie Mao, Xilin Lu, and Linzhi Chen

04-114 Study on Influences of Construction Joints and Multi-layered Longitudinal Bars on Restoring Force Characteristics in R/C Cantilever Beams 695
Koshiro Nishimura

04-093 Experimental Study on Bonding Action with Neutron Diffraction Technique..... 701
Koichi Kusunoki, Kenji Kabayama, Tomohisa Mukai, Yuichi Hatanaka, Hiroshi Suzuki, and Akira Tasai

07-040 Vibration Characteristics of Traditional Adobe-quincha Buildings Located at Lima Historic Centre 707
C. Cuadra, C. Zavala, A. Abe, T. Saito, and S. Sugano

07-089 Experimental Shear Strength of Squat Masonry Shear Walls..... 713
Mohamed A. ElGawady,and Jamal Elmapruk

04-143 Shear Strengthening for Reinforced Concrete Beams using ECC Panels 723
Koji Matsumoto, Asami Yamamoto, and Junichiro Niwa

04-061 Applicability of Tension Softening Curves for the Contribution of Steel Fibers to Shear Resistance of RSF Beams..... 729
Pitcha Jongvivatsakul, Ken Watanabe, Koji Matsumoto, and Junichiro Niwa

04-059 Experimental Study on Diagonal Compressive Capacity of Reinforced Concrete Beams using High Strength Materials 735
Patarapol Tantipidok, Koji Matsumoto, Ken Watanabe, and Junichiro Niwa

04-066 Experimental Response of Steel Fiber Reinforced Concrete Knee Joints of Rigid-framed Railway Bridges Under Cyclic Loading..... 743
Kabir Shakya, Koji Matsumoto, and Junichiro Niwa

04-166 Seismic Vulnerability and Structural Retrofitting of Municipal Theatre of Lima, Peru..... 749
R. Proaño, L. Quiro, and C. Zavala

07-177 Dynamic Identification of Rehabilitated Masonry Building by Ambient and Forced Vibration Tests 757
Rafik Taleb, Farid Bouriche, Mehdi Boukri, and Fouad Kehila

04-189 A Study on Failure Mechanism of RC Structures with Specially Shaped Columns with Consideration of Diaphragm Using PushOver Analysis 765
Pu Yang, Xiaoliang Wang, Hongliu Xia, Yi Liu, Wei Wei, and Akira Wada

Paper ID Page
04-233 Attempts at Simulating Membrane Effects in Slabs Using Finite Element Analysis 771
Saurabh Prasad and Tara C. Hutchinson
04-239 Reinforced Concrete Beam-column Joint Strengthened by Ferrocement..... 779
B. Li and Eddie S.S. Lam
04-248 Evaluation of the Damage Observed in a Reinforced Concrete Wall Building during the February 27, 2010 Chile Earthquake 789
Fabian Rojas and James Anderson
04-260 Preliminary Collapse Assessment of the Torre Alto Rio Building in The Mw = 8.8 February 27, 2010 Chile Earthquake 799
Zeynep Tuna and John W. Wallace
04-095 Development of Partially Tube-confined Reinforced Concrete Ductile Moment Frame 805
Yuntian Wu, Yan Xiao, Yingmin Li, Shuyan Ji, and Akira Wada
04-084 Estimation of Peak Impact Force due to Impact of Tsunami Water-borne Shipping Containers on RC Columns 811
M. A. K. M. Madurapperuma and Anil C. Wijeyewickrema
04-276 Flexural Behavior of Belled Pile with High-strength Longitudinal Reinforcement..... 819
Yo Hibino, Yasuji Shinohara, and Shizuo Hayashi
04-190 Seismic Damage Mechanism Control of RC Ductile Frames from a Stiffness Point of View 825
Zhe Qu, Lieping Ye, and Akira Wada
11-086 Seismic Analysis of RC Structure under Multiple Earthquakes 831
Bin Wang, Huanjun Jiang, and Xilin Lu
07-193 Analytical Investigation on Seismic Behavior of Connections Between Precast RC Columns and Steel Beams 837
Qiyun Zhu and Xilin Lu
04-288 A Fundamental Study on Structural Performance of CES Shear Wall with Different Anchorage Condition of Wall Reinforcement 843
Tomoya Matsui, Suguru Suzuki, and Hiroshi Kuramoto

Steel Structure

05-155 Braced Frames for Seismic Design in Urban Areas 851
Charles W. Roeder, Dawn E. Lehman, Po-Chien Hsiao, and Keith Palmer
05-041 Seismic Design of Recent Project in Tokyo Tech O-okayama Campus 857
Toru Takeuchi
05-216 Experimental and Analytical Validation of a Seismic Retrofit System for Existing Steel Moment-resisting Frames 865
Dimitrios G. Lignos, Daniel M. Moreno-Luna, and Sarah L. Billington
01-164 Factors Influencing the Progressive Collapse of Frame Structures and Sensitivity of the Collapse to These Factors 875
Liping Liu, Pei Cao, Yingmin Li, Akira Wada, Mingkui Xiao, and Yangbing Liu

Paper ID Page

05-042 Collapse Behavior and Ultimate Earthquake Resistance of Weak Column Type Multi Story Steel Frame under Bi-axial Ground Motion 881
Satoshi Yamada and Yuko Shimada

05-167 Effect of Yielding of Roof Members on Seismic Response Behavior of Double Layer Lattice Domes 885
Tomohiko Kumagai, Toru Takeuchi, and Toshiyuki Ogawa

10-285 The AISC 2010 Seismic Provisions for Composite Structures: Towards an Application of PBD Principles for Innovative Connections 891
Roberto T. Leon and Jong Wan Hu

05-033 Experimental Evaluation of Composite Effects on Structural Behavior of Panel Zone 899
Shoichi Kishiki and Satoshi Yamada

07-096 Cyclic Behaviour of Steel Tube-reinforced Concrete Composite Walls with High Axial Force Ratio 905
Xiaodong Ji, Jiaru Qian, and Zao Jiang

05-125 Experimental Study on the Development of a Tubular Damper For Use in Bolt Joints 915
Seiji Mukaide, Daiki Imoto, Nobuhiro Nagayama, and Motohide Tada

05-081 A Sensitivity Study of Bolt Tension Effect on Seismic Response of Special Bolted Moment Frames 921
Atsushi Sato and Chia-Ming Uang

05-175 Which Spectral Shape Really Matter to Predict Nonlinear Structural Response: Application to Steel Frames 927
Edén Bojórquez, Iunio Iervolino, and Alfredo Reyes-Salazar

05-122 Plastic Deformation Capacity of Structural Steel under Various Axial Strain Histories 935
Yu Jiao, Satoshi Yamada, and Shoichi Kishiki

05-104 Elasto-plastic Behavior of RHS Columns under Bi-axial Bending Moments 941
Yuko Shimada and Satoshi Yamada

05-016 Investigation of Cyclic Deterioration Behavior of RHS-Columns 947
Takanori Ishida, Yuko Shimada, and Satoshi Yamada

05-034 Proposal of Elastic Buckling Strength Formula for Columns in Steel Moment Frames Considering Anti-Symmetric Axial Forces Generated by Horizontal Loads 953
AkinobuTakada, Motohide Tada, Seiji Mukaide, and Yoshikazu Araki

05-014 Shear Resistance of Exposed Column Bases in Steel Braced Frames 963
Hayato Asada, Shoichi Kishiki, and Satoshi Yamada

05-157 Strength Evaluation of Interface Weld of Gusset Plate Connections 969
Yao Cui, Hayato Asada, Shoichi Kishiki, and Satoshi Yamada

08-054 Seismic Damping Controlled Shear Wall System and Its Design Methodology 977
Chao Pan and Dagen Weng

05-212 Development of a Self-centering Steel Plate Shear Wall 985
Patricia M. Clayton, Jeffrey W. Berman, Tyler Winkley, and Laura N. Lowes

Paper ID Page

10-031 Nonlinear Seismic Response of Steel Concentrically Braced Frames using Endurance Time Method 993
M. A. Hariri Ardebili, Y. Zarringhalam, M. Yahyai, and M. Mirtaheri

05-225 A Method to Detect Structural Damage Using High-frequency Seismograms 1003
Vanessa M. Heckman, Monica D. Kohler, and Thomas H. Heaton

05-273 Dynamic Analysis of a Full-scale Four-story Steel Building Experimented to Collapse by Strong Ground Motions 1009
Tran Tuan Nam and Kazuhiko Kasai

05-133 Performance of Steel Self-centering Braced Frame System During Intense Earthquake and Aftershock Ground Motions 1015
Nathan Brent Chancellor, David A. Roke, Richard Sause, James M. Ricles, and Nathaniel P. Gonner

05-357 Computer Modeling of Special Concentrically Braced Frame Structural Systems 1023
Po-Chien Hsiao, Dawn E. Lehman, and Charles W. Roeder

05-344 Three-Dimensional Tests of Two-story, One-bay by One-bay, Steel Concentric Braced Frames 1033
Keith Palmer, Charles Roeder, Taichiro Okazaki, Carol Sheiled, and Dawn Lehman

05-336 A Method for the Damage Assessment of Single-layer Latticed Shells by Performing Static Stability Analysis Twice 1041
Dabin Yang, Yigang Zhang, and Jinzhi Wu

05-047 Effect of Brace Fracture on Seismic Performance of Braced Frame 1049
Ryota Matsui and Toru Takeuchi

01-018 Comparison Study on Damage Potential of Synthetic and Recorded Ground Motions 1059
Shiling Pei, John W. van de Lindt, Stephen Hartzell, and Nicolas Luco

Bridge

06-245 Seismic Design of Highway Bridges in California 1067
Lian Duan

06-310 Seismic Behavior of Curved Steel-girder Highway Bridges 1075
Ian G. Buckle, Eric V. Monzon, and Ahmad M. Itani

06-184 Seismic Performance of Twin-cell Hollow Composite Members 1085
H.-L. Hsu and R.-Z. Lee

Abstract: Safety of occupants is of paramount importance in the design of any structure, but increasing attention is being placed on achieving structures that are also resilient. Such structures are intended to return to service quickly following a major earthquake, in some cases immediately. Such concerns may focus on structures and lifelines critical to a community's needs in the aftermath of an earthquake, but may also focus on continuity of important business and organizational activities, preservation of social and technological services (schools, communications, power, etc.), and allowing citizens to "shelter-in-place" while repairs are made to residential structures. In this paper, research to improve the resilience of buildings and bridges are highlighted. For buildings, effective approaches to minimize damage to structural and nonstructural components are stressed. In the case of bridge structures, approaches are examined whereby highway and rail bridges can be used immediately following a major earthquake to facilitate emergency response and promote rapid recovery. Results of shaking table tests, nonlinear dynamic analyses and economic evaluations are presented.

1. INTRODUCTION

Many researchers and practitioners worldwide are working to develop economical systems that can dependably permit engineered facilities to continue functioning even following a large seismic event. Such solutions are critical in the case of facilities such as hospitals, emergency command centers, and lifeline systems needed for emergency response and recovery. Moreover, the types of facilities where post-earthquake functionality should be maintained can be quite extensive, if consideration is given to facilities needed to ensure rapid recovery of a community or organization. For example, the San Francisco Planning and Urban Research Association (SPUR, 2009) has indicated that many schools, residential buildings, and even retail and commercial buildings are necessary to provide the housing and services that would enable a community to function following an earthquake. Similarly, the vitality and perhaps viability of a business depends on its ability to provide continuous service to its customers. Increasingly, there is increasing recognition that the traditional approach of designing "ductile" structures for collapse prevention is not sufficient in a modern society. Solutions that can with confidence preserve operations, or provide the promise of minimizing the disruption and cost of repairs following major earthquakes, are needed.

To minimize post-earthquake disruption, a structure or system must be able to limit the damage occurring in structural and nonstructural components, and should not exhibit permanent displacements. Structures could simply be made stronger so that they remain essentially elastic for the level of earthquake for which resilience is desired. However, this strength-based approach (1) requires more materials that add to the cost and carbon footprint of the structure, and (2) results in higher accelerations that necessitate special attention in the design of nonstructural components, equipment and contents. While many types of structures that behave nonlinearly are being explored to enhance resilience, many share the following characteristics: (1) they are designed with an explicit nonlinear deformation mechanism that has only a modest strength in order to reduce cost as well as in-structure accelerations, (2) they incorporate highly durable and/or easily replaceable energy dissipation devices to reduce forces and displacements in structural and nonstructural elements not associated with the nonlinear deformation mechanism, and (3) they exhibit self-centering characteristics that minimize permanent lateral and vertical displacements of the structure.

Systems being considered include ones with beams, columns, walls, braces and systems that exhibit origin-oriented hysteretic loops (Fig. 1a); this behavior is often achieved by use of a combination of yielding or friction to provide hysteresis and use of gravity or post-tensioning to provide self-centering capabilities. In some cases special materials, such as shape memory alloys, can be used alone to provide these hysteretic characteristics.

Another approach is to install viscous damping devices. When installed in flexible systems that remain essentially elastic during the response, viscous dampers can be quite effective in reducing forces, accelerations and drifts in the structure. However, traditional design approaches do not focus on limiting drifts and accelerations to levels necessary

to achieve resilience.

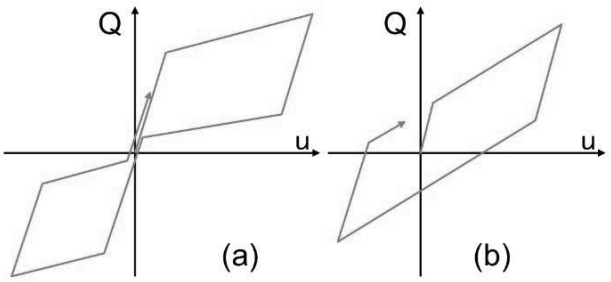

Figure 1 Hysteretic Loop Shapes for (a) Self-Centering Elements and (b) Traditional Isolation Devices

Viscous dampers, and elements having self-centering characteristics are typically installed pervasively throughout a structure. Where large nonlinear deformations are expected during the dynamic response, such systems may limit forces and accelerations experienced by structural and nonstructural elements, but they may not be able to limit displacement-related damages.

An alternative approach is seismic isolation. While seismic isolation has been in use for several decades, design codes and guidelines are often formulated to provide seismic performance comparable to fixed base buildings. While it is presumed that isolated buildings perform better than traditional structures, generally building codes permit substantial damage in the event of major earthquakes.

In this paper, several new approaches to seismic isolation of buildings and bridges are presented where resilience is considered as a prime design criterion. In such cases, isolators are provided with special hysteretic loops to limit accelerations and forces that can be developed by the supported structure, and where the structure and isolators have little or no residual displacement.

2. ISOLATED BUILDINGS

For resilience, it is convenient to consider a limit on story drifts. The drift limit should prevent significant yielding of the structural elements that might result in damage requiring inspection and repair, and permanent residual displacements. Drift should also be limited to prevent damage to nonstructural elements that are sensitive to relative displacements between stories. It can be shown on the basis of first principles that steel braced frames will begin to buckle or yield bracing elements at a story drift ratio of about 0.25% to 0.4% drift, where as moment frames in steel or concrete will yield at a drift ratio around 0.9% to 1.25%. Many types of cladding and partitions begin to display damage at a drift ration of about 0.3% with significant damage occurring by a drift ratio of 1%. Thus, in setting design criteria it is necessary to consider drift limits considering likely damage to both structural and nonstructural elements. From the above example, it is technically feasible, and perhaps economical, to isolate a moment resisting frame, but it is likely that substantial damage will occur in partitions, cladding, elevators and so on, before the structural system yields. Thus, depending on the type of nonstructural elements utilized, braced frames (or shear walls or other stiff systems) may be more consistent with the requirement of limiting damage to nonstructural components. However, it may not be necessary to preclude all damage to nonstructural elements during the resilience targeted event, so long as continued functionality is preserved and the occupants are able to "shelter-in-place" during repairs.

Many types of nonstructural elements, equipment and contents are sensitive to in-structure accelerations. To prevent acceleration related damages, it is necessary to consider a limit of floor level accelerations, or on the characteristics of pseudo-acceleration spectrum at each floor. For simplicity, we might consider a design were in the floor level accelerations are limited to 0.4g, though other values may be appropriate for certain types of elements and equipment.

While near or completely elastic behavior in the portions of the facility away from the isolation plane will eliminate the possibility of residual displacement in those locations. Some isolation systems may tend to have residual displacements. The acceptability of residual displacement in the isolation system following an intense earthquake should be carefully considered. If accounted for in the initial design with regards to accessibility and functionality of utilities, residual displacements in the isolators may not impair post-earthquake functionality, and thus be acceptable. Re-centering an isolated building following an earthquake may be economical in certain cases if needed. In other cases, isolators can be designed to minimize residual isolator displacements.

For resilient designs, it is necessary to identify a level of shaking at which resilience is desired. This may be expressed as a fraction of the maximum considered earthquake, or in terms of the confidence with which resilience can be achieved over the life of the structure (i.e., 50% confidence that the facility will remain operational following an earthquake having a 10% probability of exceedence in 50 years, or a 90% confidence that the structure will be inoperable due to earthquakes for less than 3 days during the life of the structure). It is expected that different facilities will likely have different criteria, depending on their use and importance to the community or owner. For example, some structures would be expected to be operable immediately, while others might be acceptable in terms of resiliency if their function is restored within 90 days. In all cases, a high confidence of collapse resistance is assumed. For the purposes of this paper, resiliency for the maximum considered event is targeted, consistent with important or critical facilities.

2.1 Isolation Systems

It has been noted that the design of isolated structures can be problematic due to the apparent over-conservativeness of some design provisions, and also because of challenges encountered when designing isolated systems to resist intense near-field ground motions. To resist

large near-fault ground shaking, relatively large and strong isolators are often necessitated to control displacements and maintain isolator stability. In these cases, isolators may not act effectively, especially for small events, and require relatively large design forces and trigger excessive accelerations in the superstructure [Morgan and Mahin, 2007]. Similarly, traditional designs have relied on isolation systems that have essentially bilinear hysteretic loop shapes with effective periods in the 2-3 sec. range (Fig. 1b). This type of isolator may develop large forces (and thereby drifts and accelerations) in the supported structure due to the large lateral isolator displacements that may develop in large earthquakes. Thus, efforts are underway to improve isolation for small events, limit drifts for larger events, and reduce floor accelerations.

Several approaches are being pursued at Berkeley and elsewhere to overcome these impediments to resilience, including novel combinations of elastomeric isolators and nonlinear viscous dampers. Another promising approach is the newly developed Triple Pendulum Slider [Earthquake Protection Systems, 2007]. This device has three independent pendulum mechanisms (Fig. 2).

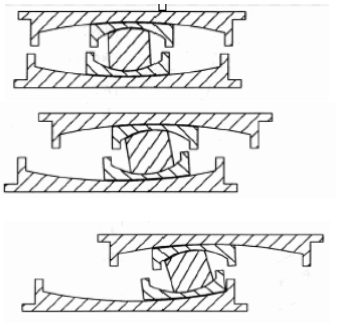

Figure 2 Triple Pendulum Bearing

By strategically selecting friction coefficients and the effective radius for each pendulum mechanism, hysteretic characteristics can be optimized for occasional, rare and very rare events (Fig. 3). Figure 4 shows hysteretic loops for different combinations of friction coefficients and radii.

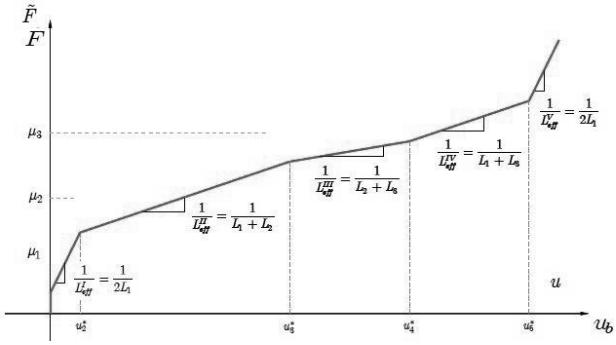

Figure 3 Envelop Force-Displacement Relation for TP isolators

One advantage of isolators of all kinds is that their behavior is highly repeatable. This is in part due to the high quality manufacturing processes and quality control tests of production bearings, but also in large part due to the simplicity of the underlying physical processes. For example, recent tests were done using TP isolation bearings, under linear, circular, square and figure eight displacement histories. A mixed kinematic/plasticity model was able to reproduce the test results with a high degree of accuracy as seen in Figure 5 (Becker and Mahin, 2011).

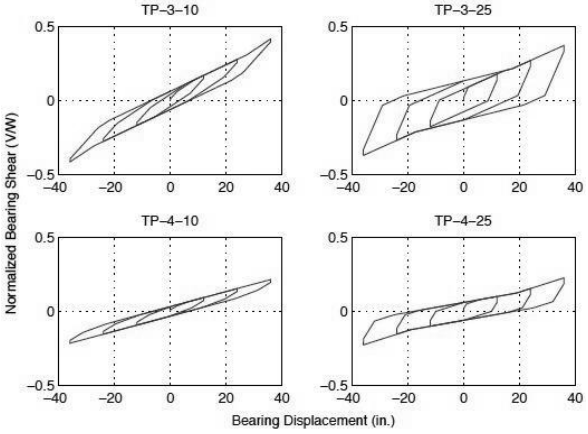

Figure 4 Representative Hysteretic Loops

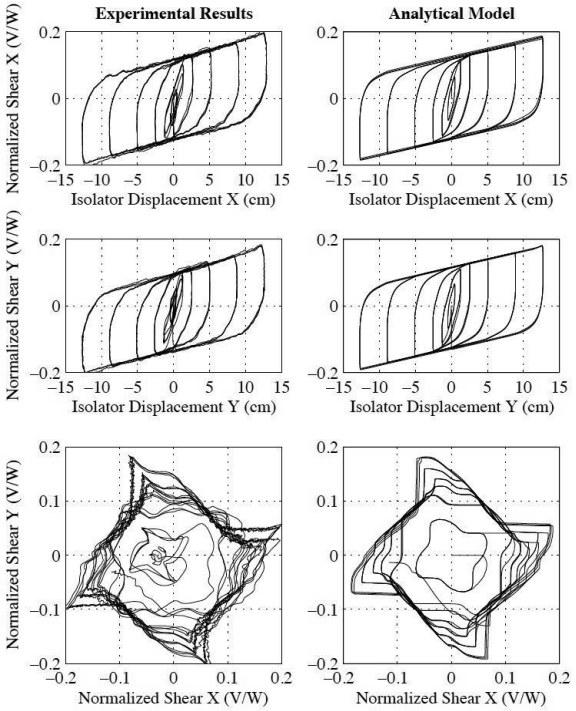

Figure 5 Comparison of Test and Numerical Response of TP isolators under square displacement excursions in the XY plane.

2.2 Isolated Building Tests and Analyses

Tests (Fig. 6) and analyses (Morgan and Mahin, 2011) demonstrate that the devices can be designed to achieve about the same isolator displacements for a large event, but with smaller drifts and accelerations in the superstructure and with a far greater degree of isolation during smaller events (Fig. 3) [Morgan and Mahin, 2011].

Numerical simulations were conducted of a three-story structure similar to that shown in Fig. 5 subjected to the suite of SAC ground motions corresponding to a 2% probability

of exceedence at a site in metropolitan Los Angeles (Somerville, 1997). For TP bearings with an effective period of 4 seconds and damping of 10% (see TP-4-10 plot in Fig. 4) the computed median isolator displacement is 770 mm, but the peak median story drift is less than 0.4% and the peak median floor level acceleration is less than about 20% g. Thus, for this type of isolation, high confidence of resilience can be obtained for even MCE level excitations.

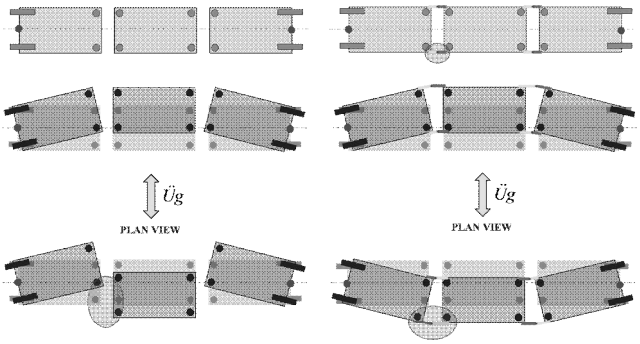
Figure 6 Test of 3-Story Isolated Building

3. ISOLATED BRIDGES

Seismic isolation is especially easily to implement for bridges where decks are attached to the supporting columns and abutments via elastomeric or other bearings. To develop improved understanding of the behavior of seismically isolated bridges and gain confidence in design methods, a series of tests and analyses of isolated bridges has been recently completed at Berkeley (e.g., Anderson, 2003). These studies included a variety of different isolator types, bridge dynamic properties, and earthquake characteristics. Three generic types of isolator bearings were considered, including lead rubber bearings, high damping bearings, and friction pendulum bearings. Extensive studies were made to characterize bearings subjected to 3D loading, and to assess the effects of aging. Bridge systems tested include one and two span bridges having substructure periods ranging from nearly zero to more than 2 seconds. More than a dozen bridge configurations were tested to assess the effects of mass eccentricity, stiffness eccentricity, bridge substructure period, bearing type, in-situ variations in bearing properties, yielding of supporting columns, and earthquake excitations. One of the bridge models tested appears in Fig. 7.

Such experimental results were used to develop improved numerical models of the isolation bearings, and to assess the sensitivity of system response to different design parameters, and to uncertainties in these parameters. Various provisions of the AASHTO Guideline Specification [1999] such as those related to treatment of bidirectional excitations were assessed in Anderson and Mahin [2003, 2004]. Overall, good performance was noted for all of the isolated systems studied.

Figure 7 Shaking Test specimen of simple supported bridge with different substructure stiffness



The technology of seismic isolation has been proven beneficial for suppressing vibrations to the superstructure due to period elongation. By allowing a majority of the energy to be dissipated within the isolation layer, structural forces and accelerations are attenuated, thereby providing an attractive system for protecting the structural and non-structural components. This is vitally important because recent implications of seismic isolation have involved long-span bridge structures. However, an isolated bridge system will inherently develop relative displacements between adjacent bridge decks, thereby damaging non-structural components such as expansion joints. Therefore, seismically isolating a bridge must also incorporate a method to control the relative displacements between bridge decks while still preserving the desired seismic response of the bridge system. Segmental Displacement Control (SDC) design was recently introduced by Earthquake Protection Systems of Vallejo, California, to achieve this goal and provide a more resilient bridge system. This concept is the subject of intense investigation.

3.1 Segmental Displacement Control Concept

As an innovative concept to isolated bridge systems, SDC design, developed by Earthquake Protection Systems (EPS), originated to evade seismic damage of long highway and railway bridges, thereby preserving the functionality after a major earthquake. Using seismic isolation concepts previously stated, the decoupled superstructure decks are connected at the expansion joints by lock-up guide devices. This device contains user defined properties in accordance with the performance of the isolated bridge system and its fundamental demands. However, the primary purpose of the lock-up guide is to resist the relative transverse displacement between bridge decks, thereby allowing for protection of the

non-structural components and a more resilient structural system.

In perspective of relative transverse displacement, the concept of SDC is shown in Figure 1, where the fundamental behavior of an isolated bridge with three decks is displayed in plan view. The dotted horizontal line references the centerline of the bridge and is parallel to longitudinal motion. The middle bridge deck is fully supported by bearings that allow longitudinal and transverse displacement, shown as circles. However, the end bridge decks are restrained in the transverse direction characterizing a typical configuration for a highway or railway bridge, shown as rectangles. Only three bridge decks are displayed in the conceptual figure because of experimental reference presented later on and the emphasis of relative transverse displacement. A real-life bridge would typically have more decks in series that are fully supported by bearings with longitudinal and transverse freedom, which resembles the middle deck in Figure 8.

(a) (b)

Figure 8 Segmental Displacement Control Design Concept Plan View: (a) Unrestrained Decks, and (b) Restrained Decks

As seen in Figure 8 (a), the bridge decks are not restrained to one another. Therefore, any seismic excitation in the transverse direction will impose relative transverse displacement between the bridge decks, inducing further damage to the non-structural components. However, Figure 8 (b) displays a pair of lock-up guides between two adjacent decks, thereby mitigating the relative transverse displacement between bridge decks and defining the mode shapes for the superstructure. These mode shapes are characteristic of longer periods and therefore produce lower forces at the hinged connections. It is noteworthy to mention that the number and position of the lock-up guides used between adjacent decks is user defined, as a single lock-up guide located at the centerline of the bridge is another option. The latter would resemble a similar connection for train cars and is in intended for future study. For the experiment presented within this paper, the lock-up guide configuration in Figure 8 (a) and (b) is investigated.

Another function of the lock-up guide is to allow a prescribed amount of longitudinal translation between adjacent decks. This translation will allow thermal movement of the bridge but during a major event or when the prescribed longitudinal displacement capacity is exceeded, the connection "locks up", providing a restraining stiffness that is characteristic of the lock-up guide dimensions and material properties. Locking up the bridge system is not only beneficial for non-structural components, but also for reducing the probability of bridge deck unseating.

3.2 Lock-Up Guide

With the concepts of SDC, the underlying behavior depends on the characteristics and design of the lock-up guide. Figure 9 shows the specific experimental lock-up guide AutoCAD sketch-up used for this research, where each end of the lock-up guide is fixed to two separate and adjacent bridge decks.

The lock-up guide contains three steel plates, or fingers, that overlap each other and are joined through a slotted-pin connection. The slot has a displacement capacity that is user defined to the performance of the bridge system in the longitudinal direction, for instance the different requirements for highway, freight railway, and high-speed railway bridges. Thermal expansion is allowed, yet for a major earthquake, the pin will "lock up" in the slot. Transverse displacement is restricted by the stiffness of the pin and the surrounding fingers strength. As seen in Figure 9, the vertical displacement and the rotations about the X and Y axes are restrained based on material stiffness. However, the lock-up guide does have the capacity to rotate about the Z axis more than 90 degree, which greatly exceeds the rotation capacity of a real bridge. The specific theoretical coordinate axes used in the Figure 9 are used based on correlation with experimental axes, where the Y axis is orientated longitudinal to the experimental bridge.

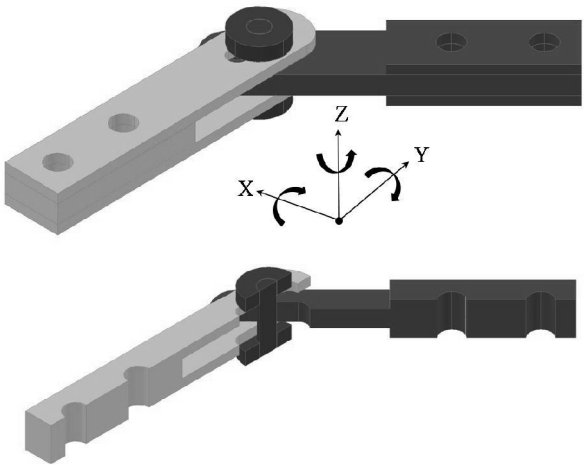


Figure 9 AutoCAD Sketch-Up of Lock-Up Guide

In transition from the end deck to the middle deck, it is important for the lock-up guide not to interfere with the performance of the isolation bearings, meaning that the displacement capacity of the slot is not less than the longitudinal distance vector for maximum rotation of the end deck. Though, based on free body dynamics of a bridge system containing lock-up guides, isolated bearing displacement is expected to be less when compared to a

system without lock-up guides.

In the longitudinal direction, force-displacement of the lock-up guide is preliminary modeled as a gap followed by elastically perfectly plastic (EPP) behavior. The stiffness and yield point are based on the dimensions of the lock-up guide. It is noteworthy to mention that once the slot is maximized, behavior of lock-up guide fingers can produce a hardening effect.

3.3 Segmental Displacement Control Experimental Results

To validate the effectiveness of SDC design for isolated bridges, an experimental program was designed to implement a series of ground motions on a shake table to a quarter scaled isolated bridge, where a direct comparison between an isolated bridge and an isolated bridge with installed lock-up guides was studied. Particular attention was also directed to the behavior of the triple and single friction pendulum isolation bearings. After research tests were completed, a public demonstration of the effectiveness and efficiency of SDC design was held at the Richmond Field Station, Berkeley, CA, where the final specimen displayed an innovative railroad expansion track on top of the isolated bridge. The following figures display a completed experimental specimen and an AutoCAD sketch up of the isolated bridge.

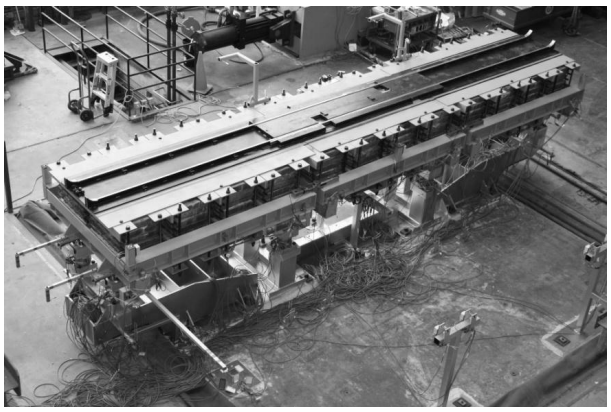

Figure 10 Scaled Experimental Isolated Bridge with Lock-Up Guides Installed

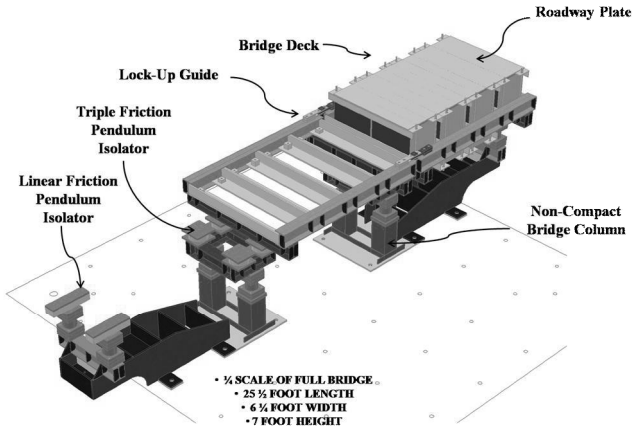

Figure 11 AutoCAD Sketch Up of Dissected Isolated Bridge with Lock-Up Guides Installed

Conclusions of the experiment resulted in large relative displacements seen for the isolated bridge with no lock-up guide. This is expected because of the difference in deck fundamental periods. After implementing 1994 Northridge, CA, Sylmar XYZ ground motion, the maximum transverse relative displacement between bridge decks was approximately 1.6", as seen in Figure 5, correlating to 6.4" for a full scale bridge. This amount of full scale displacement will most likely damage the expansion joints. However, the experiment with the lock-up guide installed shows smaller relative transverse displacements, which is critical to prevent damage to non-structural components. It is noteworthy to mention that Figure 5 does not account for relative rotation correction, which would lead to even smaller relative transverse displacements.

Overall observations suggest SDC has great potential for preserving non-structural components and a more resilient bridge system because of reduced transverse relative displacement between bridge decks. However, experimental tests also poise attention to decreased triple friction pendulum bearing displacement. Knowledge of this observation must be accounted for in an isolated bridge design.

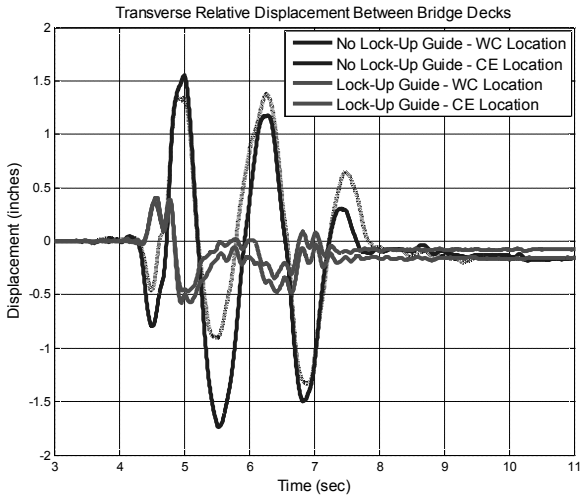

Figure 12 Transverse Relative Displacement Between Bridge Decks

4. CONCLUSIONS

The technology and design approaches described in this paper provide several alternative ways to achieve durable building and transportation structures that increase post-earthquake serviceability and reduce the need for repair. By permitting structures to undergo significant inelastic deformations during seismic events, yet suffer little damage that would require post-earthquake repairs and impair operability, structural engineers can achieve designs that are durable, dependable, and economical in terms of initial construction cost and the potential losses that might occur in the event of a damaging earthquake. As such, these approaches address the basic principles articulated by sustainable design and seismic resiliency.

Additional research is needed to refine these concepts,

especially with regards to (1) reducing cost and increasing speed of construction, (2) reducing the societal and ecological impacts of construction, (3) and refining concepts such as those presented herein and developing more generally applicable design guidelines.

Abstract: The in-situ residual strength of liquefied soil is an important factor in the evaluation of earthquake-induced deformations and post-earthquake stability for many geotechnical structures and it is a topic with considerable technical uncertainty. Limitations in the case history database and limitations in our understanding of, and ability to numerically simulate, the mechanisms of strength loss associated with pore water pressure diffusion and void redistribution constitute the major challenges in estimating the in-situ residual strength of liquefied soils. These aspects are described and discussed.

1. INTRODUCTION

The in-situ residual strength (S_r) of cohesionless or nonplastic soils liquefied by earthquake shaking is an important factor in evaluations of earthquake-induced deformations and post-earthquake stability for many geotechnical structures. For example, the slide in the upstream shell of the Lower San Fernando Dam in 1971 (Fig. 1) was attributed to liquefaction induced strength loss.

Procedures for estimating the residual shear strength continue to represent an area of significant technical uncertainty. Procedures have included laboratory testing of field samples obtained by frozen sampling techniques (e.g., Robertson et al. 2000) or by high-quality tube sampling techniques coupled with approaches for correcting the shear strength for the estimated volume changes that occur during sampling and testing (e.g., Poulos et al. 1985, Castrol et al. 1992). Empirical correlations based on back-analyses of liquefaction flow slide case histories (e.g., Seed 1987) have been preferred for practice, in part because they implicitly account for void redistribution and other in-situ mechanisms of strength loss that laboratory element testing cannot recreate.

Fig. 1. Slide in the upstream shell of the Lower San Fernando Dam in 1971 (CA DSOD files)

Challenges in advancing procedures for estimating residual shear strengths include limitations in the case history database and in our understanding of, and ability to numerically simulate, the mechanisms of strength loss associated with pore water pressure diffusion and void redistribution. These challenges are described and discussed in this paper.

2. CASE HISTORY DATABASE

It is often necessary in practice to estimate S_r for liquefiable soils spanning a greater range of in-situ relative densities than are represented in the flow slide case history database. For example, the schematic cross-section of an earth embankment dam in Fig. 2 shows a potential slope failure passing through the dam shell with a representative $(N_1)_{60}$ = 20 and the underlying alluvium with a

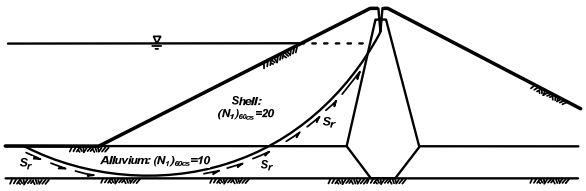

Fig. 2. Schematic of an earth dam with two zones in which liquefaction may be triggered by strong earthquake shaking (Boulanger and Idriss 2011).

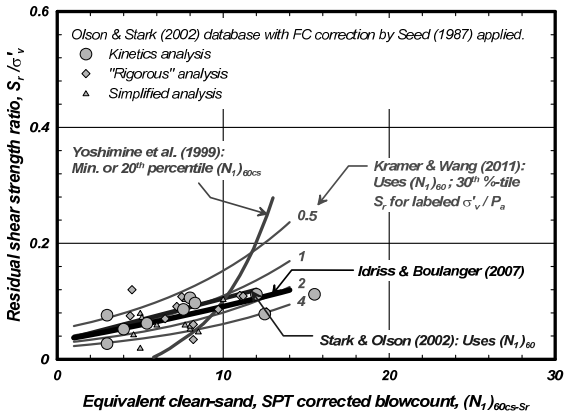

Fig. 3. Comparison of some SPT-based residual shear strength ratio correlations over the range of available case history data (Boulanger and Idriss 2011).

representative $(N_1)_{60}$ = 10. The case history database of flow slides only contains cases with $(N_1)_{60}$ values less than about 14; thus, the shell material in this example is outside the range of the case history data. However, if a liquefaction triggering analysis shows that both zones are expected to liquefy during strong earthquake shaking, then the analysis of post-earthquake stability requires that estimates be made for the shear resistance in both zones.

The range of the case history data, as interpreted by Olson and Stark (2002) and incorporating the fines adjustment recommended by Seed (1987), and some recent correlations for S_r/σ'_v- are presented in Fig. 3. This figure is illustrative of the range of conditions covered by the available databases. The information in Fig. 3 indicates: (1) the $(N_1)_{60cs}$ values are limited to less than about 14, and (2) the residual shear strength ratios are mostly limited to less than about 0.12, which is also generally less than about 20% of the pre-earthquake drained strength for these types of soils.

The four correlations shown in Fig. 3 illustrate the range of approaches used by different investigators. The Olson and Stark (2002) correlation for S_r/σ'_v is based on representative $(N_1)_{60}$ values without a fines content correction and is expressly limited to $(N_1)_{60}$ less than or equal to 12 (i.e., close to the limit of the available data). The Idriss and Boulanger (2007) correlation is based on representative, equivalent clean sand $(N_1)_{60cs}$ values computed using the fines content correction by Seed (1987), and closely follows the Olson and Stark (2002) correlation in this range of $(N_1)_{60cs}$ values. The Kramer and Wang (2011) correlation uses representative $(N_1)_{60}$ values without a fines correction, includes a dependency on confining stress, and spans across the other two correlations. The Yoshimine et al. (1999) correlation (as presented in Wride et al. 1999) is based on the minimum or 20th percentile $(N_1)_{60cs}$ value, uses the Seed (1987) fines correction, and tends to bound the data with a sharply upward-curving relationship. Despite their differences, the four correlations are consistent in indicating that the post-liquefaction shear resistance of a cohesionless soil with a representative $(N_1)_{60}$ value less than about 14 can be expected to be between 5% and 20% of its pre-earthquake drained strength, assuming a drained friction angle ranging from about 28 to 34 degrees.

3. MECHANISMS

An important challenge faced in practice is deciding how to extrapolate these correlations to $(N_1)_{60}$ or $(N_1)_{60cs}$ values greater than 14. Some of the technical issues involved in guiding this extrapolation are discussed below.

It is first useful to revisit the various definitions that have been used in the literature for the shear strength of liquefied soils. The ultimate shear resistance, or critical state strength, that is measured in undrained laboratory element tests may be denoted as S_{CS}, whereas the quasi-steady state shear resistance, which corresponds to a local minimum in the stress-strain curve from an undrained laboratory element test, may be denoted as S_{QSS}. The S_{QSS} generally coincides with the soil's transition from an incrementally contractive to an incrementally dilative response in undrained shearing, which has been termed phase transformation (Ishihara 1993). Residual shear strength, S_r, refers to the shear resistance that a liquefied soil mobilizes in the field, which can be complicated by void redistribution, particle mixing, and other field mechanisms that are not replicated in laboratory element tests. These three "strengths" are fundamentally different from a mechanics standpoint, and thus maintaining a distinction is essential.

The undrained response of saturated sand for a range of initial relative densities (D_R) and consolidation stresses in direct simple shear loading is illustrated by the results in Fig. 4 for Fraser river sand by Vaid and Sivathayalan (1996) and

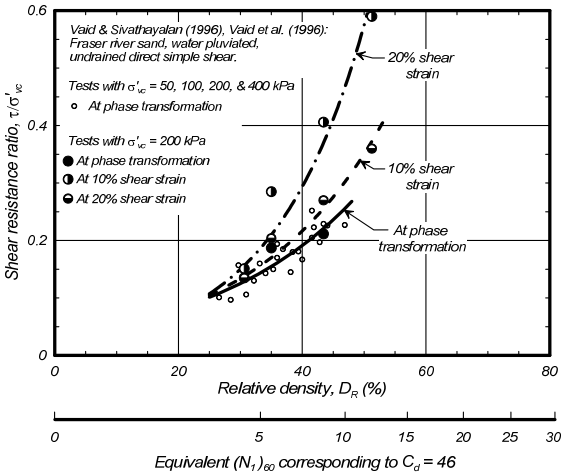

Fig. 4. Undrained shear resistance ratios mobilized in direct simple shear tests on Fraser river sand (Boulanger and Idriss 2011).

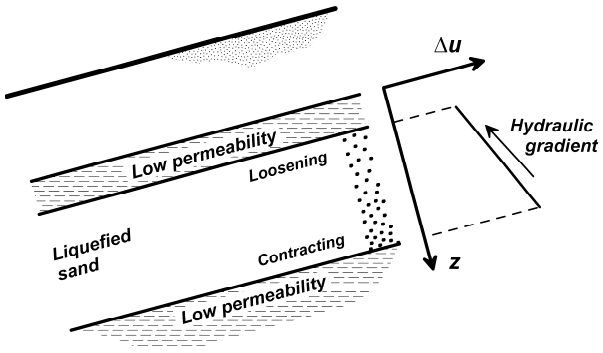

Fig. 5. Schematic of void redistribution in a confined sand layer due to upward seepage driven by earthquake-induced excess pore water pressure gradients (after Whitman 1985)

Vaid et al. (1996). The normalized shear resistance, τ/σ'_{vc}, for this sand at σ'_{vc} of 50 to 400 kPa are plotted versus D_R showing that: (1) τ/σ'_{vc} at phase transformation is relatively independent of σ'_{vc} for σ'_{vc} ranging from 50 to 400 kPa, and (2) τ/σ'_{vc} increases with both increasing D_R and increasing shear strain beyond phase transformation. These data are consistent with the trends in other laboratory testing programs (e.g., Ishihara 1993, 1996; Yoshimine et al. 1999) in showing that as the sand nears D_R of 50-60%, its dilative tendencies at σ'_{vc} less than 400 kPa result in the undrained shear resistance at large strains in simple shear exceeding the drained strength.

Relationships developed from laboratory element tests have been converted to correlations with SPT $(N_1)_{60}$ or CPT q_{c1N} values by a number of investigators. The equivalent $(N_1)_{60}$ can be related to relative density, as suggested by Meyerhof (1957), using:

$$\left(N_1\right)_{60} = C_d \left(D_R\right)^2 \qquad (1)$$

where the parameter C_d depends on the soil characteristics (e.g., Cubrinovski and Ishihara 1999). A typical value for clean sands is $C_d = 46$ (Idriss and Boulanger 2004), and this value was used to compute the equivalent $(N_1)_{60}$ values presented along the axis beneath the laboratory test data shown in Fig. 4. Thus, the undrained shear resistance of saturated sands, at σ'_v less than about 400 kPa, is shown to increase sharply as $(N_1)_{60}$ exceeds values of about 12-16. Procedures developed in this manner are based on the assumption that the in-situ void ratio will not increase (or relative density decrease) in a critical zone or layer in response to the transient pore water seepage that occurs as excess pore water pressures dissipate during and after earthquake shaking.

Void redistribution, as described by Whitman (1985), can develop where pore water seepage driven by earthquake-induced excess pore water pressure gradients causes localized loosening of the liquefied soil. This localized loosening can cause S_r to be much lower in the field than would be obtained from laboratory tests of samples at the pre-earthquake void ratio. These situations require the presence of a soil layer of significantly lower permeability overlying the liquefied soil layer, thereby impeding the outward seepage, as illustrated schematically for an infinite slope in Fig. 5.

The factors affecting void redistribution have been demonstrated through a range of physical modeling studies (e.g., Kokusho 1999, 2000, 2003, Kulasingam et al. 2004, Malvick et al. 2008) and analytical modeling studies (e.g., Yang and Elgamal 2002, Naesgaard et al. 2005, Seid-Karbasi and Byrne 2007). Shaking table tests by Kokusho (1998), for example, have illustrated how transient pore water seepage can cause dramatic strength loss and slope deformations after shaking has ceased. The four images in Fig. 6 are from a video of a fully submerged sand model with two horizontal silt seams (the white layers) showing: (a) the geometry before the start of shaking, (b) the geometry after shaking has stopped and pore water seepage from the sand below the silt seams is just starting to break up through the silt seams along the glass side walls of the container, (c) the geometry as the lower silt seam and overlying sand are weakened by the upward pore water flow and begin to flow both laterally and down the adjacent slope, and (d) the geometry as deformations are nearing their final values. These images suggest that the upward pore water seepage from the liquefied sand layer below the silt seams, after shaking had ceased, was a major factor causing the silt seams and overlying sand to flow laterally. The third image also shows the lower white silt seam initially translating out over the adjacent muddy water, illustrating how hydroplaning and intermixing with the adjacent water can accentuate the flow deformations experienced by unstable, submerged slopes. These observed mechanisms of strength loss in liquefied soils (i.e., pore water pressure and void redistribution; hydroplaning; and water entrainment) are some of the factors that complicate the back-calculation of meaningful strengths in case histories that involve submerged slide masses.

An important consequence of void redistribution is that the in-situ S_r of a liquefied soil depends not only on soil properties (e.g., densities and permeabilities), but also on the dynamic loading conditions (e.g., intensity and duration) and all the factors that affect the pore pressure dissipation process (e.g., layer thicknesses, geometry, slope angles). This means that the pre-earthquake SPT penetration resistance or pre-earthquake void ratio cannot be expected to provide a sufficient basis for accurately predicting S_r.

The potential influence of localized loosening of sand on the relationship between the shear resistance ratio (τ/σ'_{vc}) and the pre-earthquake $(N_1)_{60}$ is illustrated by a simple example shown in Fig. 7. The baseline curve in this figure corresponds to the undrained monotonic shear resistance of Fraser river sand in direct simple shear loading to 20% shear strain, as shown previously in Fig. 4. The equivalent $(N_1)_{60}$ values were computed from the D_R values using $C_d = 46$ for both Figs. 4 and 7. The other curves in Fig. 7 correspond to cases where void redistribution has caused the in-situ D_R to change by ΔD_R relative to the pre-earthquake

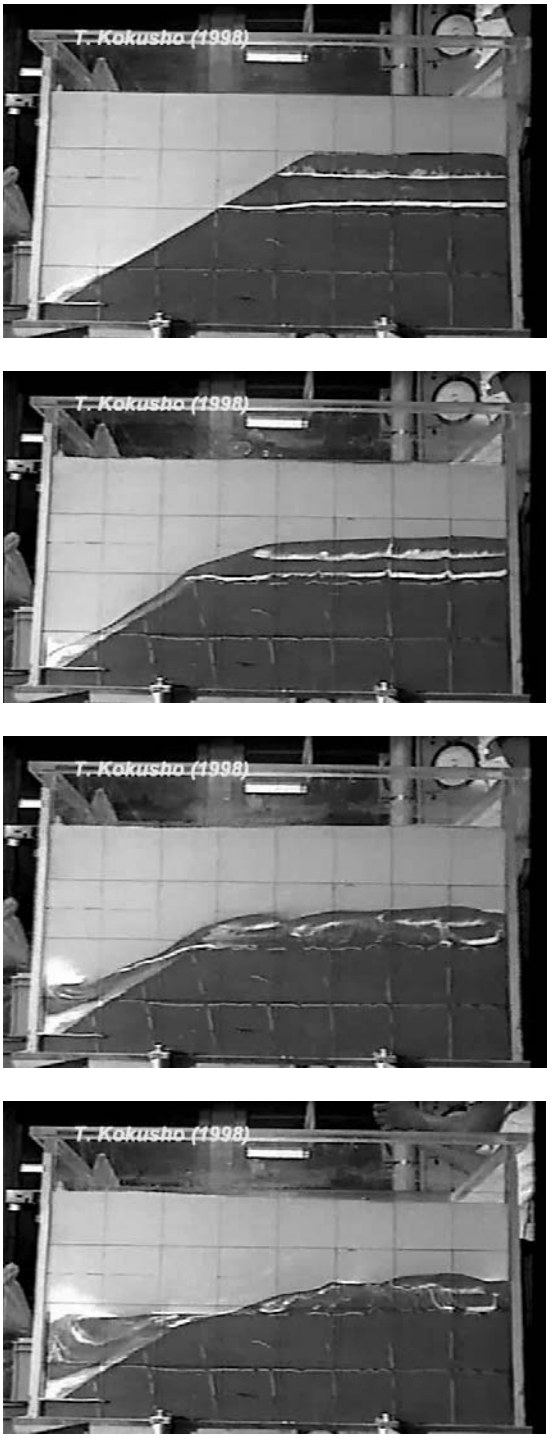

Fig. 6. Images of shaking table test by Kokusho (1998)

value. For example, the baseline curve gives τ/σ'_{vc} = 0.41 at a pre-earthquake D_R = 45% and $(N_1)_{60}$ = 9.3. If void redistribution produced ΔD_R = -0.2, the new D_R = 25% would correspond to a $(N_1)_{60}$ = 2.9 and τ/σ'_{vc} = 0.11. This reduced τ/σ'_{vc} value would, however, be plotted against the pre-earthquake $(N_1)_{60}$ = 9.3, which is why loosening causes the curves to shift downward and to the right in Fig. 7. For Fraser river sand at a pre-earthquake D_R = 45%, a ΔD_R = -0.2 would correspond to a volumetric strain of only -3.4%. This simple example illustrates how changes in D_R caused by void redistribution can strongly affect the expected relationship between S_r and the pre-earthquake $(N_1)_{60}$ values.

The potential for significant void redistribution can be expected to decrease as the soils become denser. Physical and analytical studies show that as the D_R of a sand deposit increases, the potential for void redistribution-induced strength loss decreases sharply because: (1) the consolidating portions of the deposit release less water because the post-liquefaction reconsolidation strains are smaller, and (2) the dilating portions of the deposit can accommodate the influx of more water without localizing because the sand has a greater dilatancy.

Numerical simulations of the void redistribution process are complicated by a number of factors, including limitations in commonly-available site characterization data and computational challenges in modeling coupled diffusion and localization processes (e.g., Seid-Karbasi and Byrne 2007; Kamai and Boulanger 2011). Further research on numerical simulations of this process and detailed validation studies continue to be an important need in this area.

4. DISCUSSION

Two possible scenarios were considered by Idriss and Boulanger (2007, 2008) in guiding the extrapolation of S_r/σ'_v correlations to $(N_1)_{60}$ values greater than 14, as illustrated in Fig. 8. The first scenario corresponds to conditions where the effects of void redistribution are expected to be negligible; e.g., the field conditions and stratigraphy are such that the post-earthquake pore water seepage will not be impeded by lower-permeability layers and thus the dissipation of excess pore pressures is expected to lead to densification of soils at all depths (in-situ void ratios decrease). In this case, the in-situ post-liquefaction shear resistance can be expected to be reasonably represented by relationships developed with consideration of laboratory element test results. This scenario was the basis for the upper curve which bends strongly upward at $(N_1)_{60cs}$ values of 15-17 in Fig. 8, which Idriss and Boulanger (2007) recommended only for those cases where void redistribution effects are expected to be negligible.

The second scenario in Fig. 8 corresponds to conditions where the effects of void redistribution can be significant; e.g., the field conditions and stratigraphy are such that the post-earthquake pore water seepage will, or could be, impeded by an overlying lower-permeability layer. In this scenario, the potential for void redistribution-induced loosening and strength loss may be judged to represent a serious possibility. In such a situation, the potential increases in void ratio near an impeded drainage boundary would mean that relationships guided primarily by the results of laboratory element tests could significantly over-estimate the in-situ shearing resistance (e.g., Fig. 7). For this scenario, Idriss and Boulanger (2007) recommended a lower relationship which curves more gently upward, eventually approaching drained strengths at an $(N_1)_{60cs}$ of about 32; this latter point on the residual strength curve was selected to agree with the limits of liquefaction triggering curves.

The two scenarios presented by Idriss and Boulanger (2007) present an opportunity for discussing a few technical issues regarding the development of procedures for estimating Sr.

- Can the absence of observations of flow slides in cohesionless soils with $(N_1)_{60}$ or $(N_1)_{60cs}$ values greater than about 14 be taken as evidence that in-situ shear strengths can always be expected to steeply increase as $(N_1)_{60}$ or $(N_1)_{60cs}$ values increase above 14?
- Are the mechanisms of in-situ void redistribution and particle intermixing sufficiently well understood that we know when it will, or will not, be significant? Can we omit these mechanisms in the development of procedures that will be used in practice?
- Are the case history data sufficiently well constrained or the mechanisms of strength loss sufficiently well understood to determine whether a strength (S_r) model, strength ratio (S_r/σ'_v) model, or a hybrid model is the most appropriate?

These and other questions regarding the estimation of residual shear strength warrant further discussions, and likely will continue to be topics for debate for years to come. In the meantime, further research on understanding and bounding the significance of void redistribution and other mechanisms of strength loss are needed to resolve concerns and advance this aspect of our practice.

5. CONCLUDING REMARKS

Challenges in advancing the procedures for estimating the in-situ residual shear strength of liquefied soils were described and discussed. These include limitations in the empirical case history data and in our understanding of, and ability to numerically simulate, the mechanisms of strength loss associated with pore water pressure diffusion and void redistribution. Additional research and evaluations are needed for advancing our understanding and treatment of this important area of practice.

SEISMIC BEHAVIOUR OF LARGE DAMS DURING RECENT EARTHQUAKES AND CURRENT STATE OF SEISMIC DESIGN CRITERIA FOR LARGE DAMS

Martin Wieland

Chairman, Committee on Seismic Aspects of Dam Design, International Commission on Large Dams (ICOLD)
Poyry Energy Ltd., Zurich, Switzerland
martin.wieland@poyry.com

Abstract: The following, relatively recent earthquakes had a major impact on large dams: (i) the 2001 Bhuj (M=7.5) earthquake in Gujarat province, India has affected or damaged some 245 earthen dams, most of them used for irrigation and water supply; (ii) the 2008 Wenchuan (M=8.0) earthquake in Sichuan province, China has damaged 1803 dams and reservoirs and 403 hydropower plants with an installed capacity of 3.3 GW; and (iii) the 2010 Maule (M=8.8) earthquake in Chile has strongly shaken some 13 large dams. Among these events the lessons learnt from the Wenchuan earthquake are the most significant ones as this earthquake has also affected RCC and concrete face rockfill dams. The main conclusions from these recent earthquakes are discussed. Moreover, the current state of seismic design criteria for large dams of the International Commission on Large Dams is presented.

1. INTRODUCTION

In recent years, three important earthquakes have occurred, which have damaged different types of dams, i.e.

(i) the 2001 Bhuj (M=7.5) earthquake in Gujarat province, India has affected or damaged some 245 earthen dams, most of them used for irrigation and water supply;

(ii) the 2008 Wenchuan (M=8.0) earthquake in Sichuan province, China has damaged 1803 dams and reservoirs and 403 hydropower plants with an installed capacity of 3.3 GW, most of the dams were small dams but also a few dams with heights exceeding 100 m and run-of-river power plants were affected; and

(iii) the 2010 Maule (M=8.8) earthquake in Chile has strongly shaken and affected some 13 large dams. Moreover, during recent earthquakes in Japan a large number of dams had to be inspected according to current regulations.

The lessens learnt from the Wenchuan earthquake are the most significant ones for the dam industry as this earthquake has affected both roller compacted concrete and concrete face rockfill dams, i.e. dams which are being built in increasing numbers and whose earthquake resistance had not yet been tested by previous earthquakes. Moreover, a large concrete gravity dam under construction was also severely shaken. The main conclusions and lessons learnt from the Wenchuan earthquake are discussed in the subsequent sections.

2. WENCHUAN EARTHQUAKE

2.1 Effects on Large Dams

Sichuan province is the province with the largest hydropower potential in China with some 6678 dams and reservoirs.

The Wenchuan earthquake is the earthquake, which has affected more dams than any other earthquake before, i.e. 1803 dams and reservoirs and 403 hydropower plants. It is also the most important seismic event, which occurred since the creation of the earthquake committee of the International Commission on Large Dams (ICOLD) some 40 years ago.

2.1.1 Shapai arch dam

During the Wenchuan earthquake the 132 m high Shapai arch dam, the world's highest roller compacted concrete (RCC) arch dam, was subjected to strong ground shaking.

The dam is a three-centered arch structure with vertical upstream face. The crest length and thickness are 250.25 m and 9.5 m respectively. The maximum thickness at the base is 28 m. The dam is located 30 km away from the epicenter and during the earthquake the reservoir was at normal water level. There are two vertical contraction joints and two induced joints with a spacing of about 50 m. The dam is founded on granite and granodiorite and was completed in 2003. The seismic design of the dam was based on a horizontal peak ground acceleration of 0.138 g.

During the author's visit in early April 2009 no signs of damage could be observed, however, the reinforced concrete elevator building on the crest and the superstructures of the intake towers suffered some damage, which was repairable. The powerhouse located several kilometers downstream was severely damaged by the impact of rocks originating from high elevations in the steep mountains. The movement joint of the penstock across the river failed, causing flooding of

the powerhouse.

2.1.2 Zipingpu concrete face rockfill dam

The 156 m high Zipingpu concrete face rockfill dam (CFRD) is one of the largest CFRDs in China and one of the key projects for water supply and irrigation for the Chengdu basin. The dam was completed in 2006 and represented the latest CFRD technology in China. The dam was designed for an intensity of VIII (Chinese scale), with a design peak ground acceleration of 0.26 g. The epicentral distance of the dam was 17 km. During the earthquake the reservoir level was low and its volume was 200 Mm^3. Under normal operation conditions the reservoir volume is 1100 Mm^3. The crest of the dam and the concrete face were damaged. Of greatest interest was the damage to the concrete face and waterproofing system which consisted of damage of the waterstop and the offset of the horizontal joint between the second and third stage slab construction.

After the earthquake the maximum settlement at the dam crest was 735 mm and the horizontal deflection in downstream direction was 180 mm. The cross-canyon deformation of both abutments was 102 mm.

Because of the low water level in the reservoir at the time of the earthquake, it is difficult to estimate what the earthquake behaviour of the dam, the concrete face, and the waterproofing system would have been if the reservoir was full.

2.2 Earthquake Hazard

The Wenchuan earthquake has clearly demonstrated that earthquakes are multiple hazards, which can affect large dam projects in many different ways. The seismic hazard includes the following:

- ground shaking causing vibrations in dams, appurtenant structures and equipment, and their foundations;
- fault movements in the dam foundation or discontinuities in dam foundation near major faults which can be activated causing structural distortions;
- fault displacement in the reservoir bottom causing water waves in the reservoir or loss of freeboard;
- rockfalls causing damage to gates, spillway piers (cracks), retaining walls (overturning), surface powerhouses (cracking and puncturing), electro-mechanical equipment, penstocks, masts of transmission lines, etc.
- mass movements (landslides and rockfalls) into the reservoir causing impulse waves and overtopping of dams;
- mass movements blocking rivers and forming landslide lakes whose failure may lead to overtopping of downstream run-of-river power plants or the inundation of powerhouses with equipment;
- mass movements blocking access roads to dam sites and appurtenant structures and
- ground movements and settlements due to liquefaction or densification of soil, causing distortions in dams and appurtenant structures.

Surface water waves in the reservoir and long-period reservoir oscillations (seiches) caused by ground movements are of lesser importance for the earthquake safety of a dam. Although overtopping of the dam crest is possible such as in the case of the 1959 Hebgen Lake earthquake in Montana, USA.

Usually the dam engineers are focusing on the ground shaking and neglect the other aspects. Therefore, it is recommended to prepare a hazard matrix in which along one axis the different hazards are listed and along the other one the different structures, elements and components of the dam project.

It is well known that ground shaking affects all structures (above and below ground), elements and components at the same time, whereas the other hazards listed above may only affect some of them. However, the Wenchuan earthquake has shown that in the epicentral region where thousands of rockfalls and slides occurred, the damage due to rockfalls was very serious. Some of the dam sites were not accessible for several months. For example the Shapai arch dam site was inaccessible by road and heavy construction equipment for about 10 months.

2.3 Main Lessons Learnt from Wenchuan Earthquake

Strong earthquakes can affect a large area and many dams may be subjected to strong ground shaking. This has been the case for the Wenchuan earthquake. Different types of dams have been damaged; therefore the lessons learnt from this earthquake will be relevant for the whole dam industry.

During the Wenchuan earthquake the problem of mass movements (mainly rockfalls in very steep mountains) and landslide lakes have shown to be very important new features of strong earthquakes.

In addition, an unprecedented large number of dams and run-of-river power plants have been affected by this earthquake. The Wenchuan earthquake has confirmed and demonstrated that dams, spillways and appurtenant structures must be able to withstand the multiple effects of strong earthquakes.

3. SEISMIC DESIGN CRITERIA

3.1 Background on Seismic Design of Dams

Large concrete dams have been among the first structures that have been designed against earthquakes since the 1930s, however, the knowledge about their seismic safety is actually poor, because most of them were designed using seismic design criteria and methods of dynamic analysis that are considered obsolete today. Earthquake loading was represented by a pseudo-static force expressed as the product of a seismic coefficient and the weight of the structure, acting in upstream-downstream direction plus a hydrodynamic force acting on the upstream face of the dam. This type of analysis did not consider the dynamic characteristics of the dam, although both, inertia forces and the hydrodynamic pressure were taken into account.

A significant step forward was achieved when in 1989 ICOLD published Bulletin 72 entitled Selecting Seismic Parameters for Large Dams, where new seismic design criteria were specified for dams. Accordingly, new dams

should comply with this guideline, which sets minimum seismic design criteria for dams and safety-relevant elements. This guideline has been revised in 2010. The basic concept is that the dam has to be designed for the Operating Basis Earthquake (OBE) and the Safety Evaluation Earthquake (SEE). The terms Maximum Credible Earthquake (MCE) and Maximum Design Earthquake (MDE) defined in the 1989 version of the guideline have been replaced by Safety Evaluation Earthquake (SEE).

The seismic design of dams is based on two different elements, i.e.

(i) dynamic analysis of dam subjected to OBE and SEE ground motions; and

(ii) proven design concepts and guidelines to ensure that the dam will perform well under strong earthquake action.

It is a misconception to believe that a dam with conceptual deficiencies can be made safe by using sophisticated seismic analysis tools. Powerful analysis software is available today to perform such analyses. However, the reliability of analyses is limited by the uncertainties in the seismic input, dynamic material properties, limitations in numerical modeling etc. Moreover, most computer programs for the inelastic dynamic analysis of dams are still in the research and development phase and have not been tested in practice. Although in dam engineering the behaviour of dams shall be analysed as realistically as possible, this is a difficult task for the strongest earthquake ground motion, because of the lack of observational data of modern dams, which have experienced such earthquakes. Because of these reasons and due to the fact that each dam is a prototype it is very difficult to generalize observations obtained from a few dams.

Finally, we should not underestimate the importance of the quality of the construction works on the earthquake performance of large dam projects..

3.2 Seismic Design Criteria for Dam Projects

In practice the seismic design criteria for the main structures, components and equipment of a typical hydro power plant must be defined. The following design earthquake motions are used:

(i) Construction level earthquake for temporary structures (CE): A typical return period of the CE for appurtenant structures is 50 years. For cofferdams and critical construction stages of concrete dams with blocks of variable height the CE is larger than that for appurtenant structures and can be selected based on risk considerations.

(ii) Design basis earthquake for appurtenant structures (DBE): The DBE can be selected based on earthquake codes for buildings and other structures. The seismic design shall then be performed following the corresponding building code taking into account the local soil conditions, the importance factors assigned to different types of appurtenant structures and using ductility/behaviour factors for different structural elements and systems specified in the code. If the code allows, then site-specific design response spectra can be used. In Europe, the return period of the DBE ground motion is 475 years. In North America the DBE is based on a reference return period of 2475 years.

(iii) Operating Basis Earthquake (OBE): The OBE has a return period of145 years. No structural damage is accepted, i.e. stresses in concrete dams must remain within allowable stresses. The OBE represents a serviceability limit state and is basically an economical criterion, which is of primary interest for the dam owner.

(iv) Safety Evaluation Earthquake (SEE): The SEE has no specific return period but 10,000 years are often used for large dams. The return period of the SEE is also determined based on the seismic risk of a dam. For example in Switzerland the return periods of the SEE ground motions are as follows: 10,000 years for dam category I (large dams with reservoir depth exceeding 40 m or a reservoir volume exceeding one million m3), 5,000 years for dam category II (medium size dams with reservoir depths in the range of 5 to 40 m), and 1000 years for dam category III (all other dams also including those with a height of less than 5 m). Category I and II dams are under control of the federal authorities.

Structural damage (cracks, deformations) is accepted for the SEE as long as there is no uncontrolled release of large quantities of water from the reservoir. The SEE is relevant for dam safety.

For the safety-relevant elements such as the bottom outlet and the spillway gates, which must be operable after the SEE, no damage and inelastic deformations are accepted, which would obstruct operation of these elements. Power supply and control units for the operation of these elements must also be intact after the SEE.

Thus the seismic performance criteria for the bottom outlet and spillway gates are stricter than thos of the dam body as they must be operable so that the reservoir can be lowered, and a moderate flood can still be released safely after a major earthquake.

Accordingly, the following safety classes of the different structures, elements and components can be defined:

(i) Safety class 1 includes elements and components, which must remain in an operable state after the ground motion of the SEE, i.e. bottom outlet and spillway gates.

(ii) Safety class 2 includes the dam body and other water retaining elements, which must be able to retain the water in the reservoir after the SEE until the water in the reservoir can be lowered if the dam experiences structural damage.

(iii) Safety class 3 includes mainly appurtenant structures such as the powerhouse, switchyard, transmission towers etc., which have to be able to withstand a design ground motion that is less severe than that of the SEE.

(iv) Safety class 4 includes non-critical structures like office buildings, storage facilities etc., which may be designed according to building code regulations.

(v) Furthermore, special seismic design criteria have to be established for temporary structures (cofferdams, river diversion structures etc.) and for critical construction phases.

For the seismic analysis and design of the hydro-mechanical and electro-mechanical equipment the design ground motions at the supports of these components have to be used. These support motions at the dam crest may be completely different from the earthquake ground motion at the rock surface obtained from the seismic hazard analysis.

4. SEISMIC ANALYSIS OF DAMS

4.1 Concrete Dams

For the analysis of a dam subjected to the OBE ground motion, linear-elastic dynamic analysis methods developed in the 1970s are still suitable. The great advantage of such analyses is that two engineers solving the same problem should get the same answers, if the geometry, material properties and boundary conditions are the same. Today such analyses seem to be straightforward, however, there are still problems with the realistic modeling of the dynamic interaction effects of the dam with the reservoir and the foundation rock, the material damping and the effect of non-uniform ground motions especially in the case where three-dimensional analyses are needed.

In the case of the SEE ground motions, some structural damage is accepted, which is usually characterized by inelastic phenomena, e.g. joint opening, formation of cracks, hysteretic behaviour of materials, sliding and rocking motions, etc. The inelastic dynamic analyses are much more demanding and complex than any linear-elastic analyses, and besides experience and engineering judgment a thorough understanding of the main inelastic features governing the dynamic response are needed. In addition, these analyses require an in depth knowledge of the numerical limitations of the nonlinear algorithms involved.

Many engineers still try to avoid nonlinear seismic analyses, for example, by assuming high damping values or considering too low SEE ground motions in order to reduce the dynamic response, so that a linear-elastic analysis could be justified. It is, however, expected that there will be an increasing demand for nonlinear dynamic analyses of dams in the future.

4.2 Embankment Dams

The first dynamic response analysis of an earth dam was made by Mononobe et al. already in 1936. Earth dam design prior to the 1960s was mainly empirical using judgment guided by past experience. However, there was a severe lack of precedence of dams which had been subjected to strong shaking by an earthquake.

Basically, the seismic safety and performance of embankment dams is assessed by investigating the following aspects:

- permanent (inelastic) deformations experienced during and after an earthquake (e.g., loss of freeboard);
- stability of slopes during and after the earthquake, and dynamic slope movements;
- build-up of excess pore water pressures in embankment and foundation materials (soil liquefaction);
- damage to filter, drainage and transition layers (i.e., whether they will function properly after the earthquake);
- damage to waterproofing elements in dam and foundation (core, upstream concrete face or asphalt membrane, geotextiles, grout curtain, diaphragm walls in foundation, etc.,);
- vulnerability of dam to internal erosion after formation of cracks or formation of loose material zones due to high shear (shear bands);
- vulnerability of hydromechanical equipment to ground displacements and vibrations; and,
- damage to intake and outlet works (safe release of the water from the reservoir may be jeopardized after the earthquake).

Different material models can be used for the inelastic dynamic analysis of dams. Today the most widely used method for the seismic analysis of embankment dams is the equivalent linear method developed in the early 1970s. In this method the shear strain-dependent shear modulus and damping ratio are taken into account in an iterative process using linear-elastic dynamic analyses.

5. THE ROLE OF ICOLD IN THE EARTHQUAKE SAFETY OF LARGE DAMS

The Committee on Seismic Aspects of Dam Design is one of ICOLD's oldest technical committees, which at present comprises dam and earthquake experts from 32 different countries from all continents. It has prepared a number of guidelines on various aspects of seismic analysis, design and seismic monitoring of dams. These guidelines are considered as seismic guidelines in most countries which do not have any specific codes or regulations for dams. Since 1984 the following guidelines have been prepared (Wieland, 2003):

- Bulletin 52 (1986): Earthquake analysis procedures for dams (Report prepared on behalf of the Committee on analysis and design of dams of ICOLD, O. C. Zienkiewicz, R. W. Clough, H. B. Seed),
- Bulletin 62 (1988): Inspection of dams following earthquakes – guidelines (revised in 2008),
- Bulletin 72 (1989): Selecting seismic parameters for large dams (revised in 2010),
- Bulletin 112 (1998): Neotectonics and dams,
- Bulletin 113 (1999): Seismic observation of dams,
- Bulletin 120 (2001): Design features of dams to effectively resist seismic ground motion,
- Bulletin 123 (2002): Earthquake design and evaluation of structures appurtenant to dams, and
- Bulletin 137 (2011): Reservoirs and seismicity: state of knowledge.

Bulletin 137 is concerned with reservoir-triggered seismicity which has attracted much attention in connection with large dam projects and it has also been argued that the Wenchuan earthquake was triggered by the reservoir stored by the Zipingpu dam although there is no evidence, which supports this allegation. An expert team of ICOLD and the Chinese National Committee on Large Dams, which visited

some of the large dams affected by the Wenchuan earthquake in spring 2009 has not found any link between this earthquake and the Zipingpu reservoir.

The publication with the greatest impact on the seismic design of dams is Bulletin 72, which was revised in 2010. In this guideline the concept of two earthquake level for the seismic design of dams was introduced internationally, i.e. the Operating Basis Earthquake (OBE) and the Safety Evaluation Earthquake (SEE) ground motions. Today, most dams are designed against earthquakes using this concept, which can be considered as the minimum seismic design requirement for dams.

Bulletin 120 complements Bulletin 72 as it includes conceptual features for the seismic design of dams, which are extremely important as it is well-known that it will be difficult to have a dam to perform well during an earthquake when the basic seismic design concepts are not observed.

6. CONCLUSIONS

The importance of the seismic load case in the design of dams has changed considerably. Rational concepts of the ground motion a dam has to be able to withstand have been developed, i.e. a dam must be able to withstand the SEE ground motion. Furthermore, we have to realise that all structures, elements and components of a hydropower plant will be subjected to ground shaking if an earthquake occurs. Therefore, all of them have to be checked and designed for earthquake action.

Moreover, the Wenchuan earthquake has clearly shown that the seismic hazard is a multiple hazard, and all of them have to be considered.

Simple nonlinear analyses methods are still widely used for the seismic analysis of dams, such as the Newmark sliding block method and the equivalent linear method for the analysis of the embankment dams. These methods are, however, nearly 40 years old.

The methods for nonlinear dynamic analysis of dams are, however, still under development. Nonlinear seismic analyses need substantial engineering judgment. The proper formulation of the goals of the seismic analysis is probably the most difficult task required to ensure that such an analysis can actually ‘succeed’. Relatively simple models should be preferred to complex models employing nonlinear constitutive laws using parameters that are either not available or very hard to determine.

REFLECTIONS ON EVOLUTION OF NEAR-FIELD EARTHQUAKE ENGINEERING

Tatsuo Ohmachi

Professor, Department of Built Environment, Tokyo Institute of Technology, Japan
Ohmachi@enveng.titech.ac.jp

Abstract: Reflecting on his 32 years of teaching and research at Tokyo Tech, the author addresses an urgent necessity to establish a new field of study; namely, near-field earthquake engineering. Several landmark events that motivated the author to devote himself to the field, as well as more recent events that the author was actively associated with are summarized.

1. INTRODUCTION

It was July 1, 1979 when I moved to Tokyo Institute of Technology (Tokyo Tech) from the Electric Power Development Co. Ltd. (EPDC), and joined the earthquake engineering laboratory as Associate Professor. My boss was Professor Hiroyoshi Kobayashi who had been engaged in hazard assessment and mapping of ground motion intensity in the event of the expected Tokai earthquake, with a the help of his doctoral student, S. Midorikawa.

In the previous year, 1978, the Large Scale Earthquake Countermeasures Act came into effect in Japan. A main target of this act is the Tokai earthquake which is supposedly imminent and expected to occur beneath Suruga Bay where an earthquake of magnitude (M) 8 or larger has not occurred since 1854. Following this Act, instrumentation arrays were set up to monitor precursors of an earthquake and data from the arrays are telemetered to Tokyo where the Japan Meteorological Agency would review the data and decide whether a meeting of the Earthquake Assessment Committee should be convened.

Discussions with Professor Kobayashi and his colleagues deeply impressed me with their hazard assessment work, applying the state-of-the art technology to a seismic fault model with site-dependent geological conditions. Since then, I have been motivated to study near-field earthquake engineering. In the following sections, I discuss several landmark earthquake events listed in Table 1 that motivated me to devote myself to the near-field earthquake engineering in chronological order.

2. LANDMARK EARTHQUAKE EVENTS

2.1 The 1984 Nagano-ken Seibu earthquake (M6.8), Japan

In early January, 1985, I had an opportunity to investigate damage to a tunnel running zigzag across the source area of the Nagano-ken Seibu earthquake which occurred on September 14, 1984. The tunnel is a headrace tunnel for hydroelectric power generation, having a horseshoe-shaped cross section about 3 m in diameter. Tunnel damage was mainly horizontal shear cracking of the concrete lining and concentrated at three different locations along the tunnel. To my surprise, the three damage locations were on a straight line having an orientation consistent with a mechanism solution of the earthquake, as shown in Fig. 1. On this basis, it was estimated that the tunnel damage had been caused by subsurface faulting, and that the straight line was evidence of the faulting, although no trace of the faulting was found on the ground surface.

Table 1 Landmark events in near-field earthquake engineering

Year	Landmark Earthquake Events	Special Features
1984	Nagano-ken Seibu (M6.8), Japan	Tunnel damage and upthrow of boulders
1985	Michoacan (M8.1), Mexico	Uplift of seabed at Caleta de Campos
1990	Luzon Island (M7.8), Philippines	Fault trace on ground surface
1994	Northridge (M6.7), USA	High acceleration exceeding 1 g
1995	Hyogo-ken Nanbu (M7.2), Japan	Jumping of bell house and Level 2 motion
1999	Chi-chi (M7.5), Taiwan	Collapse of a concrete gravity dam
2000	Tottori-ken Seibu (M7.3), Japan	Sudden Change in reservoir water level
2003	Tokachi-Oki (M8.0), Japan	Tsunami generation observed by JAMSTEC
2008	Iwate-Miyagi Nairiku (M7.2), Japan	Strong motion records of about 4 g and nonlinear response of a rockfill dam

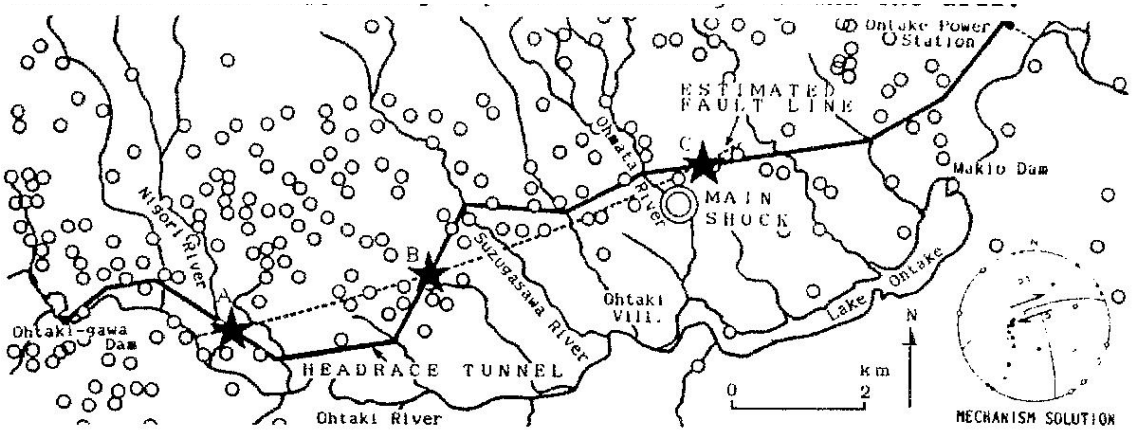

Fig. 1 Location map of earthquake damage to the headrace tunnel, Japan

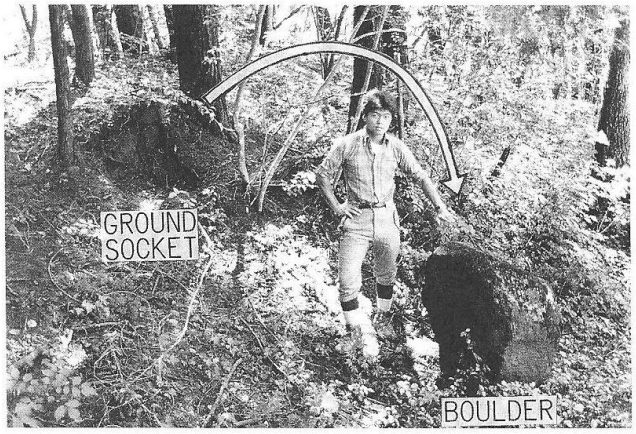

Fig. 2 Upthrow of a boulder in the near-field of the 1984 earthquake, Japan

In August, 1985, we made a presentation of the tunnel investigation (Kobayashi et al., 1985) at a poster session of the 23rd general assembly of International Association of Seismology and Physics of the Earth's Interior (IASPEI) which was held in Tokyo. In the next booth, there was another poster presentation dealing with upthrow of boulders observed in the near-field of the same earthquake (Umeda et al., 1985). I was very much interested in their presentation in which extremely high peak ground acceleration (PGA) as much as 1 to 10 g where g is acceleration due to gravity, was estimated from the jumping. Though PGA of 1.25 g had already been observed at the Pacoima dam during the 1971 San Fernando earthquake (M6.6), I felt the estimated PGA of 10G was unbelievable. What is worse, the estimated PGA was increased to 8 to 16 g later (Umeda et al., 1987). A site investigation which included the areas where upthrow of boulders were reported was conducted by my colleagues, later, as shown in Fig. 2.

2.2 The 1985 Michoacan earthquake (M8.1), Mexico

The Michoacan earthquake occurred on September 19, 1985, along the Pacific coast of Mexico. While my colleagues went out to Mexico city for the earthquake investigation, I stayed back in my laboratory and found a paper by Newmark on upthow of objects during earthquakes (Newmark, 1973) which states "although it is necessary that the actual acceleration of a near-surface object be greater than the acceleration of gravity for it to move upward relative to the ground, this is not necessarily an indication that the general vertical ground acceleration is indeed greater than that of gravity". This is because the upward movement or upthrow takes place when the earthquake response of the objects exceeds the acceleration of gravity. Inspired by this paper, I collected things available in my room such as steel balls and a sponge rubber mat, and repeated shake-table experiments by trial and error.

Finally, I succeeded to demonstrate the jumping of steel balls which were originally embedded in hollows of the sponge rubber mat, only by horizontal table motion. The experiments were followed by numerical simulations shown in Figs. 3 and 4. In Fig. 4, it is interesting to note that maximum response accelerations in both horizontal and vertical directions were in excess of 10 g, while the ground motion acceleration was less than 1.5 g.

In January, 1986, I visited the source area of the Michoacan earthquake as a member of the Japan Society of Civil Engineers (JSCE) investigation team. At Caleta de Campos, one of the inhabitants told us that the sea surface had settled down significantly after the earthquake. In fact it could be observed as a shell line about 1m 1 m above the sea surface, as shown in Fig. 5, which was, in our estimation, caused by the uplift of the seabed as a result of the seismic faulting. Later we were pleased to find that earthquake ground displacement calculated from strong motion records showed an uplift similar to that observed by us.

2.3 The 1990 Luzon Island earthquake (M7.8), Philippines

On July 16, 1990, a major earthquake occurred in the central part of Luzon Island, Philippines. In Dagupan city,

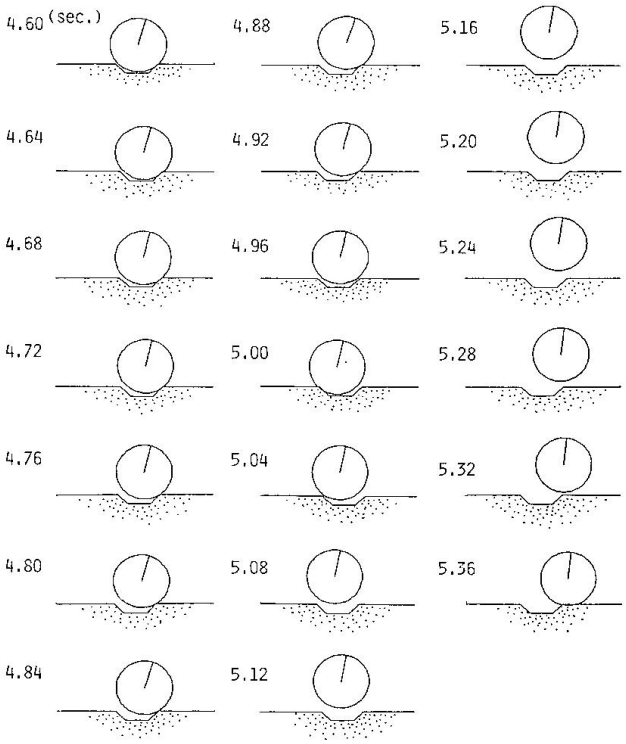

Fig. 3 Snapshots of numerical simulation of upthrow of objects

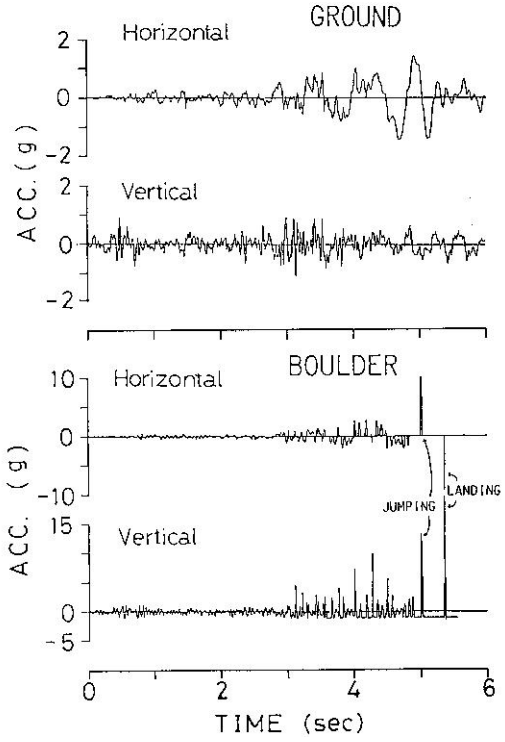

Fig. 4 Time histories of the numerical simulation

Fig. 5 Uplift of seabed witnessed at Caleta de Campos, Mexico

many building were damaged by soil liquefaction, while a refurbished hotel building in Baguio city had collapsed due to the intense earthquake shaking. For the first time in my life, I observed a seismic fault that had appeared on the ground surface, in the suburbs of Digdig town (Fig. 6).

2.4 The 1994 Northridge earthquake (M6.7), USA

Before the dawn of January 17, 1994, this earthquake occurred in the middle of the San Fernando Valley, California. At Tarzana strong motion station 5 km distant from the epicenter, the PGA was 1.82 g and 1.18 g in the

Fig. 6 Surface rupture witnessed in the suburbs of Digdig town, Philippines

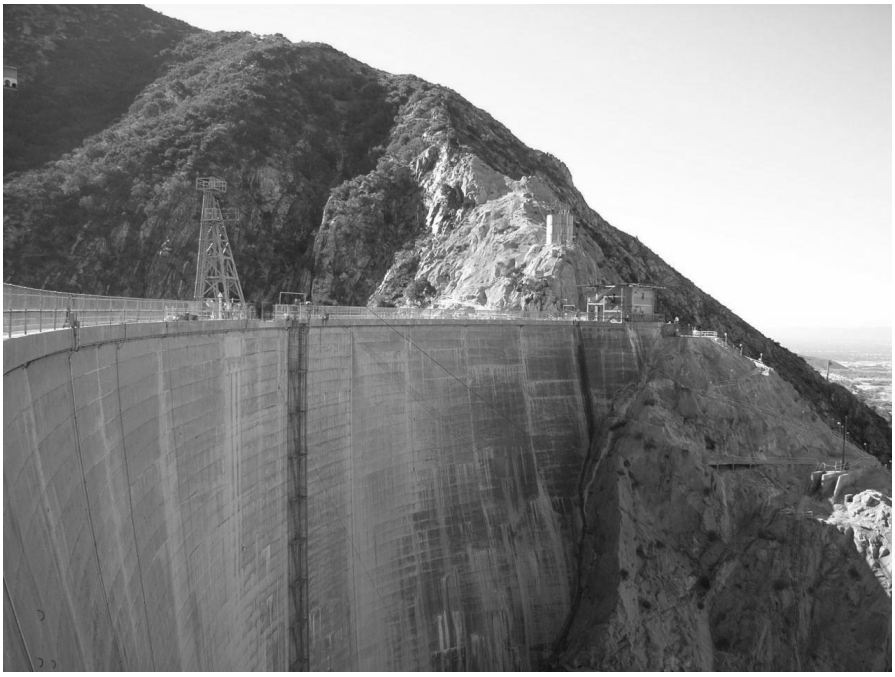

Fig 7 Left bank of the Pacoima arch dam, USA

horizontal (H) and vertical (V) directions, respectively. Despite such high accelerations, surprisingly, little damage was observed around the station.

On the left bank of the Pacoima dam which is a 111 m high arch dam, the PGA was 1.53 g and 1.39 g in the horizontal (H) and vertical (V) directions, respectively. It is noted that in the 1971 San Fernando earthquake (M6.6), an earthquake acceleration of 1.25 g (H) was recorded, which was the first time in history that accelerations exceeding 1 g were observed. Since then, the 1971 earthquake records have been widely discussed and it has been concluded that the high acceleration was attributable to the effect of the narrow ridge shown in Fig. 7, where the accelerometers were installed. This conclusion was further confirmed by the 1994 earthquake because PGA observed at another rock station at the dam site was 0.54 g (H) and 0.43 g (V), respectively.

Fig. 8 A Japanese bell house that was uplifted during the 1995 earthquake, Japan

2.5 The 1995 Hyogo-ken Nanbu earthquake (M7.2), Japan

Similar to the Northridge earthquake, the Hyogo-ken Nanbu earthquake occurred before dawn on a winter day on January 17, 1995. I was amazed to see the serious damage to different types of civil engineering structures. The damage suggested ground motion intensities much higher than those used in traditional seismic designs of structures, which was demonstrated by several strong motion recordings of the main shock in and around Kobe city.

Meanwhile on Awaji Island, no strong motion recording was recovered, even though some areas were assigned the highest seismic intensity 7 on the Japan Meteorological Agency (JMA) scale. On being informed that the uplifting of a Bell House shown in Fig. 8 had been observed at Saimyo-ji temple located in an intensity 7 area, I could not help visiting that location for more detailed information. This was because, as shown in Fig. 9, I had studied the uplifting of a Bell House several years before the 1995 earthquake, and learned that it could provide much information associated with earthquake ground motion (Ohmachi et al, 1997).

Following the 1995 earthquake, the Japan Society of Civil Engineers (JSCE) issued the "Proposal on Earthquake Resistance for Civil Engineering Structures" three times in May 1995, January 1996 and June 2000. One of the requirements of the proposals is to consider two levels of earthquake input motion for seismic design of structures; namely, Level 1 and Level 2 motions. I took part in drafting the proposals on the Level 2 motion (Fig. 10) and studied earthquake input motion in detail during that time.

Based on these experiences, I was involved in the formulation of the Guideline for Seismic Safety Evaluation of Dams (Draft) issued in 2005, and the Revised Guideline

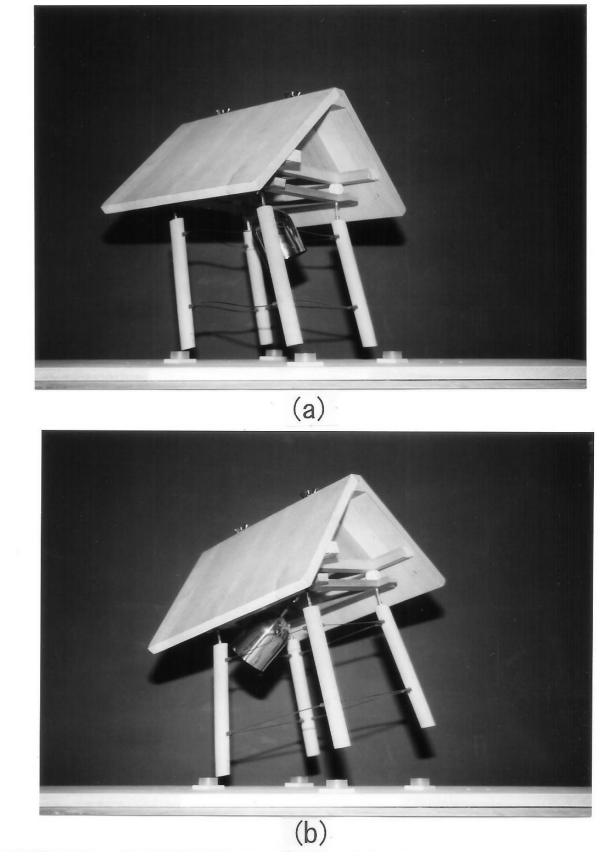

Fig. 9 A shake-table experiment for the upthrow of a bell house

Fig. 11 The Shih-kang dam collapsed by the 1999 earthquake, Taiwan

for Seismic Safety Evaluation of Water Works issued in 2010.

2.6 The 1999 Chi-chi earthquake (M7.5), Taiwan

Among several cases of dams damaged by the Chi-chi earthquake, the most severe case was the collapse of the Shih-Kang dam. It was a 357 m long concrete gravity dam, equipped with 18 spillway gates and 2 sediment flushing gates. Due to dislocation along the ramified seismic fault planes, the right half side of the dam and intake tunnel on the left bank side were crushed completely with 7.5 m and 3.5 m differences in level, respectively. Figure 11 shows the Shih-Kang dam severely damaged by the earthquake.

2.7 The 2000 Tottori-ken Seibu earthquake (M7.3), Japan

This earthquake occurred on October 6, 2000, in the western part of Tottori prefecture. The Kasho dam located in the near field of this earthquake, is a 46.6 m high concrete gravity dam constructed in 1989. Strong motion accelerometers at the dam registered a peak acceleration of

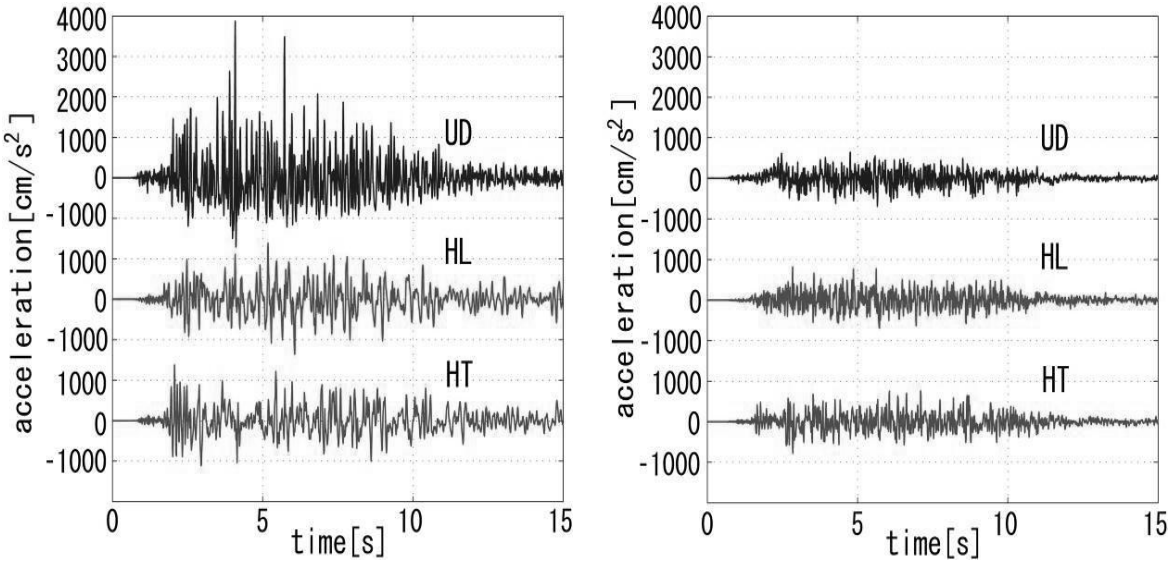

Fig. 12 Three-component acceleration records at IWTH25 station:
(a) surface record (left) and (b) borehole record at a depth of 260m (right)

2051 gal at the top of the dam and 531 gal in the lower inspection gallery (Japan Commission of Large Dams, 2002). Despite such high accelerations, the dam did not suffer serious damage, the only damage was cracking of the concrete floor in the sub-gate control room. Although no increase in water leakage was recorded, the water level of the reservoir suddenly dropped 6 cm immediately after the main shock. The reasons for the drop in water level were not clear and raised concern among dam engineers.

On hearing about this drop in water level, I recalled the radiation pattern of a strike-slip of a point source faulting, and tried to attribute the drop in the water level to the change in the slope of the reservoir bed. In fact according to a ground survey conducted around the reservoir, there was a slight decrease in the slope of the ground surface. Moreover, integration of the acceleration records in the gallery gave a permanent uplift of about 5 cm, and a 34.9 m long plumb line installed in a vertical shaft within the dam showed a change in the slope of the dam. To my satisfaction, these observed changes in the slope were in fairly good agreement with those from a numerical simulation using a seismic fault model.

2.8 The 2003 Tokachi-oki earthquake (M8.0), Japan, and tsunami

The Tokachi-oki earthquake (M8.0) occurred off the southeastern coast of the Tokachi district at 04:50 on September 26, 2003. In the source area, an offshore monitoring system deployed by Japan Agency for Marine-Earth Science and Technology (JAMSTEC) succeeded in recording detailed data associated with the tsunami generation process for the first time in history. Analysis of the JAMSTEC monitoring data showed that three kinds of water waves were involved in the dynamic tsunami generation process; that is, water pressure waves of short period, a tsunami of long period, and preceding waves of intermediate period.

Since 1995, we have developed the "dynamic tsunami simulation technique", which takes into account both the dynamic seabed displacement and acoustic effects of the seawater. Through the dynamic simulation, the three kinds of water waves were predicted, but had to be validated by actually observed data. In this context, the JAMSTEC data was very important not only for general scientific purposes but also for our study on near-field tsunamis which aims to develop state-of-the-art technology for an effective tsunami warning system.

2.9 The 2008 Iwate-Miyagi Nairiku earthquake (M7.2), Japan

This earthquake occurred on June 14, 2008 near the boundaries of Iwate and Miyagi prefectures. During the earthquake, extremely high accelerations were recorded at the KiK-net IWTH25 station, as shown in Fig. 12. The peak acceleration in the vertical component of the surface record in Fig. 12(a) was about 4 g and the upward vertical acceleration was much larger than the downward counterpart, while in the borehole record at a depth of 260 m in Fig. 12(b), the upward and downward accelerations have symmetric vertical amplitudes. Some researchers have suggested that the asymmetric large amplification in the vertical acceleration is because the ground surface was tossed into the air during the main shock like a body on a trampoline (Aoi et al., 2008, and Yamada et al., 2009).

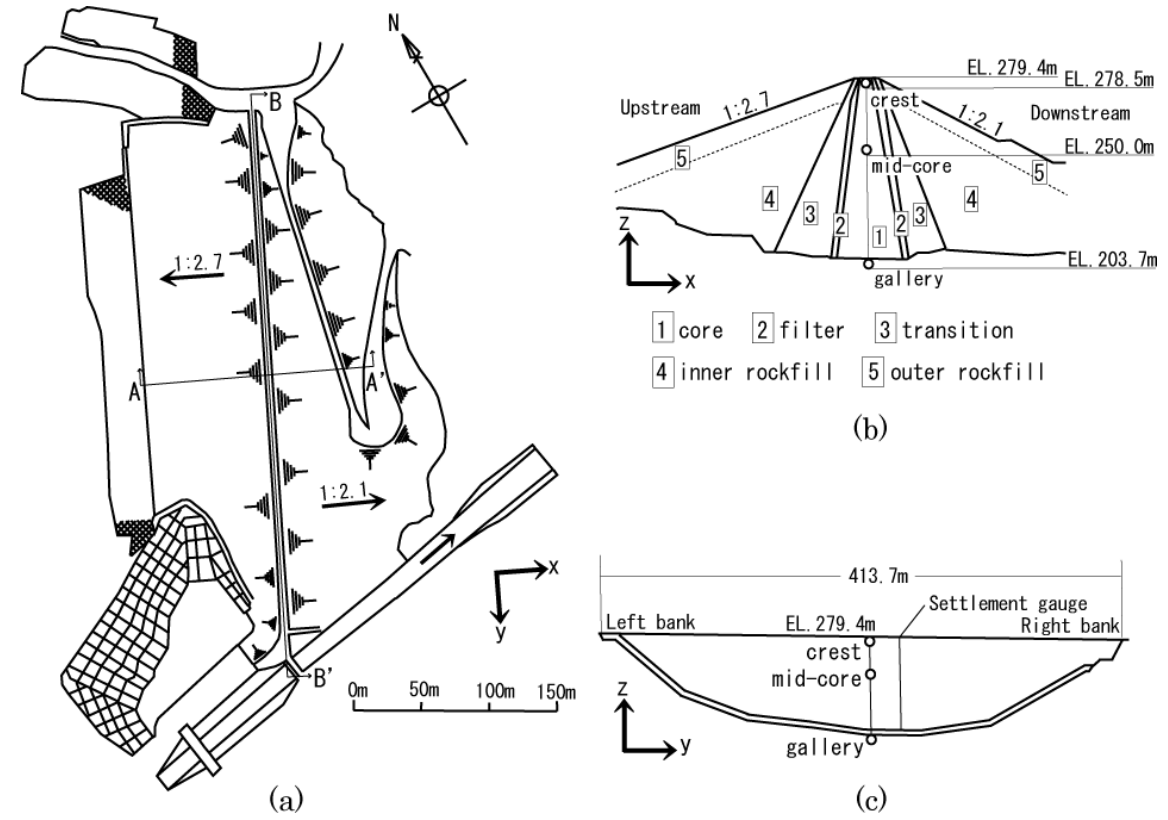

Fig. 13 (a) Plan, (b) cross section A-A' and (c) cross section B-B' of the Aratozawa dam with seismometers located at crest, mid-core and gallery. Arrows with x, y and z indicate positive directions of observed accelerations

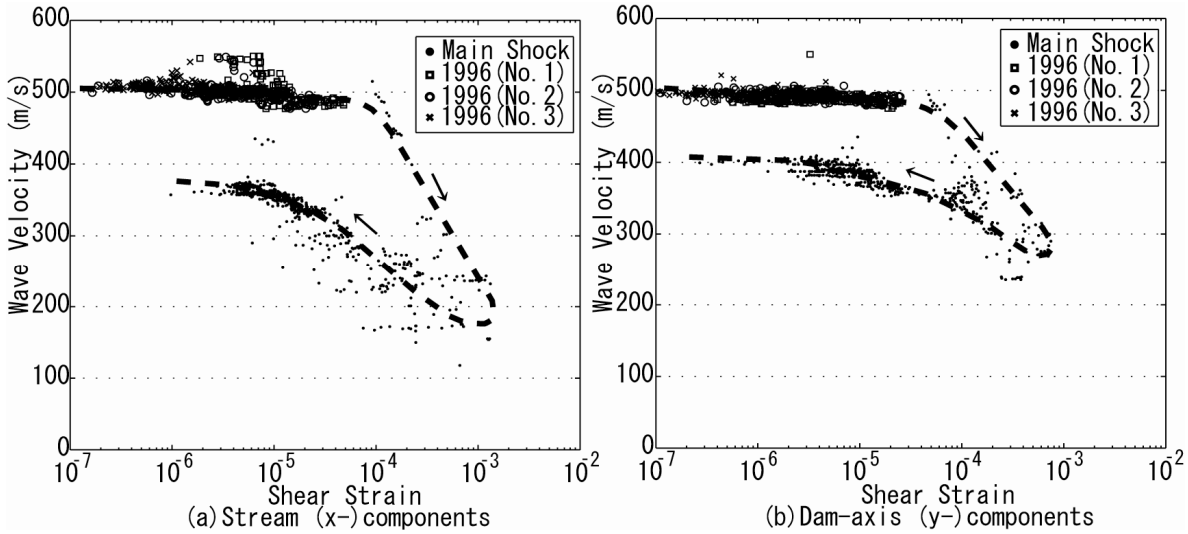

Fig. 14 Strain dependent shear wave velocities evaluated from strong motion records

Field investigations, shake-table experiments, and numerical simulations were conducted to reproduce the acceleration time histories of the surface record. The vertical component of the surface record looks similar to the one from the simulation shown in Fig. 4, but dissimilar in detail. Thus, we concluded that probably the influence of the interaction of the station house with the underlying ground had been included in the surface record.

During the earthquake, the Aratozawa dam which is a 74.4 m high rockfill dam with a central clay core (Fig. 13),

was severely shaken but suffered only minor damage. The earthquake acceleration exceeded 10 m/s^2 at the gallery, inducing large shear strains in excess of 10^{-3}. Due to the large strains, the shear wave velocity and shear modulus showed a significant decrease from their initial values, as shown in Fig. 14. The full recovery of the decreased wave velocity took almost one year.

3. CONCLUDING REMARKS

In most earthquakes, the strongest ground motions are observed in the near-field, where not only the number of casualties is largest, but also devastation of human society is most serious. Hence, in earthquake prone countries like Japan, it is well known that the near-field of a major earthquake which by definition is located in the vicinity of causative seismic fault is the most dangerous and vulnerable area. Due to scarcity of detailed observation data, the causes and effects of the near-field earthquakes (NOT CLEAR) have not been fully understood to date even by experts in earthquake engineering. However, since the 1995 Hyogo-ken Nanbu earthquake which is often referred to as the Kobe earthquake, this situation has changed significantly, at least in Japan. At the present time, systematic observation arrays for earthquakes have been set up throughout Japan, including arrays for tsunamis which are in the process of being formed, along the Pacific coast of Japan. We are often surprised to see observed data from these arrays, which are sometimes beyond our expectations and filled with inspiration for new ideas.

For these reasons, I would like to draw attention to the urgent necessity to establish a new field of study, namely, near-field earthquake engineering (直下地震工学 in Japanese). It is my firm conviction that research in near-field earthquake engineering will never fail to enrich traditional earthquake engineering, and make effective significant contributions to reduce earthquake risk in our society as well.

Abstract: In this decade, large shaking tables were installed at the UC San Diego in USA and the E-Defense in Japan. The bed of the E-defense can support 1200 metric tons and 20m tall structures. This is very large comparing to the past facility and is very strong machine, but actual buildings are bigger and taller than the one that could be on the table. Total weight of a tall building will be heavier over 100,000 metric tons and height of a tall building is higher than 300m in Japan and800m in the world.
Researchers can test only 5 story buildings at the E-defense and test 10-story buildings but very small floor area at the UCSD. We cannot test actual buildings. Then, we need new wise ideas for understanding and knowing the behaviors of actual large structures due to large earthquakes. We will discuss the history of Japanese researches and introduce 4 wise and innovative dynamic tests.

1. EARTHQUAKE ENGINEERING GROWING BY PAST SEVERE DISASTERS

Before Galileo Galilee had written "Two New Sciences", the first textbook of structural mechanics about 370 years ago, we have not any equation for knowing strength of a beam or a column, but humankind is wise and has some intuition. Old carpenters or old contractors could built very beautiful buildings and architectures such as Pyramids in Egypt, Parthenon in Greece, Pantheon in Rome or 5 story pagodas in Japan and so on more than 1000 or 2000 years ago. These buildings have very good performance for a long time, but many buildings were also collapsed by many reasons. In some cases, engineers in the ancient time learned better construction technology by observing collapses and failures. In the 20th century, we have had many severe earthquake disasters and we have learned much from these events and understood the structure behavior better under earthquakes.

a. Building structures have to have adequate lateral strength.
b. Structural members and total structures have to have some deformability.
c. A structure has to have enough integrity.
d. Supporting own gravity weight after an earthquake is fundamental importance.
e. Location of construction, soil condition, and foundation are also fundamental importance.
f. Soil-structure interaction has significance influence to a response of a structure. In some cases, beneficial effect would be, but other case, adverse effect would be to the responses of the structure.
g. A pattern of maximum response of story shear forces could be defined for an earthquake event, but it also changes due to characteristics of earthquakes such as frequency content. The enemy cannot be defined in our science.
h. Strong columns and weak beams structure is preferable.
i. Strong shear-walls or steel braces are very effective to increase seismic capacity.
j. Negative slope of stiffness makes a structure instable.
k. Not only horizontal movements but also rotation along Z-axis has strong effect to collapse behavior of a structure.
l. Joints of beam to column or joints of brace to beam-column are very important. Details are very important.
m. Supplemental damping devices increase a seismic capacity. Passive controlled structure is one of good seismic structure examples.

This paper was presented as a keynote address in the 3rd international conference on advances in experimental structural engineering being held concurrently with the PEER annual meeting and the Loma Prieta earthquake 20th commemorative symposium in October 2009.

n. Seismic isolation is also one of good seismic structure examples
o. Three important roles of seismic design are 1) Preventing collapse of building to save human life, 2) Reparable structure after an earthquake to keep a building property, 3) Keeping a function of building to reduce business interruption due to an earthquake. If possible, we, structural engineers, want to make a building that can cover these three roles.
p. Expectation of public for a good earthquake performance is growing up year by year.
q. Resilience of life, city and country is next important words for structural engineers.

2. ENGINEERS MUST KNOW WHAT WILL HAPPEN BEFORE IT HAPPENS

Structural engineers want to know how a building behaves when an earthquake hits it in future. They have to know what will happen in the building that they are designing and building. We can test beams, columns and joints of these members taking a part from actual building structures. When we have enough research money, we can test two-story to several story of whole building structure. Regretfully, we cannot test more than ten story-building structures, since we have not large enough testing laboratory in the world.

We have an analytical approach using high-speed computers to be able to know the structural behavior under earthquake loadings. When we can grasp the mechanical properties of structural members and structural frames through the results of individual component tests, we can make a mathematical nonlinear model in the computer. Calculation itself has not any problem now, because that we can use high-speed and large-capacity computers. Then we can get a lot of information from the calculated results.

The structural test is the induction process, but the numerical analysis is the deduction process. The structural design is also deduction process and synthetic approach. This is very important. We are using many engineering products such as mobile phones, automobile cars, airplanes and so on, these products are made by mass-production and these functions are checked right after when consumers start to use. On the contrary to these products, building structures are made individually. Since a severe earthquake may be occurred rarely, actual performance can be revealed only when the earthquake happens.

Humankind has built many buildings and many big cities. But not all we have done are based on our experiences. Then we have to know what will happen in the actual building structures in future earthquake event by any possible ways before any troubles happen. The static tests and the dynamic tests should give us a lot of important information and important knowledge.

3. AIMS OF STRUCTURAL TESTS AND NEEDS OF REALISTIC TESTS

As discussed above, the structural tests give us important knowledge and many ideas. We do not need to explain more why we do structural tests. Structural materials such as concrete, steel and other materials can be changed to increase strength. Structural engineering is a field of design works and, the innovative engineers will make new structures or new structural systems beyond those we had past. Then we have to test the structures or new structural systems.

a. Understanding and knowing the structures better.
b. Making safer structures, more economical structures and higher performance structures.
c. Finding weak point of our structures before an actual earthquake hits them.
d. Avoiding failures and increasing the reliability of the structures.
e. Getting the government permission of new ideas.
f. Making a design guideline, a design standard and a design code.
g. Increasing sympathetic friends of engineers and researchers understanding about new ideas and new deign.
h. Persuading the building owners about our design and persuading general public about new ideas.
i. Increasing understanding of the structural behavior for young students and young engineers. The experimental test is good experience for young people.

For these aims, realistic dynamic tests are most effective method and they have strong visual persuasive power. In this paper, we would like to introduce some examples of our researches in last 30 years.

4. TINY SEISMIC ISOLATED STRUCTURES WITH HORIZONTAL HEAVY INERTIA MASSES

Professors Hideyuki Tada and Mineo Takayama have tested tiny seismic isolated structures using also small

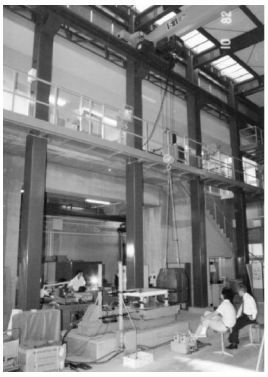

Photo 1 & 2 Tiny seismic isolated structure with heavy iron weight

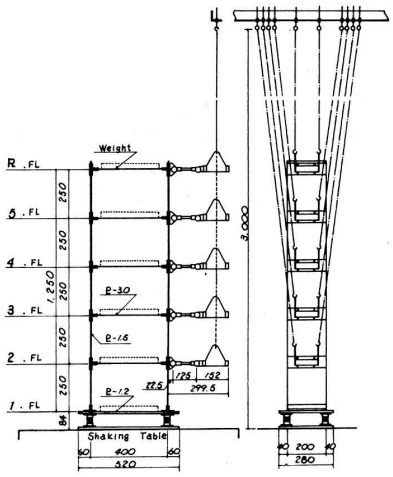

Figure 1 5-story seismic isolated structure and 5-horizontal inertia masses

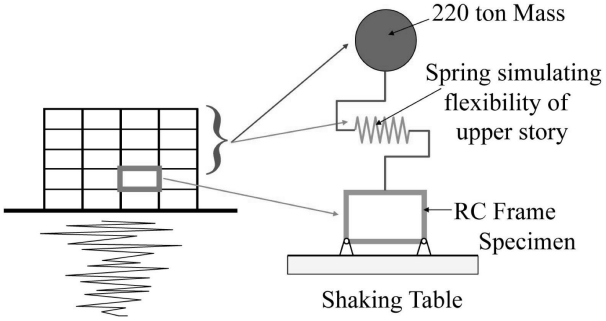

Figure 2 Additional mass and flexibility

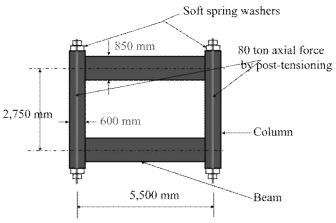

Figure 3 Introduction of column axial forces

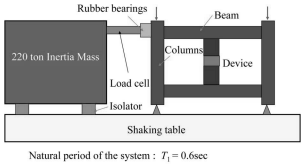

Figure 4 Elevation view during test

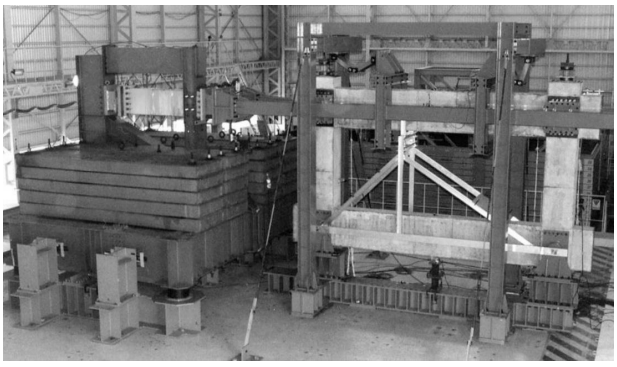

Photo 3 Very heavy steel inertia weight and reinforced concrete frame

supporting one floor and the diameter of the rubber is only shaking table in October 1982. 4 rubber bearings were 30mm. Fundamental natural period is too short because that the floor is light and stiffness of rubber is little high. In many cases, small specimens have short natural period. At that time, they could not capture the typical behavior of seismic isolated structures. They needed heavy horizontal inertia weight. Then, 5 metric-tons iron weight hanged from crane was connected to the side of the specimen. Fundamental natural period of the total system become long enough to show the dynamic behavior of seismic isolated structure as shown in Photo-1 and Photo-2. Next step, the same research group has done 5-story seismic isolated structure using same idea as shown in Fig-1. This system has 5-separated horizontal inertia masses hanged from the high tower in the laboratory.

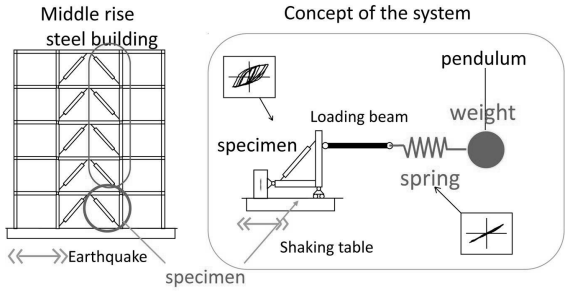

Figure 5 Model steel frame and a specimen with inertia weight and spring

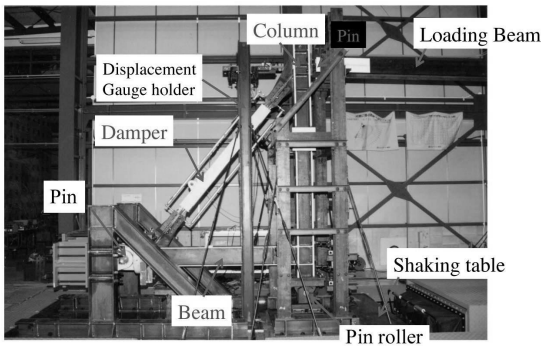

Photo 4 Beam, column and buckling restrained brace on the shaking table

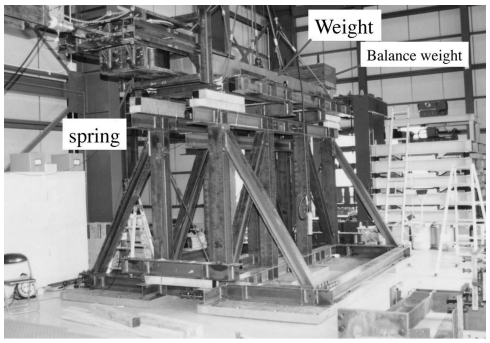

Photo 5 Inertia iron weight and spring of 2 rubber bearings

5. SEISMIC RETROFITTED REINFORCED CONCRETE FRAMES ADDED SUPPLEMENTAL DAMPERS

The research team of Dr. Masanori Iiba and Professors Satsuya Soda, Eiichi Inai, Hiroshi Kuramoto and Akira Wada has done reinforced concrete frames having supplemental dampers with horizontal inertia mass set on 4 flexible rubber bearings at the large-scale earthquake simulator of the National Research Institute for Earth Science and Disaster Prevention in 1998. The reinforced concrete frames we tested were designed by old Japanese building code and seismic capacities were not adequate. But we could get many useful data and BBC took a film of our tests and broadcasted to the world through the program called "Tomorrow's World".

6. PASSIVE CONTROLLED STEEL FRAMES WITH HORIZONTAL INERTIA MASS

The research team of Professors Satoshi Yamada, Masayoshi Nakashima, Toru Takeuchi and Akira Wada has done steel frames having supplemental dampers with horizontal inertia mass hanged from the crane beam at the shaking table of the Disaster Prevention Research Institute, Kyoto University in 1999. We tested only one story frame taken from a several story steel frame. Horizontal weight simulates other part of story of the original building. Soft spring made of rubber bearings simulates flexibility of other part of the original frame. Total system composed of the specimen frame, soft spring and horizontal mass has 0.6 natural period. We could test many frames using this system with not much research money.

7. COLLAPSE TESTS OF VERY SMALL STEEL FRAMES IN HIGH GRAVITY CIRCUMSTANCE OF CENTRIFUGE MACHINE

The centrifuge machines have been used for the static or dynamic stability tests in the research field of soil mechanics and foundation engineering. When the specimen size is 1/10 of the actual scale of a structure, total weight of the structure become 1/1000, but sectional area of the member is only 1/100. Then, stress level become 1/10 of actual stress in the structure. Nonlinear effect of the structural member cannot be treated correctly in the 1/10 specimen. P-delta effect becomes also very small when the specimen's weight is too light. The research group of Dr. Hideo Katsumata, Professors Satoshi Yamada and Akira Wada have done the collapse tests of very small steel frames in the very high gravity circumstance of centrifuge machine at the Technical Research Institute of Obayashi Corporation. 3, 12 and 30 story steel frames have tested here. The centrifuge could produce 100G gravity and the testing container could have a 2m high specimen. We could test 200m tall buildings using this strong machine theoretically. Since the scale of a specimen is 1/100, it was very difficult to make the specimen precisely.

7.1 3-Story Weak Columns and Strong Beams Steel Frame

The first try was a test of a 3-story steel frame shown in Fig.6 and Photo 7. The frame had 4 columns in every floor, sectional shape of all columns was 1mm thickness and20mm diameter tube. Beams were very strong. Then, the shear capacity of each floor was equal. We took the test under 30G and shake the container horizontally. Finally, the columns at ground floor were broken, just after that, second and third floor collapsed. Most dangerous collapse mode was happened. We took several valuable video movies.

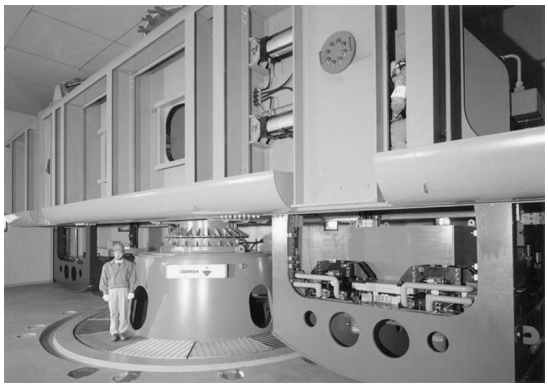

Photo 6 Big centrifuge and container at the Obayashi Technical Research Institute

7.2 12-Story Strong Columns and Weak Beams Steel Frame

The second try was 12-story frame. The frame was made as weak beams and strong columns structure. We took the test under 60G and shake the container horizontally. It had perfect vibrations under medium horizontal acceleration. Next, we applied large horizontal acceleration to the container, then the frame become unstable as shown in Photo 9. Finally, the whole frame was perfectly collapsed as shown in Photo 10.

7.3 30-Story steel frame having center wall and strong outrigger beam

The third try was 30story frame having a center wall and a strong outrigger at middle height. We took the test under 60G and shake the container. The relationships of story shear and story deformation getting from the test were very beautiful, almost all stories yielded and ductility factors were around 2 to 3. The center wall and the outrigger were very effective to control the vibration mode. These members should increase the seismic capacity of the building structures.

8. CONCLUSIONS

Actual buildings become bigger and larger every year, and many cities in the world are growing larger every year. Structural engineers must engineer safer buildings and safer cities for people. We have to know how the structures behave under strong earthquakes. We need to do not only the static structural test but also dynamic test. But often, the test facilities have some limitation. Researchers and engineers have to use these facilities under the combination with deep thinking and innovative ideas.

After the Loma Prieta Earthquake in 1989, many professors and engineers discussed about the performance based earthquake engineering. Japan experiences 20% of strong earthquakes in the world, but only 1% to 2% buildings are constructed by using seismic isolation or passive controlled devices. We need to promote these new technologies and increase the number of practical applications in not only Japan but also in all countries exposed to the earthquake risk.

Earthquake Risk Assessment and Corresponding Contingency Plans of the Major Cities of Bangladesh

A. S. M. Maksud Kamal

Professor, Department of Geology, Dhaka University and Urban Risk Reduction Specialist
Comprehensive Disaster Management Programme (CDMP)
maksud.kamal@cdmp.org.bd

Abstract: Comprehensive Disaster Management Programme (CDMP) of the Ministry of Food and Disaster Management (MoFDM), Government of Bangladesh took a component to assess earthquake risks and to develop spatial contingency plan for risk management of the three major cities, viz., Dhaka, Chittagong and Sylhet city corporations of the country. Following five steps were undertaken to accomplish seismic risk assessment: fault mapping and modeling, determination of ground shaking in PGA, development of fragility curves for the building typology, assessment of their vulnerability and generation of risk scenarios through deterministic and probabilistic seismic hazards. Later on, contingency plans have been developed based on damage scenarios for national level, all major responding organizations and respective city corporations. Contingency plan at national level developed following UN cluster system that reflects emergency coordination mechanism between the lead and support agencies belonging to each cluster. Contingency plan of the major responding organizations detailed-out the rules and responsibilities of all relevant organizations to response during emergency, while the GIS-based city level contingency plans illustrate spatial lay-out regarding rescue and evacuation operations. The plans are placed to the organizations through government mechanism to make their use optimal and effective during emergency through repeated simulation drills.

1. INTRODUCTION

Bangladesh is regarded as a supermarket for natural disasters. Flood, cyclone, storm-surges, river erosion, landslides, drought, earthquake and climate induced hazards can be named. Though the country has not been jolted by devastating earthquake in the last one hundred years,, historical evidences reveal that eight big earthquake occurred with magnitude >7.0 in and around Bangladesh in the last 250 years. Great Indian earthquake of 12 June, 1897 (magnitude≈ 8.3-8.7) though had its epicenter about 230 kilometers away from Dhaka, but caused extensive damages mostly in the north-eastern part of the country. Moreover, during 2007-2009, the country got very minor to moderately low seismic disturbances more than 130 times. Being located in the seismotectonic regime of youngest Himalayan mountainous terrain, the countries stretching across this mountainous belt are hotbed for seismic activity due to the existences of geological plate boundaries and the corresponding development of active fault zones in the region. Considering the potential threat of the earthquake hazards, Comprehensive Disaster Management Programme (CDMP) of the Disaster Management and Relief Division (DMRD), Ministry of Food and Disaster Management (MoFDM) has been taken initiatives to assess earthquake risks of the major cities viz., Dhaka, Chittagong, Sylhet and subsequently develop the scenario-based contingency plan and introduce other interventions to reduce the seismic vulnerability of the country. This study also supports government to take decision on enhancing or developing the policy instruments towards ensuring a resilient urban built environment.

2. STUDY AREA

UN-HABITAT (2008/2009) analyses show that 17 per cent of the cities of the developing world experienced very high growth rates of 4 percent or more. The major cities of Bangladesh have been experiencing the same rate or more population influx with rapid horizontal extension of the urbanized areas. With an urban growth rate more than 4 percent annually, Dhaka, which already hosts more than 13 million people, is one of the fastest but unplanned growing cities in Southern Asia, and is projected to accommodate more than 20 million by 2025. Likely, Chittagong and Sylhet are also accommodating around 4 percent growth of population with lateral extension of the township areas. Due to phenomenal growth of the building stocks after the independence in 1971, good number buildings constructed before development and approval of building code in 1993, poor construction practices without following building code, urban sprawling on unsuitable land, high population density and narrow road networks in the

cities, poor capacities of the major responding organizations during the period of emergency and minor awareness among city dwellers multiply the earthquake vulnerability of the cities mentioned. Considering the rapid unplanned urbanization and potential threat of seismic hazard, three major cities, viz, Dhaka, Chittagong and Sylhet city corporations (Figure 1) are considered for seismic risk assessment in the view point of disaster risk management.

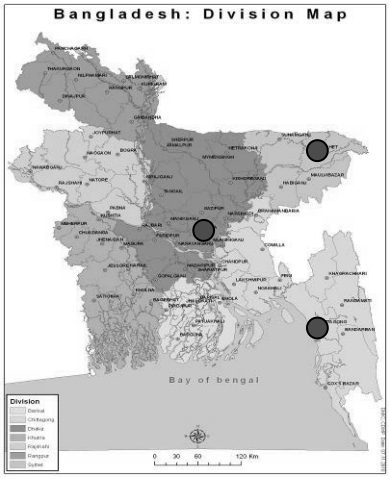

Figure 1: The red dots indicate the study area

3. SEISMIC HAZARD ASSESSMENT

3.1 Time-predictable fault modeling for characteristic earthquake

Characteristic earthquake is defined as the one that has constant recurrence period and displacement on the specific fault. It is well-known that active fault generates characteristic earthquakes. If the time of the latest and penultimate events on the active fault is revealed, the recurrence period and the elapsed time since the latest event are known and the probability of future earthquake occurrence can be estimated. This is a kind of prospect of future earthquake occurrence based on the time- predictable model. The time-predictable model on an active fault can be estimated if at least the occurrence periods of two historical earthquakes are known. In Bangladesh, the historical earthquakes are not well-documented. Successful trench investigations have not been conducted before accomplishing this study. Based-on historical evidences of seismicity (Figure 2), literature-reviews, high resolution 3-D satellite image (CORONA and SPOT) interpretations, field survey and trench investigations in potential target sites, C^{14} dating of 24 samples led to develop a time predictable fault model (Wells and Coppersmith, 1994) for the active fault of the country. Three active faults have been identified in the, viz., Plate Boundary Fault (PBF is divided into 3 segments), Dauki Fault and Madhupur Blind Fault. Figure 3 and 4 represent the active faults and trench investigations while table-1 shows that result of time predictable fault model. Fault model is suggested on the basis of the present information which need revision in future based on more detailed investigations.

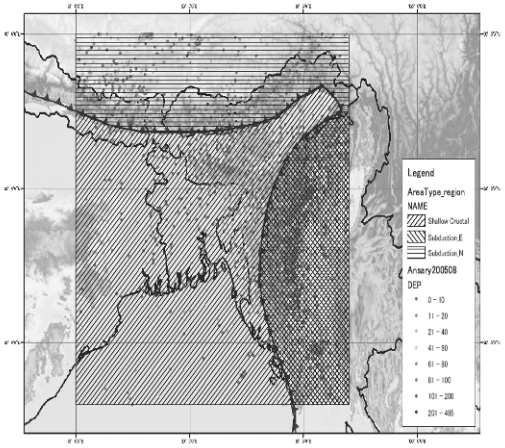

Figure 2: Historical seismicity in and around Bangladesh

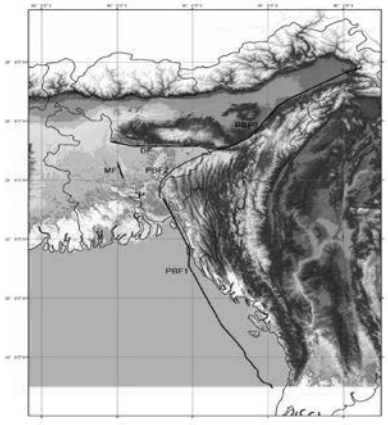

Figure 3: Major active fault locations in the country

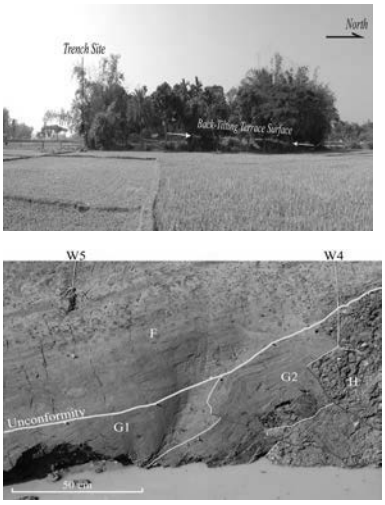

Figure 4: a: Elected back-lilted terrace at Gobrakhali b: West wall of the trench showing fault displacement

Table 1: Time predictable fault model of Bangladesh

Segment		Events	Observed Recurrence Period	Elapsed Time since Last Event (years)	50 year Prob. Time-Dependent (%)	Estimated Magnitude (Mw)	Length (km)
Plate Boundary Fault (PBF)	PBF-1	**AD 1762** AD 680 to 980 [1)] BC 150 to AD 60BC 1395 to 740	900	246	1.1	8.5	795
	PBF-2	before 16th century	> 900	> 508	> 6.7	8.0	270
	PBF-3	before 16th century	> 900	> 508	> 6.7	8.3	504
Dauki Fault (DF)		AD 1897 AD 1500 to 1630 (AD 1548 ?)	349	111	7.0	8.0	233
Madhupur Blind Fault (MF)		AD 1885	350	123	8.7	7.5	60
Non-characteristic but relating to fault (PBF-2, PBF-3, DF)		AD 1918 (PBF-2) AD1869, 1943, 1954, 1988 (PBF-3) AD 1664, 1923, 1930 (DF)	20	-	-	7.0 - 7.4	-

The time of events, recurrence period, elapsed time since the latest event and the 50 years probability of future earthquake occurrence for each active fault are shown in in the Table. The Brownian Passage Time (BPT) model is adopted as the probability density function. The aperiodicity α is presumed to be 0.5 followed after Parsons (2004) etc.

3.2. Baserock and Seismic Motion Analysis

The deterministic approach was adopted for the earthquake motion estimation in this study. The earthquake motion for engineering seismic baserock and sub-surface layer amplification were determined separately. Four formulas from Next Generation Ground Motion Attenuation Model (NGA, 2008) are applied and average value was used. The stochastic Green's function study (Kamae et.al., 1991) was also conducted for verification. The amplification by sub-surface soil layers was evaluated by the amplification factor which was decided by average shear wave velocity from ground surface to 30 meters depth. The ground of each grid was classified based on the modified National Earthquake Hazard Reduction Program (NEHRP) provisions. The amplification factors of NEHRP provisions were verified by the response analysis at 19 points through PS loggings.

The PGA, PGV and Sa (h=5%, T=0.3 and 1.0 sec) at engineering seismic baserock (Vs30=760m/sec) reflected that in Dhaka the PGA in Dhaka is 130 to 230 gals for MF (Figure). The most important earthquake in Chittagong is PBF-1 where PGA is estimated 650 to 770 gal. The most important earthquakes in Sylhet are DF and PBF-2. PGA by DF is 180 to 240 gal and 160 to 240 gal by PBF-2.

The PGA, PGV and Sa (h=5%, T=0.3 and 1.0 sec) at ground surface were calculated. The PGA in Dhaka by MF is 220 to 410 gal. The PGA in Chittagong by PBF-1 is 600 to 770 gal where amplification of surface layer is very little or deamplified because of non-linearity of soils. The PGA in Sylhet by DF is 270 to 420 gal and 230 to 420 gal by PBF-2. Figure 5, 6 and 7 represents the base rock motion, ground amplifications and ground motions at Dhaka for different faults.

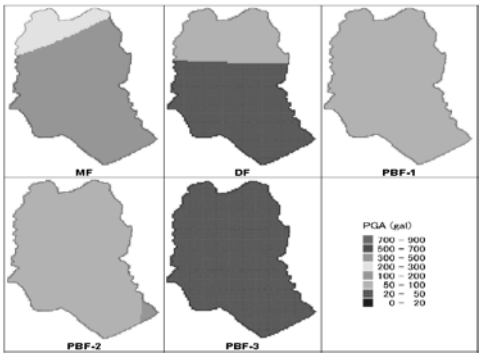

Figure 5: Base rock motion in Dhaka

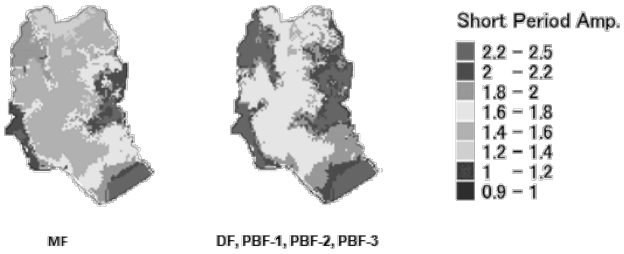

Figure 6: Ground amplification for PGA and Sa (0.3) in Dhaka

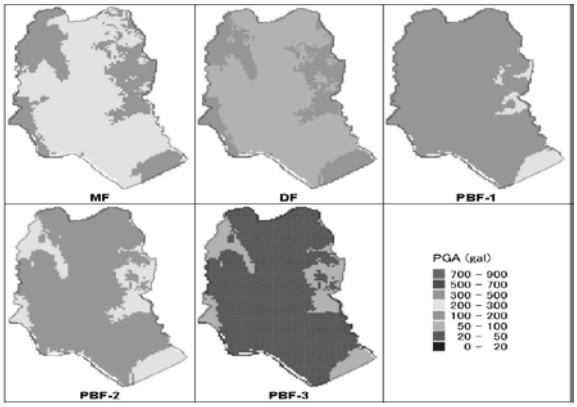

Figure 7: Ground surface motion at Dhaka

4. SEISMIC VULNERABILITY ASSESSMENT

To assess the vulnerability of the exposures building stocks, lifelines and essential facilities database in GIS were developed using high resolution satellite images as well as field survey. It is estimated that there are 326,000, 182,000, and 52,000 buildings in Dhaka, Chittagong, and Sylhet City Corporation areas respectively (Figure 8 and 9). Afterwards, building stocks were differentiated into structural types. Such as, in Dhaka city corporation area, reinforced concrete and masonry buildings are 85000 and 180,000 respectively.

Dhaka Chittagong Sylhet

Figure 8: Building footprints

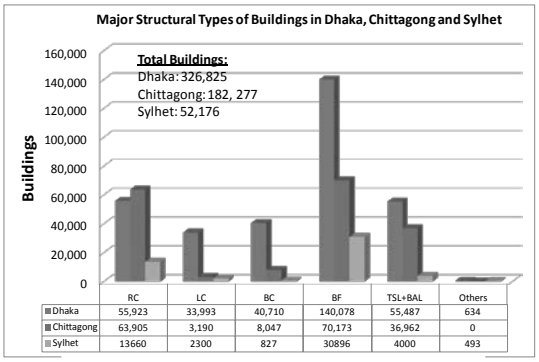

Figure 9: Building typology

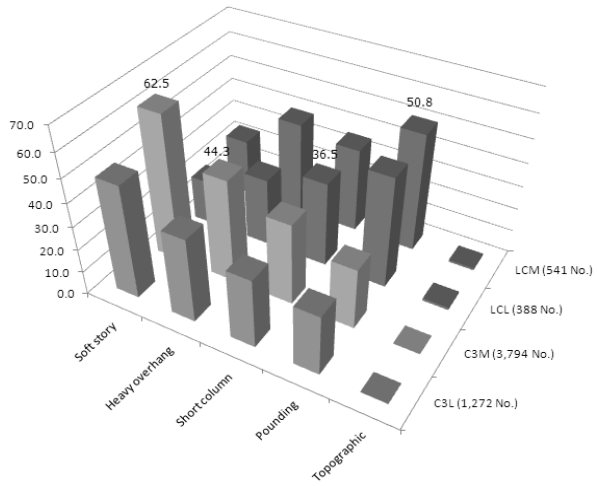

Figure 10: Relationship between the vulnerability factor and structural types in Dhaka

To asses the vulnerability of the building, three level survey were conducted in this study. The vulnerability factors considered in level one survey were number of stories, occupancy class, structural type, number of occupants during the day and the night, age of the building, presence of soft story, presence of heavy overhangs, shape of the building in plan view (rectangular, narrow rectangular, irregular), shape of the building in elevation view (regular, setback, and narrow tall), pounding possibility, building in slope land, visible ground settlement, presence of short columns, visible physical condition (poor/average/good). Figure 10 represent the relationship between the vulnerability factors and structural types. In the Level-2 survey, a sketch of the building plan at the ground story, the dimensions of columns, concrete and masonry walls were measured. Level-3 survey was conducted for dynamic measurement on few selected buildings in three cities. Main objective of this survey is to understand the behavior of different types of buildings during earthquake. For dynamic measurement of buildings, micro tremor, schmidt Hammer, ferro Scanner,

vibration shaker, hydraulic Jack with Deflection Meter were used.

For the lifeline inventory mainly for transportation and utility system were conducted. In the 3 cities, transportation system consists of (1) highway transportation system, (2) railway transportation system, (3) bus transportation system, and (4) ferry transportation system. While utility system consists of (1) potable water system, (2) natural gas system, (3) electricity power system, and (4) communication system, and for Dhaka (5) waste water or sewage network. The lifeline inventory in Dhaka City Corporation area includes over 1270 kilometers of highway road, 10 highway bridges, and pipe line lengths for portable water, waste water and natural gas are 1100, 630 and 830 kilometers respectively. While in Chittagong, the lifelines include 639 kilometers of highway road, 4 highway bridges, and 792 kilometers of potable water and gas pipes. In Sylhet, the lifelines include 148 kilometers of highway road, 2 highway bridges, and 268 kilometers of potable water and gas pipes.

Utilizing the same methodology for lifeline inventory, essential facility inventory was developed. The essential facility inventories in this study consist of 3 categories: (1) Medical care facilities, i.e. hospital and medical clinic, (2) emergency response facilities, i.e. police station, fire station and emergency operation center and (3) schools. There are 600 hospitals, 2700 schools, 10 fire stations, 62 police stations and 18 emergency response agency offices in Dhaka City Corporation area. While in Chittagong, there are 162 hospitals, 1033 schools, 12 fire stations, 11 police stations and 11 emergency response agency offices. And in Sylhet, there are 87 hospitals, 211 schools, 2 fire stations, 6 police stations, and 9 emergency response agency offices.

Based on the vulnerability factors of the building stocks and lifelines, vulnerability maps were developed which show the characteristics of the buildings, essential facilities, and lifelines that make them susceptible to the damaging effects of earthquake. From the collected database and vulnerability maps, the major findings regarding to the seismic vulnerability of building, lifeline and essential facilities can be summarized as the followings: The vulnerability factor which is the most common in Dhaka city is soft story (52%). The common vulnerability factor in both Chittagong and Sylhet city is heavy overhang (38% and 46%, consequently). Among occupancy classes in all city corporation areas, residential class is the major proportion. Their proportions are 80.0%, 82.0% and 85.0% in Dhaka, Chittagong and Sylhet, respectively. Among structural type of non-engineered buildings from the survey results, brick in cement mortar masonry with flexible roof is the most common type in all cities. For engineered buildings, concrete frame with masonry infill walls is the most common class. From the survey results, age of buildings has been related to structural types. For example, it was found that most buildings with concrete slab-column frames are constructed less than 10 years. On the other hand, most masonry buildings with concrete floors ages more than 10 years. Also, light reinforced concrete buildings (LC) are found to be older than reinforced concrete buildings. As expected, all residential types have an average number of occupants per floor area in the daytime less than the nighttime; nevertheless, the other occupancy classes as commercial, industrial, government and education have the number of occupants in the daytime more than the nighttime.

5. RISK ASSESSMENT

Risk is the conditional probability and magnitude of damage occurs on the exposures to a hazard event. For assessing the seismic risk the fragility functions (capacity of the buildings to withstand during different level of strong ground motions) has been developed for the structural types of the buildings and life line systems. For instances for the development of fragility functions of the building stocks following vulnerability factors are considered: number of story, presence of soft-story and torsional irregularities as determined by infill wall arrangement, presence of heavy-overhangs, Presence of soft-story as determined by 1st story height, variation in concrete strength. Combing the fragility functions of the buildings and infrastructures with the hazard maps (ground shaking of the scenario earthquakes) building damages and functionality of the lifelines and critical infrastructures were estimated using a software known as Hazard United States (HAZUS). Before calculating the damage scenarios, HAZUS has been customized considering the Bangladesh perspectives. To run the assessment, city corporation wards are divided into smaller area called cluster to generate detail level of statistical data for corresponding analysis. In Dhaka city corporation area, 552 clusters are generated in 91 wards. While, 41 wards of Chittagong city corporation are divided into 285 clusters, and 27 wards of Sylhet City Corporation into 82 clusters.

Risk assessment reveals that if an earthquake occurred at Madhupur fault with magnitude 7.5, about 72,000 buildings (Table-2) will be totally damaged during this time. It is estimated that about 140000 buildings will be completely damaged at 8.5 magnitude earthquake originated from plate boundary fault-1. During an earthquake at 8.0 magnitude originated from Dauki fault about 25000 buildings will be damaged beyond repair. There will be severe damage to essential

facilities like Hospital, schools, police stations after different level of earthquakes in Dhaka, Chittagong and Sylhet. For instances, here, damage scenarios are shown for Dhaka calculated for Madhupur fault earthquake. This earthquake will cause moderately to complete damage at about 250 hospital or clinics, 1300 schools as well as 30 police and 4 fire service stations (Table- 3). In Dhaka there are about 60000 hospital beds available for use. On the day after the earthquake, it is estimated that only 24,200 hospital beds (41%) will be available for use by patients already in the hospital and those injured by the earthquake. After one week, 54% of the beds will be back in service. By 30 days, 72% will be operational. During this period there will be around 80 leaks and 270 breaks in water supply system, 100 leaks & 360 breaks in waste water system and 60 leaks & 190 breaks in gas supply network.

Table 2: Expected Building Damage by Building Type in Dhaka City Corporation Area: Scenario Case 1 (Madhupur fault)

Dhaka : Case 1										
	None		*Slight*		*Moderate*		*Extensive*		*Complete*	
	Count	*(%)*	*Count*	*(%)*	*Count*	*(%)*	*Count*	*(%)*	*Count*	*(%)*

Table 3: Expected Damage to Essential Facilities in Dhaka City Corporation Area: Scenario case1

Dhaka : Case 1				
Classification	Total	Facilities		
		At Least Moderate Damage >50%	Complete Damage >50%	With Functionality >50% on day 1
Hospitals	600	241	10	224
Schools	2,737	1,173	90	895
EOCs	18	8	2	7
Police Stations	62	30	0	15
Fire Stations	10	4	0	3

Madhpur Fault earthquake will generate a total of 30 million tons of debris. If the debris tonnage is converted to an estimated number of truckloads, it will require 1,200,000 truckloads (@25 tons/truck) to remove the debris generated by the earthquake. Only the building related economic losses for this earthquake are estimated more than 6000 million USD.

Risk assessment has been calculated for Dhaka, Chittagong and Sylhet for all possible earthquakes to be originated in the three fault lines, viz, Madhupr fault, Dauki fault and Plate Boundary faults. This is first effort in Bangladesh to conduct hazard, vulnerability and risk assessment through seismic microzonation mapping of the cities. Characterizations (recurrence period and magnitude determinations) and further identifications of the fault zones, accurate buildings and lifelines system vulnerability assessment and fragility functions development of the buildings are highly crucial in this context. Consecutive studies will further improve the results definitely. Once the hazard scenarios are changed, vulnerability and risk will also bring updated results.

The objective of assessing the risk scenarios were to develop the scenario-based spatial contingency plans for addressing the systematic and realistic approach of preparedness and responses during the period of emergency.

6. DEVELOPMENT OF EARTHQUAKE CONTINGENCY PLAN

6.1 Concept of Contingency Plan

Usually many agencies are involved in accomplishing the activities for preparedness, response and early recovery to reduce the risk of any big

disasterous event. Experiences have shown that all agencies need to work together *under a well-designed and fully-coordinated plan for optimum and efficient preparedness, response and early recovery, usualy known as Contingency Plan*, in a systematic manner so that their capacities and resources are best utilized to fulfil the need complimenting and supplementing other agencies. Realizing the need of coordinated and comprehensive emergency response, United Nations has been promoting its humanitarian response activities in a cluster approach. This approach is proved to be effective and efficient in responding to recent disasters, for instances, the response during October 8, 2005 Kashmire earthquake in Pakistan. Hence, it has been assumed that this concept of response operations in functional clusters be applied in Bangladesh also in case of possible earthquake disaster.

6.2 Contingency Plan Developed for Major Responding Agencies Of Bangladesh

From CDMP-I initiatives, scenario-based contingency plans have been developed for national level, three city corporations (Dhaka, Chittagong and Sylhet) and *key major responder agencies*- viz., Armed Forces Division (AFD), Fire Service & Civil Defense (FSCD), Directorate General of Health Services (DGHS), Disaster Management Bureau (DMB), and Directorate of Relief and Rehabilitation (DRR) to respond first during any emergency. Figure 11 illustrate the development procedures of contingency plan. Moreover, lifelines & utilities (Dhaka Power Distribution Company Limited, Dhaka Water Supply and Sewerage Authority, Titas Gas Transmission and Distribution Company Limited, Bangladesh Telecommunication Company Limited), and humanitarian assistance providers have also been addressed in the contingency planning process. These plans adopt scenario-based contingency planning approach that involves the development of specific scenarios through the hazard, vulnerability mapping and damage estimations. In the formulation process of the plan, the main focus is given to the worst case scenario by assuming that- if plan is developed for the worst case making it flexible, then there shall have the preparation for anything, anytime.

6.3 Funtionability of National Earthqauke Contingency Plan

Under National Earthquake Contingency Plan, all response activities are grouped into nine relevant operational functional clusters based on the similarity of works, normal time and disaster time mandates of different relevant organizations and possible complimentarity in the resources and capacities. Beside emergency opeartions, preparedness and early recovery actvities are also assigned for each functional clusters to reduce the earthqauke vulnerability to a certain manageable level. The proposed operational

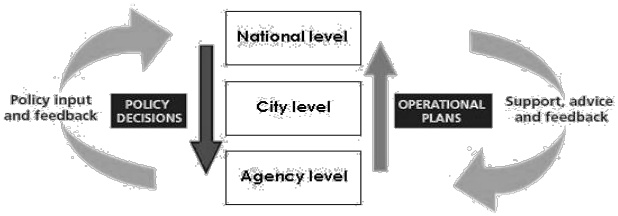

Figure 11: Development procedures of contingency plan

functional clusters with lead and support agencies under National Earthqauke Contingency Plans are: Emergency Operations Cluster 1– Overall Command and Coordination (lead–Disaster Management Bureau), Emergency Operations Cluster 2 – Search, Rescue and Evacuation (lead-fire service and Civil Defence), Health Cluster- (Director General of Health services), Relief Services (Food, Nutrition and other Relief) cluster (lead-Directorate of Relief and rehabilitation), Shelter (including Camp Management) cluster (lead-DMB), Water Supply, Sanitation and Hygiene Cluster (lead-Local Government Bodies: City Corporations/pourashava), Restoration of Urban Services Cluster (lead-Local Government Bodies: City Corporations/pourashava, Transport (Road, Rail, Air, Sea) Cluster (lead-BRTA, BIWTA, Bridge Authority, Security and Welfare Cluster (lead-Bangladesh Police). The role of Armed Force Division is actively associated with all the clusters as support agencies.

6.4 Agency Level Contingency Plan (A Case Study)

With regard to each functional cluster, spatial planning requirements in terms of locating facilities at appropriate locations, need assessment based on spatial coverage, identifying alternative locations and routes for emergency supplies, identifying emergency evacuation routes and places for

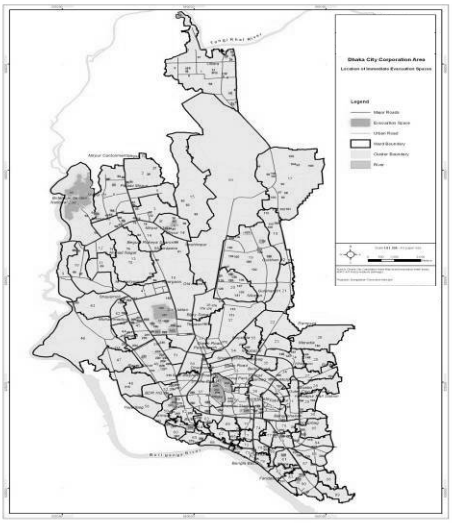

Figure 12: Possible open spaces in Dhaka

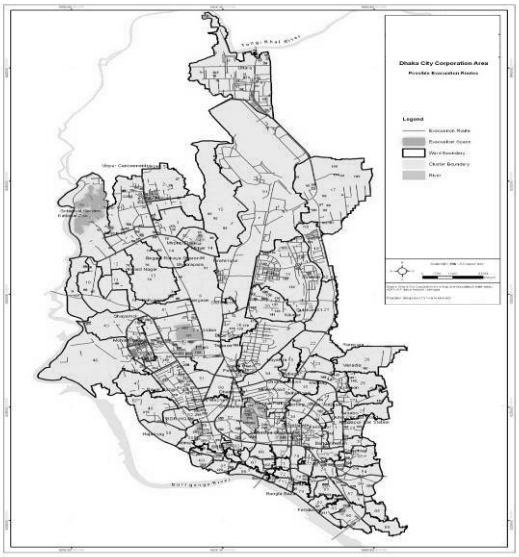

Figure 13: Possible open evacuation roads in Dhaka

temporary shelters and medical facilities, pre-positioning of facilities etc. have been identified and mapped under GIS environment that would enable the key emergency responders to act in a coordinated as well as cohesive way. For instances, the total number of displaced population needing temporary shelter has been estimated at around 870,000 within the Dhaka city during Madhupur earthquake. This is estimated as 50% of the displaced people need immediate shelter after the earthquake and the remaining 50% will manage their shelter in their relatives and other places. Open spaces within the city corporation area that are more than 2500 square meters (area with capacity for sheltering 500 families or more) are mapped and their shelter capacities are calculated. The total open spaces within Dhaka City area have only about one fourth capacity of the total population needing shelters. Figure 12 and 13 show open spaces and evacuation routes to be used during emergency.

The population evacuated in immediate shelter requires about 3800 cubic meters of emergency water with the rate of 15 liters per capita per day. The populations who are taken outside require about 9,200 cubic meters of water per day. So the total emergency water needed in the emergency shelters is about 13,000 cubic meters per day. Pre-positioning of this amount of the water at the above planned spaces is before earthquake is the most appropriate way to provide immediate emergency water. To manage toilets in the immediate shelters spaces is the main challenge related to sanitation. Sphere standard demand one toilet for each 20 people in the emergency shelter. The calculation shows that about 12,700 toilets are needed in the open spaces within Dhaka City and additional 30,700 toilets need to plan for the people of Dhaka who need immediate shelter outside Dhaka city. The total number of skilled/trained workers required for repairing the potable water and waste water system within Dhaka city corporation area after an earthquake is about 1800 people per day to repair the system within 7 days. If it is planned to repair in 14 days, it require about 900 skilled workers per day and require about 420 people working per day to repair the system in 30 days time. Skilled workers required to repair overhead water tank and waste water treatment plant is not calculated here, as it require thousands of skilled workers if planned to repair within a month, which is practically not possible even if planned. It requires 3-6 months to repair the overhead tanks and treatment plant, even if the required manpower is available. The total estimated cost require for repairs is about 27 Million US Dollars. It is assumed that the repair cost for the waste water treatment plant, probability of which to be functional after the earthquake is 40-50% has been assumed that 25% of the replacement cost. Priorities for recovery of different components within the system are also made in this plan.

6.5 Contingency Plan is the Living Document

The contingency plans have been developed with around 30 interactive meetings with the agencies. Moreover, two workshops have been conducted in national level to validate the plans. The plan is a measure of the quality of the process. A good planning process will produce a good plan. Even though the earthquake that occurs may be very different from the one planned for, the plan will still be useful. A good contingency plan ensures better preparedness for any emergency that may occur, even one that is very different from the scenario in the plan. Legal provisions and organizational set up, functional response roles and responsibilities assigned for the agency, operating procedures guideline and readiness checklists are also outlined in this plan. Contingency plans are the living documents. With the increase of knowledge and resources, the plan can be updated. Disaster Management and Relief Division (DMRD) of the Ministry of Food and Disaster Management have forwarded the plan to the respective organizations. In order to understand and operate the plan, trainings on incident command system and restoration of lifelines within shortest possible time have been provided to the professionals of the major responding organizations. To cope with emergency situations, organizations are planning to exercises the plan through simulation drills.

7. CONCLUSION

The Government of Bangladesh (GoB) has made a gradual shift in disaster management towards a comprehensive risk reduction approach that recalls and learns from past experience in order to anticipate and reduce the impact of future risks. The traditional

disaster management model focusing on disaster relief and recovery has done little to redress these rising levels of risk. The Ministry of Food and Disaster Management, has (through Comprehensive Disaster Management Programme-CDMP) adopted a more holistic approach that embraces processes of hazard identification and mitigation, community preparedness, integrated response efforts and where relief and recovery activities are planned within an all-risk management framework that seeks to raise the capacities of at-risk communities while lowering their vulnerability to specific hazards. Following the mission and vision of the Government of Bangladesh (GoB), this study is one of the outputs under Earthquake and Tsunami preparedness component of CDMP-I. The study addresses the earthquake hazard, vulnerability, risk and damage assessment following the standard methodology. Then using the scenario-based risk assessment, sub-sequent mitigation/contingency plans have been developed for the major responding organizations, city corporations and national level. The contingency plans which address the gaps and needs are being utilized for re-strengthening the preparedness and response mechanisms of the relevant organizations. Moreover, following the guidelines of contingency plans, various awareness raising activities has been launched and policy instruments are being updated and developed aiming to escalate better understanding to implement the documents in practices at all level.

MAJOR GROUND MOTION RESEARCH PROGRAMS AT THE PACIFIC EARTHQUAKE ENGINEERING RESEARCH CENTER (PEER)

Yousef Bozorgnia

Executive Director, PEER, University of California, Berkeley, California, USA
yousef@berkeley.edu

Abstract: At the Pacific Earthquake Engineering Research Center (PEER) there are three major ground motion research programs: (a) Update of ground motion prediction equations (GMPEs) for shallow crustal earthquakes in active tectonic regions (NGA-West2); (b) development of next generation attenuation relationships for stable continental regions (NGA-East); and (c) global GMPEs for the Global Earthquake Model (GEM). This paper presents an overview of these "mega" research programs.

1. INTRODUCTION

The Pacific Earthquake Engineering Research Center (PEER), with headquarters at the University of California, Berkeley, has traditionally had major research projects on the engineering characterization of ground motions. PEER's ground motion projects are part of a larger research theme for Performance-Based Earthquake Engineering (PBEE). Currently there are three major ground motion research programs at PEER: (a) Update of ground motion prediction equations (GMPEs) for shallow crustal earthquakes in active tectonic regions (NGA-West2); (b) development of next generation attenuation relationships for stable continental regions (NGA-East); and (c) global GMPEs for the Global Earthquake Model (GEM). This paper presents an overview of these mega programs at PEER.

2. NGA-WEST 2

In 2003, PEER initiated a large research project to develop next generation attenuation relationships for shallow crustal earthquakes in active tectonic regions (NGA-West1). The project concluded in 2008, and provided two important practical deliverables: (1) a strong motion database of recorded ground motions, and (2) a set of peer-reviewed ground motion prediction equations (GMPEs), or what engineers call attenuation models. Many researchers, practitioners, and organizations throughout the world are now using the NGA-West1 models. For example, NGA programs are either being initiated or planned for areas such as Japan, Taiwan, and Europe.

The NGA-West1 database is one of the largest strong motion databases in the world. It includes over 10,000 components of ground motion recordings from all over the world along with their associated metadata, such as moment magnitude, six different source-to-site distance measures, fault mechanism, shallow site characteristics, depth to bedrock, among others.

The NGA-West1 GMPEs represent a major advancement in ground motion prediction made possible by the extensive update of the PEER strong-motion database and the supporting studies on 1-D ground motion simulation, 1-D site response, and 3-D basin response sponsored by PEER (Power et al., 2008). The NGA-West1 generated five GMPEs: Abrahamson & Silva (2008), Boore & Atkinson (2008), Campbell & Bozorgnia (2008), Chiou & Youngs (2008), and Idriss (2008). These models superseded the previous GMPEs developed by the five developers, and are capable of predicting ground motions for magnitudes up to 8.5 and distances out to 200 km. Style of faulting, hanging wall and footwall effects, linear and nonlinear site effects and depth to basement rock (basin depth) are among features incorporated in most of the NGA-West1 models. The NGA-West1 models went through an extensive peer-review process by the US Geological Survey (USGS), and three of the models were adopted by the USGS for the 2008 edition of the US National Seismic Hazard Maps (Petersen et al., 2008).

As successful as the original NGA-West1 program was, there are some additional and complementary ground motion issues and supporting topics that could not be addressed in the program due to time constraints. The goal of a follow-up study, NGA-West2, is to fill these gaps. Specifically, the NGA-West2 is addressing the following technical issues.

2.1 Directivity Models for NGA Relationships

The original plan for the development of the NGA-West1 ground motion relationships was to develop the models in two steps: (a) to develop the NGA models without

explicitly including near-fault directivity effects; and (b) to subsequently examine the near-fault directivity effects and add additional terms to the NGA-West1 relationships to incorporate such near-fault effects. Step (a) of the NGA-West1 development was completed, and PEER is now examining the near-fault directivity effects to be added to the NGA models.

2.2 Directionality of Ground Motions

Direction (azimuth) and relative amplitudes of the maximum and minimum horizontal ground motions at a site located close to an active fault are important in determining the damage and loss to a structure. For example, at sites very close to active faults, the fault-normal direction can experience significantly larger intermediate- and long-period ground motions than the fault-parallel direction. The ground motions estimated from the current NGA-West1 models are for the average ("geometric mean") of the two horizontal components. PEER is examining these directionality effects and will incorporate these effects into the NGA-West2 models.

2.3 Models for Vertical Ground Motions

The ground motions estimated from the current NGA-West1 models are for the average ("geometric mean") of the two horizontal components. Some structural and non-structural components are sensitive to the vertical input motion, especially in near-source areas. PEER is developing new ground motion prediction equations for the vertical component.

2.4 Updating NGA Models for Small Magnitude Data

In the last few years, there have been a large number of ground motion recordings for low-magnitude events. Preliminary analysis of a limited subset of these recordings have indicated that the NGA-West1 models may over-predict low magnitude ground motions. PEER is collecting thousands of low-magnitude California recordings to update NGA models.

2.5 Updating NGA Models for Moderate & Large Magnitude Data

In the last few years, there have been important moderate and major shallow crustal (i.e., non-subduction type) earthquakes in California and other active tectonic regions throughout the world that can be used to verify and/or enhance the current NGA-West1 models. Examples of such events are the 2004 Pakfield (California) earthquake as well as recent events in Japan, Italy and China with magnitudes as large as 7.9. These new recordings can serve to validate the large-magnitude scaling characteristics of the NGA models.

2.6 Scaling of NGA Models for Damping

The current NGA-West1 models for linear-elastic spectra are for 5% viscous damping. In reality, structural and non-structural systems can have different damping ratios than 5%, depending on the system type and level of input ground motions. Current guidelines to translate the 5% damped elastic spectra to other damping values pre-date the NGA project and are possibly outdated. PEER is developing a new damping model that can be used to adjust the 5% damped spectral predicted by the NGA models to other damping values.

2.7 Development of Epistemic Uncertainty Model for NGA

There is a need to add an epistemic ("model to model") uncertainty that is not necessarily captured by the use of multiple NGA models. There is currently no consensus epistemic uncertainty model to use with the NGA models. In this task, PEER will develop a consensus epistemic uncertainty model for the NGA models that can be used by all users of these models.

2.8 Further Development of Site Response in NGA

The current state of the practice in some seismic hazard analyses is to: (a) perform a probabilistic hazard analysis using the NGA models for NEHRP B/C boundary site conditions corresponding to V_{S30} =760 m/sec, and (b) apply the NEHRP site coefficients to adjust the estimated NGA ground motions to the desired NEHRP site class. The issue with this process is that: (a) the NEHRP site coefficients were developed over a decade ago, long before the NGA models; and (b) the NEHRP site coefficients are inconsistent with those predicted by the site terms included in the NGA models. In this task, PEER is examining the discrepancy between the NEHRP site coefficients and the site factors predicted by the NGA models and attempt to resolve any discrepancy.

3. NGA-EAST PROGRAM

The goal of NGA-East program is to develop next generation GMPEs for stable continental regions (such as Central & Eastern North-America). The NGA-East includes seven working groups (WGs) each of which is focused on a specific technical area. The WGs support the NGA-East program by providing guidance on research needs and/or research products. Below is a short overview of the main tasks associated with each Working Group.

Database WG: To develop an exhaustive database of recorded motions in Central & Eastern North-America (CENA) and other Stable Continental Regions (SCRs), with the associated metadata.

Path/Source WG: To develop regionalized models for correlated sets of source (stress-drop) and path parameters (attenuation and Q).

Simulations WG: To coordinate the validation and forward modeling of ground motion simulation, considering different methods. The Simulations WG relies on input from the Database, Path/Source, and Geotechnical WGs.

Geotechnical WG: To develop a simplified model to remove site effects from recorded dataset; define the reference rock shear wave velocity and kappa values, and

the range of conditions to which they apply. The Geotechnical WG is also tasked to develop a site effects model for NGA-East.

Sigma WG: To develop standard deviation models for the NGA-East project. This WG uses information from all the WGs.

Vertical Motions WG: To develop models for V/H ratios to be applied to the horizontal ground motion models. This WG relies on information from the Database WG.

GMPE Developers WG: To develop a suite of GMPEs for CENA.

The NGA-East and NGA-West2 program are interacting with each other, especially for the Vertical and Sigma WGs.

4. GLOBAL GMPEs FOR GEM

Building on the most recent advances in the field, the global GMPEs program has gathered a distinguished international team of experts to use a unified, transparent and collaborative approach to select a harmonized suite of GMPEs that can be used at the global and regional levels.

The program is coordinated by PEER and sponsored by the Global Earthquake Model (GEM), an international organization with the mission to engage the global community in the design, development and deployment of state-of-the-art models and tools for earthquake risk assessment worldwide.

Based on a systematic and consistent set of evaluation criteria, existing GMPEs for each major tectonic environment will be screened and selected by the research teams. The selected GMPEs will provide a consistent platform for the ground motion component of the GEM hazard model(s). The GEM program at PEER is organized into the following tasks:

Task 1A: *Define of a consistent strategy for modeling ground motions.* The issues that are addressed in this subtask are as follows: (i) consistency in the model parameters (magnitude, distance, style-of-faulting, site classification, etc.) and in the ground motion parameters (PGA, PGV, spectral acceleration, etc.); (ii) balancing the approaches to modeling ground motions (e.g. empirical versus numerical simulations). The working group will develop a consistent strategy for developing global ground motion models for active crustal regions, subduction zones and stable continental regions.

Task 1B: *Examine methods for estimation of site effects in parametric ground motion models.* The parametric ground motion models all use some simplified site classification method to account for the site effects. To apply the ground motion models requires having estimates of the site classification for the entire region of interest. Therefore, an efficient method for estimating the site classification, consistent with the classification used in the ground motion models, will be completed by correlating available site classifications with other parameters that are available for the entire region.

Task 2: *Compile and critically review GMPEs.* In this task, recent sets of candidate GMPEs will be compiled and reviewed. The GMPEs will be representative of the global (worldwide) data sets for four tectonic categories of earthquakes:

(a) shallow crustal earthquakes in active tectonic regions,
(b) shallow crustal earthquakes in stable continental regions,
(c) subduction zone interface and intraslab (Wadati-Benioff) earthquakes.
(d) volcanic earthquakes.

Task 3: *Select or derive a global set of GMPEs*. In this task, the GMPEs compiled and screened in Task 2 will be reviewed, adjusted (if needed) and selected as the Global GMPEs. For each tectonic region, the selection and adjustment will be based on review of the applicability to a wide range of magnitude, distance and so forth, and the compatibility of the GMPEs with the recorded regional ground motion data.

Task 4: *Include near-fault effects.* A working group will provide recommendations regarding correction of GMPEs for near-fault effects, including directivity and directionality. The working group for this task will examine various existing adjustments of GMPEs to include near-fault effects.

Task 5: *Build a database of waveforms.* There will be three databases of recorded waveforms for different tectonic environments:

(a) A very comprehensive database for shallow crustal earthquakes in active tectonic regions has already been developed by PEER. As mentioned previously, under the NGA-West2 program, the database is significantly being improved and expanded. The new database will be available through PEER web site.

(b) A database of waveforms for stable continental regions (SCRs) developed within the scope of the NGA-East program, and will be made available through PEER web site.

(c) A waveforms database for subduction regions will be provided through the PEER website.

Task 6: *Design the specifications to compile a global database of soil classification.* In this task, a working group will propose a set of *specifications* to compile consistent global database of geological soil classifications based on V_{s30} and designed to be consistent with the soil categories in the NEHRP and EuroCode 8 building codes.

5. CONCLUDING REMARKS

PEER is coordinating three “mega” research programs on different aspects of ground motion hazards. These programs are multi-disciplinary involving geologists, seismologists, geotechnical and structural engineers. The ground motion hazard programs at PEER also include academicians, practicing engineers and end-users. Such strong collaborative efforts among various disciplines and sectors have proven to yield high quality final products, and a greater impact on the earthquake engineering and scientific communities.

Abstract: This study collects recorded ground motions from the near-source region of large earthquakes and considers to what extent this historic record can inform expectations of future ground motions at similar sites. The distribution of observed peak ground acceleration (PGA) is well approximated by the lognormal distribution, and we expect the observed distribution to remain unchanged with the addition of data from future earthquakes. However, the distribution of peak ground displacements (PGD) will likely change after a well recorded large earthquake. Specifically we expect future observations of PGD greater than those previously recorded. We use seismic scaling relations to motivate the expected distribution of PGD as uniform on the logarithmic scale, or at least fat-tailed. Since PGA does not scale with fault rupture area or slip on the fault, there are no such scaling relations to predict the observed distribution of PGA. The observed records show that there is essentially no correlation between PGD and PGA for near-source ground motions from large events. The large uncertainty in a future value of PGD in the near-source region of a large earthquake exists despite the ability of earth scientists to accurately model long-period ground motions. In contrast, the relative certainty in a future value of PGA exists despite the inability to model short-period ground motions reliably. The stability of the observed distribution of PGA with respect to new ground motion records enables us to predict the distribution of future PGA and to calculate the probability of exceeding the largest recorded PGA.

1. INTRODUCTION

The current practice of seismic structural design assumes an expectation of future ground motions. An engineer first defines the likely and most severe ground motions that may excite a structure at a particular site in its anticipated lifetime. Then the engineer specifies a lateral force resisting system with a capacity sufficient to withstand these expected demands. This approach to design problems works well if the definition of future ground motions is reliable. Unfortunately, predicting the future is a notoriously difficult endeavor.

Past experience primarily informs the seismic design of structures. ASCE 7-05, the standard adopted by the 2006 International Building Code for seismic design, requires the use of at least three recorded ground motion time histories for structural designs based on seismic response histories (American Society of Civil Engineers, 2006). If there are fewer than three appropriate recorded ground motions, simulated motions may be used to meet the requirement. Also, structural engineers develop their judgments through their own experiences and the experiences of their predecessors. Experience and the historic record may be necessary, but not sufficient, evidence for anticipating the future ground motions at a given site. This study considers the extent to which recorded ground motions can inform the prediction of future ground motions.

Throughout this study we distinguish ground motions dominated by short-period versus long-period energy content. All seismic ground motions can be decomposed according to the relative amounts of energy in harmonic waves of every period. Generally speaking, the energy in ground motions from smaller, more frequent earthquakes is mostly from the short-period content, whereas the energy in ground motions from larger, less frequent earthquakes is primarily in the long-period content. This distinction between short- and long-period energy also categorizes a structure as short- or long-period according to the structure's fundamental period. The lateral force-resisting system of a structure with a short fundamental period tends to be susceptible to short-period ground motions. Similarly, a structural system with a long fundamental period is particularly sensitive to long-period ground motions.

This study collects recorded ground motions from the near-source region of large earthquakes and considers to what extent this historic record can inform expectations of future ground motions at similar sites. We find that future peak ground accelerations (a good intensity measure for short-period ground motions) can be readily predicted from existing records, but the experience of past large earthquakes does not adequately predict future peak ground displacements (a good intensity measure for long-period

ground motions). These observations directly affect the design of structures, since building codes rely explicitly or implicitly on recorded ground motions: existing measures of peak ground acceleration from records are a reliable predictor of future peak ground accelerations, but future peak ground displacements may differ significantly from measures of peak ground displacement from existing records.

2. DATA

We collect ground motions from ten historic earthquakes to generate distributions of observed peak ground acceleration and displacement. Specifically, we use ground motions only from earthquakes with magnitudes greater than 6.0 and from sites in the near-source. We define the near-source region to be within 10 km of the surface projection of the fault rupture. We choose this number because it is small enough to demonstrate the source scaling, but large enough to include a sufficient number of records to characterize the statistics. We disregard the soil class at the instrumented sites.

Table 1 lists important features of the data set. The earthquakes include the major events in the years 1979 through 2004. The data set covers a range in moment magnitude from 6.0 to 7.8, with wide gaps between 6.0 and 6.5 and between 6.9 and 7.3. Nonetheless, the data well represent the ground motions of interest. The Chi-Chi and Parkfield earthquakes are well recorded, each with over forty near-source records. (In fact, the Chi-Chi strong ground motion data set is the largest for a major earthquake [Shin and Teng, 2001].) However, the Landers, Hyogoken-nanbu, Izmit, and Denali ruptures are poorly recorded, since each has fewer than five near-source records. Table 1 also lists the focal depth of each hypocenter, ranging from 12.0 km to 21.2 km, as well as the fault rupture model used to define the near-source area.

We obtained ground acceleration time histories from several databases around the world. The COSMOS Virtual Data Center, which includes the California Strong Motion Instrumentation Program and the United States Geological Survey seismic networks, was the source for ground motions from the Imperial Valley, Loma Prieta, Landers, Northridge, Denali, and Parkfield earthquakes. The ground motions for the Hyogoken-nanbu earthquake were from: the Japan Meteorological Agency; the Committee of Earthquake Observation and Research in the Kansai Area in Japan (Toki *et al.*, 1995); and the Japan Railway Institute, whose records were scanned and digitized by Wald (1996). (Seismometers in the CEORKA network record velocity, but CEORKA processes the records to provide acceleration time histories.) The national strong-motion network in Turkey recorded ground motions in the Izmit earthquake (Akkar and Gülkan, 2002), and we collected them from two sources: the Earthquake Research Department of the General Directorate of Disaster Affairs in Turkey (Earthquake Research Department, 2004); and the COSMOS Virtual Data Center, which archived records from the National Earthquake Monitoring Center, Kandilli Observatory and from the Earthquake Research Institute, Boğaziçi University. The Central Weather Bureau Seismic Network in Taiwan recorded the ground motions for the Chi-Chi earthquake, and Lee *et al.* (2001) disseminated them. The K-NET (Kyoshin Net, 1996) and KiK-net (KiK-net, 2000) seismic networks, operated by the National Research Institute for Earth Science and Disaster Prevention in Japan, were our sources for the strong ground motions of the Niigataken-chuetsu earthquake.

The geographic distributions of instrumented sites in the near-source regions are not uniform. The density of sites per near-source area is not constant for all events, and the sites do not evenly represent all near-source regions. For nine of the ten earthquakes used in this study, Yamada *et al.* (2007) showed the sites in comparison to the fault rupture surface projection and the near-source region. As examples of particularly poor distributions of instrumented sites (for our purposes), many of the ground motions from the 1979

Table 1 Earthquake Data Set Used for the Near-Source Ground Motion Analysis

Earthquake	M_w	N	Focal Depth (km)	Fault Model
1979 Imperial Valley	6.5	14	12.0	Hartzell and Heaton (1983)
1989 Loma Prieta	6.9	8	19.0	Wald *et al.* (1991)
1992 Landers	7.3	1	15.0	Wald and Heaton (1994)
1994 Northridge	6.6	17	16.8	Wald *et al.* (1996)
1995 Hyogoken-Nanbu	6.9	4	20.3	Wald (1996)
1999 Izmit	7.6	4	17.0	Sekiguchi and Iwata (2002)
1999 Chi-Chi	7.6	42	21.2	Ji *et al.* (2003)
2002 Denali	7.8	1	15.0	Tsuboi *et al.* (2003)
2004 Parkfield	6.0	47	12.0	Ji *et al.* (2004)
2004 Niigataken-Chuetsu	6.6	9	13.0	Honda *et al.* (2005)

Moment magnitude (M_w) and focal depth are cited from the Harvard Centroid Moment Tensor solution. The preliminary determination of the epicenter is used for the focal depth. The number of near-source records for each earthquake (N) is also tabulated. The fault models are used to define near-source stations.

Imperial Valley earthquake are from sites forming a line perpendicular to the fault, and most ground motions from the 1999 Chi-Chi earthquake are from sites on the foot wall. Despite the non-uniform geographic distribution of the recorded ground motions, we treat each record as a sample of the ground movement in the near-source region.

To determine the peak ground acceleration and displacement of a recorded ground motion, we process each time history. We first remove the bias from the acceleration record by subtracting the mean of the pre-event interval. Then we integrate twice to generate the displacement time history. We remove the longest period content of the displacement time history with a fourth-order Butterworth filter (13.3 s corner period) to avoid problems caused by a shift in the baseline. Filtering in this way can produce a peak ground displacement smaller than what would have been calculated from the unfiltered record. Nonetheless, these filtered records still contain rich long-period content. We then find the square root of the sum of the squares of the north-south and east-west components at each time step of the record. The peak ground measure is the largest such value over all time steps. This measure of peak ground motion is also known as the vector amplitude (Kanno *et al.*, 2006). Yamada (2007) compared PGAs and PGDs calculated from the horizontal components or from the vertical component and found that they have a similar trend with respect to moment magnitude. We use only the horizontal components to calculate the peak values since most engineered structures are more vulnerable to lateral than vertical excitation.

In addition to the recorded ground motions, we also consider a recurrence of the 1906 San Francisco earthquake. We use the simulated ground motions generated by Aagaard *et al.* (2008) closest to sites in the California Integrated Seismic Network as of December 2007. To be consistent with the choice of recorded ground motions, we only include sites within 10 km of the historic rupture on the San Andreas fault. These selection criteria result in 87 "records" of a recurrence of the 1906 San Francisco earthquake. These ground motions are long period (periods greater than 2 s), so we use a fourth-order Butterworth filter (25.0 s corner period) and calculate only the peak ground displacement of each record.

3. OBSERVED DISTRIBUTIONS OF PGA AND PGD

For our collected set of recorded ground motions, Figure 1 plots the peak ground accelerations and displacements as functions of the moment magnitude of the generating earthquake. Each data point is denoted with a symbol, and the least squares regression lines for the peak ground measures as functions of magnitude are shown. At each magnitude, the peak ground acceleration (PGA) and peak ground displacement (PGD) data are approximately lognormally distributed about their respective regression lines. Note that PGA saturates at magnitudes greater than 6.0, as evidenced by the approximately zero slope of the regression line. The saturation of short-period ground

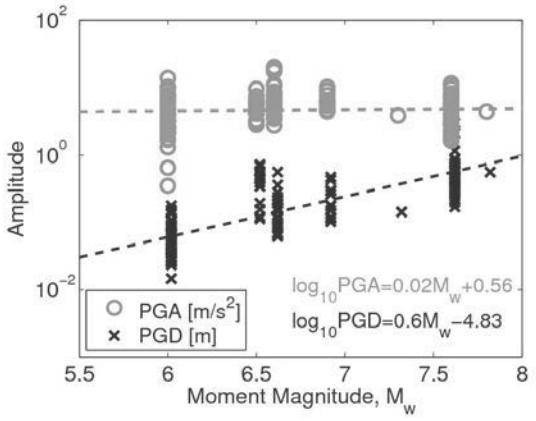

Figure 1 Near-source PGA and PGD as a function of moment magnitude. The dashed lines are least-squares regression lines for the two intensity measures, and the equations for these lines are also given.

motions in the near-source has been observed previously by Rogers and Perkins (1996) and Somerville (2003). In contrast, the logarithm of PGD increases linearly with respect to magnitude, with a slope of 0.6. Previous studies have discussed this linear trend (e.g., Wells and Coppersmith, 1994; Campbell and Bozorgnia, 2008). We expect this slope to be in the range of 0.5 to 0.75 based on the following argument.

Given the definition of seismic moment, M_0, ($\log M_0 = \log \mu + \log S\bar{D}$) and the relationship between seismic moment and moment magnitude, M_w, ($\log M_0 = 2/3(M_w + 10.73)$), we find:

$$\log S\bar{D} = 2/3(M_w + 10.73) - \log \mu , \qquad (1)$$

where S is the rupture area, $\bar{D}$ is the average slip, and μ is the crustal rigidity. If we assume the rupture area is approximately the square of the rupture length (reasonable for small to moderate earthquakes [Aki, 1972; Kanamori and Anderson, 1975]) and PGD is proportional to the average slip, (1) implies that:

$$\log PGD = 1/2 M_w + \text{a constant.}$$

If we assume the rupture area is proportional to the rupture length (reasonable for large earthquakes, [Scholz, 1982]) and PGD is proportional to the average slip again, Equation (1) then implies that:

$$\log PGD = 3/4 M_w + \text{another constant.}$$

Thus we expect the slope of the relationship between the logarithm of PGD and moment magnitude to be between 0.5 and 0.75 for the combination of moderate and large earthquakes.

As mentioned previously, PGA is known to saturate at magnitudes greater than 6, and the logarithm of PGD is known to increase linearly with respect to magnitude. Thus, there is essentially no correlation between these two

intensity measures for near-source ground motions from large events. Figure 2 plots PGA versus PGD for the near-source records used in this study and for additional far-source records. The far-source PGDs and PGAs are from ground motions recorded in magnitude greater than 6 earthquakes at distances greater than 10 km from the fault. Unlike the far-source records, the near-source PGD and PGA are very weakly correlated.

Figure 3 compares the marginal distributions of PGA and PGD to a base-10 lognormal distribution. The histogram of the PGA data is consistent with a lognormal distribution: on a logarithmic scale, the PGA data are clearly peaked, symmetric about the mean, and have thin tails. This observation is consistent with Figure 1 since the mean PGA is approximately constant for magnitudes greater than 6.0, and the PGA data appear to be lognormally distributed about the mean with constant variance. The near-source PGA of earthquakes with magnitude greater than 6.0 can be approximated by the lognormal distribution:

$$p(PGA) = \frac{1}{0.56 PGA\sqrt{2\pi}} e^{-[\ln PGA - \ln 4.64)^2 / 0.64]}, \qquad (2)$$

where ln represents the natural logarithm. The histogram of the PGD data, however, is inconsistent with a lognormal distribution: on a logarithmic scale, the PGD data are roughly uniform over the range of observed PGD. The PGD data are not peaked because the mean PGD is correlated with magnitude. At a given magnitude, the PGD data appear lognormally distributed, but since the mean increases with magnitude, the projection of the data as a marginal distribution becomes more uniform than peaked.

Figures 4 and 5 are histograms of the PGA and PGD data, respectively. For the PGA data, we show a subset of the observed data with the Chi-Chi data removed as well as the full data set. The distribution of the subset without the Chi-Chi data appears lognormal. The addition of the Chi-Chi data does not change the shape of the distribution; including the Chi-Chi PGA data simply increases the height of the histogram. This exercise suggests that a lognormal

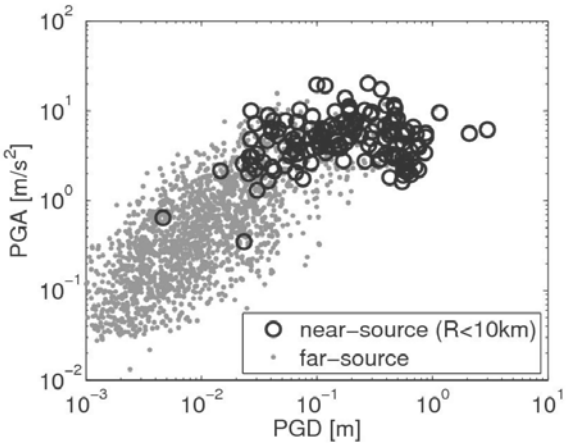

Figure 2 Relationship between PGD and PGA. The near-source records are the same data used in this study. The far-source records are the records from earthquakes with magnitude greater than 6.0.

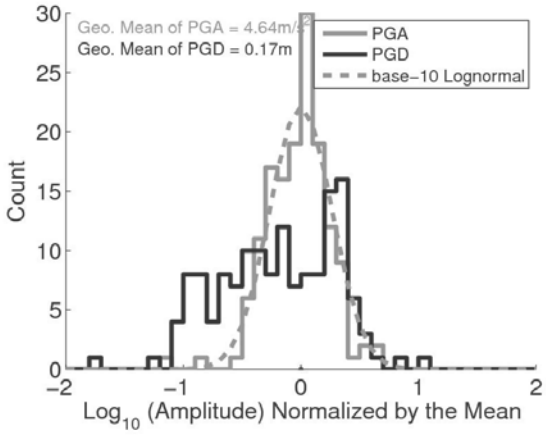

Figure 3 Comparison of observed near-source PGA and PGD histograms to a base-10 lognormal distribution. The lognormal distribution shown has a geometric mean (4.64 m/sec^2) and geometric standard deviation (1.77 m/sec^2) calculated from the PGA data.

distribution is a good approximation for existing, recorded PGA at near-source sites in earthquakes with magnitudes greater than 6.0, and this distribution will remain approximately lognormal with the addition of future data. The saturation of PGA at large magnitudes supports our claim: since the mean and standard deviation of PGA are approximately constant for each large earthquake, data from future earthquakes will also have the same mean and standard deviation and thus cannot change the shape of the PGA distribution.

Now consider the observed distribution of PGD in Figure 5. Similar to the analysis of the PGA data, we show the distribution of PGD for a subset of our recorded data set that does not include ground motions from the Chi-Chi earthquake. This distribution is roughly uniform on a logarithmic scale over the range of this subset. Adding the PGDs from the Chi-Chi earthquake extends the range of PGD at large values; there are several PGDs from the

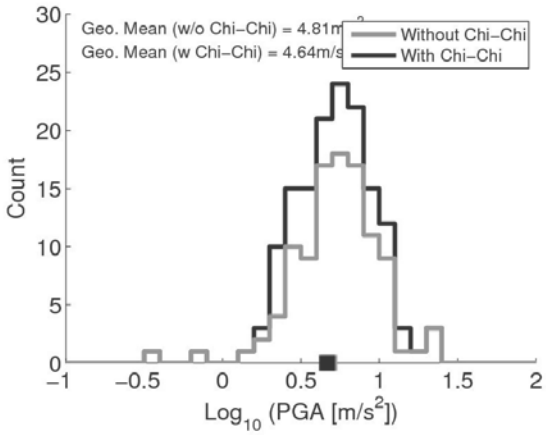

Figure 4 Histogram of the near-source PGA for earthquakes with magnitude greater than or equal to 6.0. The black and gray lines are histograms of the full data set with and without the Chi-Chi earthquake records, respectively. The squares on the horizontal axis indicate the geometric mean of each component, and their values are shown on the plot.

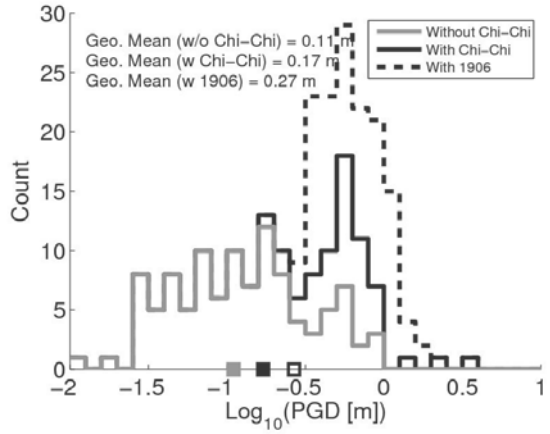

Figure 5 Histogram of the near-source PGD for earthquakes with magnitude greater than or equal to 6.0. The black and gray lines show the distribution of recorded PGD in our data set with and without the Chi-Chi observations, respectively. The dashed lines augment the recorded data set with an imagined repeat of the 1906 San Francisco earthquake. The squares on the horizontal axis indicate the geometric mean of each set of data, and the values are listed in the plot.

Chi-Chi ground motions that are larger than observations from other large earthquakes. The spread in the distribution of observed near-source PGD widens notably with the inclusion of this single earthquake.

We use a simulation of ground motions in the 1906 San Francisco earthquake to imagine the effect of the next large, well-recorded earthquake on this distribution of PGD. If the 1906 earthquake recurred and was recorded with existing instrumentation, Figure 5 shows the effect on the "observed" distribution. The simulated data add to the histogram at the largest observed PGDs. In other words, many of the simulated PGDs are in the range of the largest recorded PGDs. Certainly the next large, well-recorded earthquake will not be a repeat of the 1906 San Francisco earthquake, but a future rupture has the potential to produce numerous recorded ground motions with PGDs at the high end of, or greater than, those recorded at present.

Earthquakes with magnitudes greater than 6.0 change the observed distribution of PGD, either by extending the distribution or by adding data at previously recorded values. The increase of PGD with magnitude (Figure 1) helps to explain this point. Although PGD is lognormally distributed at a given magnitude, the mean of the logarithm of PGD increases linearly with magnitude. Thus, the magnitude of each event determines where its observed PGDs add to the distribution of PGD from all events, either beyond the observed range or within it. This finding is in contrast to our statements about the distribution of PGA: records from future, well-recorded earthquakes will not change the observed distribution of PGA, whereas they may change—and many change substantially—the observed distribution of PGD.

4. THEORETICAL DISTRIBUTIONS OF PGA AND PGD

In this section we first use empirical scaling relationships to derive the expected marginal distribution of PGD in the near-source region of large earthquakes. First, we assume that the number of earthquakes N with magnitudes greater than M is given by the Gutenberg-Richter relationship:

$$N = 10^{a-bM} = \int_M^\infty N_M \, dM \,, \qquad (3)$$

where N_M is the number of earthquakes with magnitude between M and $M + \Delta M$. In a different form,

$$N_M = \frac{dN}{dM} = b\ln(10)10^{a-bM} = 10^{A-bM} \,, \qquad (4)$$

where $10^A = b\ln(10)10^a$, a constant. The moment magnitude can be rewritten in terms of the seismic moment, M_0, which is equal to the product of the crustal rigidity, μ, average slip on the fault, $\bar{D}$, and the area of fault rupture, S:

$$M_w = 2/3\log_{10} M_0 - 10.73 = 2/3\log_{10}(\mu \bar{D} S) - 10.73 \,.$$

Thus,

$$N_M = 10^{A+10.73b} 10^{-2/3b\log_{10}(\mu \bar{D} S)} = c(\bar{D}S)^{-2/3b} \,,$$

where $c = 10^{A+10.73b}\mu^{-2/3b}$, a constant.

One of two assumptions can be made at this point, depending on the size of the earthquake. For moderate earthquakes, the fault rupture length, L, is approximately equal to the fault rupture width, which implies that the fault rupture area is approximately L^2. For large earthquakes, the rupture length is much larger than the approximately constant rupture width, which implies that the rupture area is proportional to the rupture length. We also assume in both cases that the average slip on the fault is proportional to the length of the fault rupture. Thus,

$$N_M \propto (\bar{D}L^2)^{-2/3b} \approx \bar{D}^{-2b} \quad \text{if } S \approx L^2 \quad \text{(moderate events)}$$
$$N_M \propto (\bar{D}L)^{-2/3b} \approx \bar{D}^{-4/3b} \quad \text{if } S \approx L \quad \text{(large events)}$$

The total rupture area for all earthquakes of magnitude M is:

$$N_M S \approx N_M \propto \bar{D}^{-2b}\bar{D}^2 = \text{constant for } b = 1,$$
$$N_M S \propto \bar{D}^{-4/3b}\bar{D} = \bar{D}^{-1/3b} \quad \text{for } b = 1.$$

Assuming a uniform geographic distribution of seismic instrumentation, Equation (5) implies that the total number of near-source records at a particular magnitude is either constant or weakly dependent on magnitude, depending on the assumed geometry of the fault rupture. Furthermore, the peak ground displacement in the near-source is proportional to the average slip on the fault (Aagaard *et al.*, 2001). These results can be combined with the observations from Figure 1 to generate a rough approximation of the marginal probability density function for the logarithm of PGD.

If we assume the rupture area is approximately square

(that is, consider moderate earthquakes), then the total number of near-source records is constant for all magnitudes. Given enough time, all magnitude 6 earthquakes will produce the same number of near-source records as all magnitude 7 earthquakes or all magnitude 8 earthquakes. Figure 6 (top) combines this result with the observations that the mean PGD increases with magnitude and PGD is lognormally distributed at a given magnitude. The resulting marginal distribution of PGD is approximately uniform because the total number of recorded ground motions is constant for all magnitudes.

Alternatively, if we assume the rupture length is much larger than the rupture width (that is, consider large earthquakes), then the total number of near-source records decreases with magnitude, since magnitude depends on average slip. Figure 6 (bottom) shows the relative number of near-source ground motions at each magnitude given that the total number is proportional to the mean PGD raised to the negative one-third power. The resulting marginal distribution of PGD is not uniform, but it is also not lognormal; it is something in-between the two.

We cannot develop a similar argument for the marginal distribution of PGA because the relationship between PGA and faulting is not clear. At this time, seismologists are developing finite element models to simulate broadband ground motions and thus predict PGA in the near-source region. However, these models require sophisticated fault and velocity models to propagate short-period seismic waves or require a stochastic description of PGA. Unlike PGD, which can be related to slip on the fault, it is difficult to use a fundamental, physical understanding of faulting and wave propagation to predict PGA. Yamada *et al.* (2007) shows that the distribution for near-source PGA seems to be compatible with the hypothesis that the total radiation of high-frequency energy scales with the rupture area. This hypothesis is consistent with the observation that the PGA weakly depends on the slip on the fault.

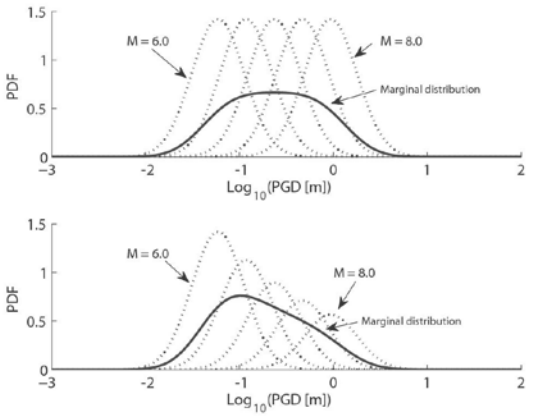

Figure 6 Theoretical marginal distribution of PGD. Seismic scaling relations predict that the number of recorded PGDs at a given magnitude in the near-source region is constant (top, moderate earthquakes) or weakly dependent on magnitude (bottom, large earthquakes). Given enough observations, the resulting, expected marginal distribution of PGD more closely resembles a uniform—not normal—distribution on the logarithmic scale.

5. A PARADOX

This discussion of predicting PGA and PGD from the fundamentals of faulting and wave propagation leads directly to a paradox: the PGA in a future earthquake can be easily predicted from past earthquakes even though short-period ground motions cannot be easily simulated, whereas the PGD in a future earthquake cannot be predicted even though long-period ground motions are routinely simulated. Given only the information that a site is in the near-source of an earthquake with magnitude greater than 6.0, the recorded ground motions used in this study show that PGA is well approximated by a lognormal distribution, but the distribution of the logarithm of PGD is roughly uniform with an unknown point of truncation. Thus, using past observations of ground motions can produce a relatively certain prediction of PGA and a quite uncertain prediction of PGD. This is in contrast to the present capabilities of simulating ground motions. Long-period ground motions can be readily generated from models of faults and seismic velocity structures. Currently, however, generating short-period ground motions is not routinely done as it requires much more detailed models or stochastic descriptions.

The resolution of this paradox considers the assumed information. Simulating ground motions assumes a magnitude and either generates a slip distribution (dynamic source modeling) or assumes a slip distribution (kinematic source modeling). Our study of recorded ground motions assumes only that the earthquake has a magnitude greater than 6.0. Knowing the magnitude does not help predict the PGA since PGA saturates with magnitude, but knowing the magnitude helps to predict PGD since the logarithm of PGD is proportional to the magnitude.

However, we need to predict more than the magnitude of future events; the near-source PGD is best predicted by slip on a near-by segment of a fault.

Thus, the ability of seismologists to generate reliable long-period ground motions (and thus reliable predictions of PGD) in an earthquake of known magnitude does not imply that they can predict the PGD in the next large-magnitude earthquake, unless they can also reliably predict slip.

6. IMPLICATIONS FOR SEISMIC RISK

Engineers often use ground motion intensity measures in place of full time histories to predict seismic structural responses. Although the interaction of the complete ground motion time history with the structure defines the response, a characteristic of the ground motion—as measured by the intensity measure—is often sufficient to predict the structural response for many types of structures. The most common intensity measure is spectral acceleration at the fundamental period of the structure (abbreviated $S_a(T_1)$). Other scalar and vector intensity measures based on spectral

quantities have been proposed as well (e.g., Baker and Cornell, 2005; Luco and Cornell, 2007). For six- or twenty-story, steel, moment-resisting frames, Olsen (2008) showed that, among the considered intensity measures, the peak inter-story drift ratio was best predicted by $S_a(T_1)$, assuming that the lateral force-resisting system was not compromised. However, large permanent drifts and collapse due to P-Δ are predicted better by a combination of large peak ground velocity (PGV) and PGD. Near-source ground motions with large PGDs are almost always accompanied by large PGVs. Thus, in the near-source region, PGDs are often associated with simulated collapse. Thus, although $S_a(T_1)$ is widely used as an intensity measure, there is evidence that an alternate intensity measure may predict structural response better, depending on the structure type and response of interest.

The maximum value of the appropriate intensity measure likely to be experienced at a site is often of interest for seismic risk assessment. This maximum value depends on an expectation of future ground motions, which is informed by existing recorded ground motions as well as the current understanding of the physical mechanisms. This study shows that the maximum likely PGA within 10 km of a fault that produces a magnitude greater than 6.0 earthquake can be reliably derived from a lognormal distribution, since the empirical marginal distribution of such PGAs is stable with respect to new records and consistent with a lognormal distribution. Determining the maximum likely PGD in the same geographic region is more problematic given the available recorded ground motions with large PGDs. This study shows that the current empirical marginal distribution of PGD is fat-tailed, if not uniform on a logarithmic scale to a physical limit. This physical limit has not yet been determined, and simulation of ground motions from plausible large earthquakes (for example, the repeat of the 1906 San Francisco earthquake) suggests that the next large, well-recorded earthquake will contribute several measured PGDs between the current largest recorded PGDs and the suspected physical limit. Given this evidence, we find the calculation of the maximum likely PGD difficult—if not impossible—given the current knowledge.

These results have a direct bearing on seismic risk assessment. If the appropriate intensity measure for a structural response of interest is PGA, then recorded ground motions with the largest observed PGAs can be used as representative of future ground motions with the largest PGAs. The predicted structural responses based on existing large PGAs would be reliable even after the next large earthquake. However, if the appropriate intensity measure is PGD, the largest observed PGDs may not be representative of the future largest PGDs. Consequently, structural responses based on the largest recorded PGDs may not be representative of structural responses in the future largest PGDs. Consider tall buildings as an example. Their response to ground motions with PGDs of 0.2 m or 2 m or 10 m range from elastic to catastrophic failure. If this type of building is located within 10 km of an earthquake with magnitude greater than 6, each response is roughly equally likely if each level of ground motion is approximately equally likely. This study provides evidence to caution against assuming that recorded ground motions with the largest PGDs are representative of unrecorded or future ground motions with the largest PGDs.

This study supports the argument made in Heaton (2007). Among other questions, Heaton (2007) asks whether the current structural design philosophy of performance-based earthquake engineering is appropriate for the design of long-period structures. PBEE assumes that the reliability of a structure's performance—be it, seismic response or lifetime cost—can be predicted during the design phase. Heaton (2007) points out that such a reliability analysis is credible only if the hazard is well-described by a knowable and finite uncertainty. The present study suggests that a future PGA (and thus the peak amplitude of short-period ground motions) is readily predictable from past records with a known, finite uncertainty. In contrast, a future PGD (or peak amplitude of long-period ground motions) cannot be anticipated with certainty because first, each large earthquake changes the observed marginal distribution of PGD, and second, the uncertainty of this distribution at present is quite large.

7. CONCLUSIONS

For ground motions recorded within 10 km of a fault producing an earthquake with magnitude greater than 6.0, the observed distribution of peak ground acceleration is lognormal, but the observed distribution of peak ground displacement is approximately uniform on a logarithmic scale, or at least fat-tailed. We expect the distribution of PGA to remain approximately lognormal with the addition of data from future earthquakes. However, the distribution of PGD will likely change after a well-recorded large earthquake, and specifically we expect the range of recorded PGD to expand at the largest values. The observed records show that there is essentially no correlation between PGD and PGA for near-source ground motions from large events.

Seismic scaling relations motivate the expected distribution of PGD as uniform on the logarithmic scale, or at least fat-tailed. This result implies that every peak ground displacement is approximately equally likely at a given site—to a physical limit—even though an earthquake large enough to produce large displacements is infrequent. There are no such scaling relations to predict the lognormal distribution of PGA because PGA does not scale with fault rupture area or slip on the fault. The large uncertainty in a future value of observed PGD exists despite the ability of earth scientists to accurately model long-period ground motions. In contrast, the certainty in a future value of PGA exists despite the inability to model short-period ground motions reliably.

The design of short-period structures with modern building codes is reliable in part because earthquakes with magnitude greater than 6 produce a stable marginal distribution of PGA with respect to future earthquakes. The mean and standard deviation of PGA in the next large

earthquake can be predicted reliably from the historic distribution of PGA. The design of long-period structures, however, should not rely on the same argument: the observed marginal distribution of PGD may change after the next well-recorded large earthquake. The emphasis on recorded ground motions for structural design using seismic response histories assumes that future ground motions will be sufficiently similar to recorded ground motions. This study demonstrates that this assumption is not valid. Thus, there must be a different approach to the design of long-period structures that does not rely heavily on past observations of PGD to predict future amplitudes of long-period ground motions. This approach should acknowledge that, for any site in the near-source region of a major fault, every PGD is similarly likely in the logarithmic sense. That is, 1 m of future peak ground displacement is approximately as likely as 10 m of future peak ground displacement. The optimal design of long-period structures should be the most economical design that is robust in large ground motions.

Abstract: The 2010 Maule, Chile earthquake (Mw8.8) produced many strong motion records. At Concepcion where many high-rise buildings suffered severe damage, a strong motion accelerogram with long period contents was observed. In this paper, local site effects on the record are examined based on the microtremor and aftershock record. The relation between the building damage and ground motion characteristics is also discussed.

1. INTRODUCTION

A gigantic earthquake with Mw8.8 occurred in Chile on February 27, 2010. The effects of the earthquake were observed over a wide area with a length of more than 500 km. The numbers of affected people and damage houses are about 2 millions and 370,000, respectively (Elnashai et al. 2011). The monetary loss is roughly estimated at 30 billion US$. The earthquake also produced many strong motion records. Among the records, a record with large amplitude and longer period was observed at Concepcion where many high-rise buildings had severe damage. In this paper, we examine the characteristics of the record in relation to local site effect and building damage.

2. OUTLINE OF EARTHQUAKE AND STRONG MOTION RECORDS

Large earthquakes have frequently occurred along the coast of Chile due to subduction of the Nasca plate to the continental plate. The 2010 Maule, Chile earthquake occurred in the seismic gap along the coast of Chile where the last large earthquake (M8.5) occurred in 1835 (Beck et al. 1998). The magnitude of the earthquake is 8.8 in Mw and the length of the aftershock area is approximately 500km. The fault models of the earthquake have been proposed by several researchers. For example, Poiata and Koketsu (2010) estimated a reverse fault model with a strike and dip of 11° and 18°, respectively. The fault length is estimated to be 450-500 km long. Figure 1 shows the surface projection of the slip distribution. The maximum fault slip is 9 m.

Strong motion records from the Maule earthquake are obtained by two strong motion networks such as RENADIC [Red Nacional de Acelerógrafos del Departamento de Ingeniería Civil de la Universidad de Chile] (Boroschek et al. 2010) and RSN [Red Sismologica Nacional by Dept. Geophysics of the University of Chile] (Barrientos 2010). Figure 2 shows the distribution of the peak horizontal accelerations in the epicentral region. The peak accelerations higher than 0.3 g are observed at many sites.

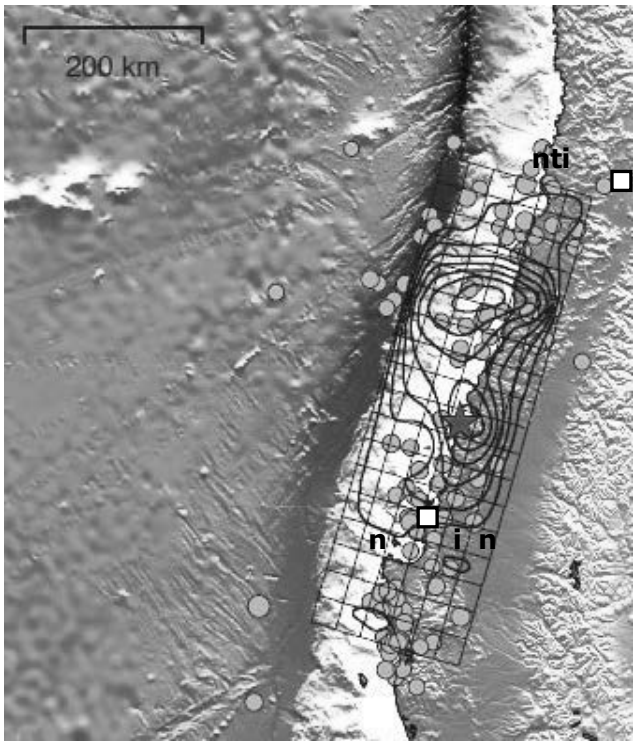

Figure 1 Fault Model (Poiata and Koketsu 2010)

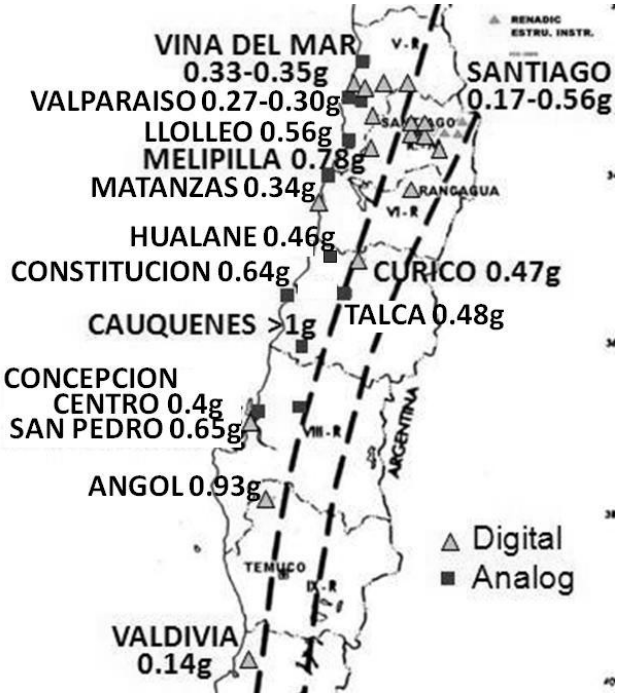

Figure 2 Distribution of Peak Horizontal Accelerations

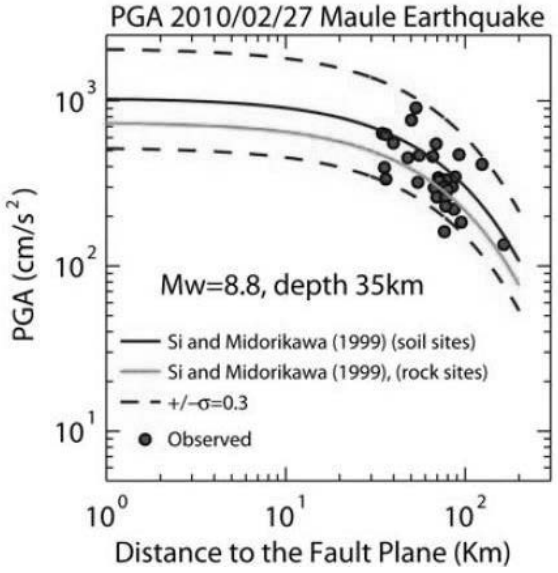

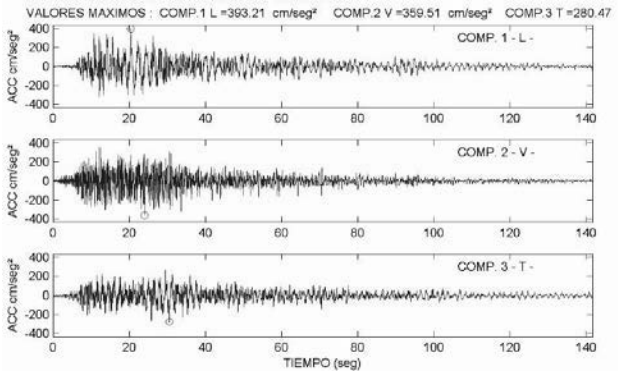

Figure 3 Attenuation of Peak Horizontal Accelerations (Pulido et al. 2011)

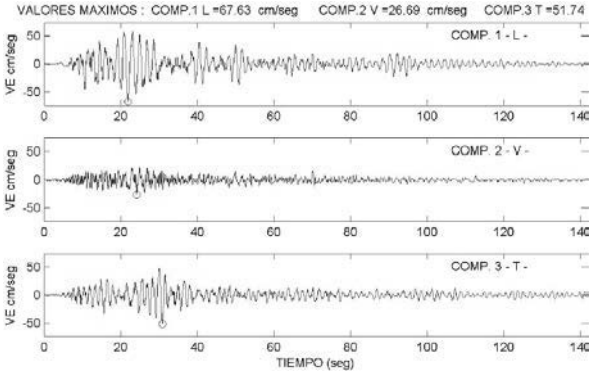

Figure 3 shows the attenuation of the peak horizontal acceleration (Pulido et al. 2011). In the figure, the curve from the empirical relationship by Si and Midorikawa (2000) is also plotted. The data from the earthquake is consistent with the existing relationship.

3. STRONG MOTION RECORD AT CONCEPCION

Among the strong motion records, an accelerogram observed at the downtown of Concepcion where many high-rise buildings suffered severe damage, has large amplitude and longer period contents. Figure 4 shows the acceleration and velocity time histories of the record. The peak horizontal acceleration and velocity are about 0.4g and 70 cm/s, respectively. The record was obtained at the basement floor of a three-story school building. The building suffered moderate damage.

(a) acceleration

(b) velocity

Figure 4 Acceleration and velocity Time Histories of Record at Concepcion (Boroschek et al. 2010)

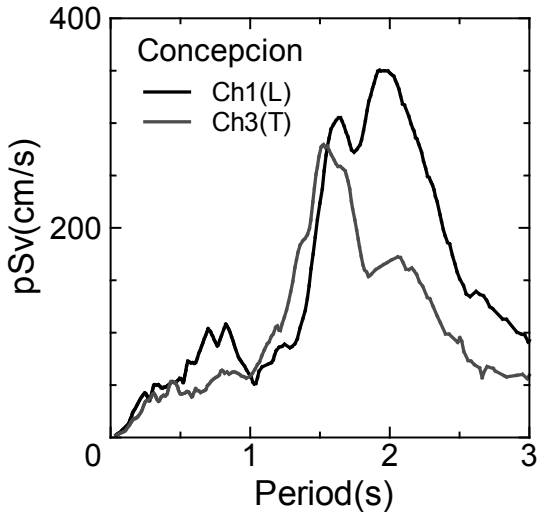

Figure 5 Pseudo Velocity Response Spectra (h=0.05)

Figure 5 shows the pseudo velocity response spectra of

the record (h=0.05). In the spectra, there are two strong peaks at periods of 1.5 and 2 seconds. At the peaks, the response amplitudes are very high such as about 350 cm/s at period of 2 seconds. The high response value is comparable with those of the records at Kobe in the 1995 earthquake and at Mexico City in the 1985 earthquake, where catastrophic damage was observed.

4. LOCAL SITE CONDITIONS AT CONCEPCION

To examine the local site effect, the microtremor measurement was conducted at the site. Figure 6 shows the overall response of the measurement system which is almost constant with ground velocity up to 2 seconds. As shown in Fig. 7, the H/V spectral ratio of microtremor has peaks at periods of 1 and 1.5 seconds. During the measurement, a small aftershock record was observed by chance. Figure 8 shows the aftershock record, indicating the predominant period of 1 to 1.5 seconds.

The surface soil of Concepcion consists of sand, and the estimated depth to the bedrock is 100 m or more. Table 1 shows the estimated velocity profile (Nicolau del Roure et al. 1980). The shear-wave velocity of surface soils is about 200 m/s. Figure 9 shows the computed amplification factor from the soil model, showing the predominant period of 1.5 sec.

Table 1 Soil Profile Model (Nicolau del Roure et al. 1980)

		ρ	

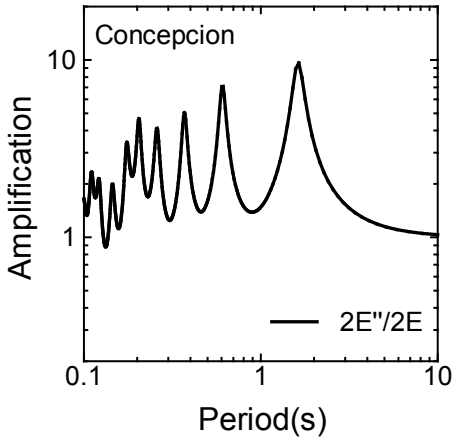

Figure 9 Computed Amplification Factor

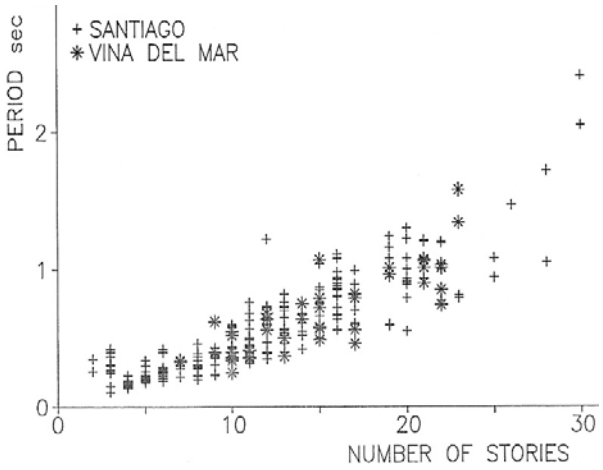

Figure 10 Number of Story vs. Period of Buildings from Ambient Vibration Test (Midorikawa 1990)

The results of the microtremor, the aftershock record and the computed amplification factor show strong local site effects at the site. In the results, the strong peaks are commonly found at periods of 1 and 1.5 seconds. The periods are 40 to 50 percents shorter than those in the strong motion records. As the period during strong shaking will be longer due to nonlinear soil response, the predominant periods of the strong motion record can be explained by local site effects.

In the city, more than seventy buildings suffered severe damage (Municipality of Concepcion 2010). High-rise buildings with 15 to 20 stories seem to be prominent in the damaged buildings. Figure 10 shows the relationship between the story number and vibration period of RC buildings from the ambient vibration test in Chile (Midorikawa 1990).

The period of the 15 to 20 story building which is prominent in the damage building seems 0.5 to 1 sec. at the ambient motion level. At the strong motion level, the period becomes longer due to nonlinear building response, suggesting that resonance of the building response with ground motion may have occurred during the earthquake. Importance of seismic microzoning studies is reconfirmed to evaluate local site effects for damage assessment in urban areas.

5. CONCLUSIONS

The 2010 Maule, Chile earthquake (Mw8.8) produced many strong motion records. Among them, an accelerogram observed at the downtown of Concepcion where many high-rise buildings suffered severe damage, has large amplitude and longer period contents. The pseudo velocity response spectrum has peaks at periods of 1.5 and 2 seconds, and the amplitudes are very high such as about 350 cm/s at period of 2 seconds. The predominant periods of the strong motion record correspond to those of the microtermor, the aftershock record and the computed amplification factor, suggesting strong local site effects. The periods also coincide with the vibration periods of high-rise buildings which suffered severe damage. This suggests that resonance of the building response with ground motion may have occurred during the earthquake. Importance of seismic microzoning studies in urban areas is reconfirmed.

Abstract: Recent studies have shown that the proper treatment of ground-motion variability and, particularly, the correlation of ground motion are essential for the estimation of the seismic hazard, damage and loss for distributed portfolios. We analyzed the effects of variations in parameters of the correlation components on such estimations using Taiwan area as the example. A scenario earthquake modeling, probabilistic seismic hazard assessment (PSHA), and a portfolio containing a set of hypothetical building and bridges were used for the purpose. We showed that the impact of ground-motion correlation on seismic loss and damage estimation depends on level of hazard and probability level of interest (return period). On the other hand, the relative influence of each type of correlation (between-earthquake and spatial correlations) is not equal. Thus, for practical estimations we should emphasize the following. If information on correlation models is not available, it is necessary to obtain upper and lower bound estimates by assuming the extreme characteristics of correlations (the perfect correlation and the uncorrelated ground motion). If the difference between the bound estimates cannot be neglected, one should make correspondent assumptions about the correlation based on reported models and results of their application.

1. INTRODUCTION

During last decade an increasing attention has been focusing on studies of ground-motion correlation. The term is related to similarity of ground-motion aleatory variability, or residuals between observations and results of modelling, during different earthquakes and different locations. The proper treatment of ground-motion correlation, which contains the between-earthquake and the site-to-site (spatial) components, is essential for the estimation of seismic hazard, damage and loss for widely located building assets (portfolios) and spatially distributed structures (lifelines).

Several studies analyzed the influence of ground-motion uncertainty and correlation on characteristics of loss distribution considering particular scenario earthquakes (e.g. Lee et al. 2004; Lee and Kiremidjian 2007; Molas et al. 2006; Goda and Atkinson 2009; Crowley et al. 2008; Sokolov and Wenzel 2010) and multiple events in probabilistic hazard and loss analysis (e.g. McVerry et al. 2004; Wesson and Perkins 2001; Park et al. 2007; Goda and Hong 2008, 2009).

The parameters of ground-motion correlation may vary over wide ranges, and it is still necessary to analyze the relative influence of the variation on estimations of aggregated loss for a portfolio (widely located constructions of several types) and on characteristics of joint hazard and damage. Sokolov and Wenzel (2010), using a single (scenario) earthquake, compared the effects of variations in parameters of the between-earthquake correlation and in the spatial (site-to-site) correlation on the seismic loss and damage estimations for hypothetical portfolio and critical elements of a network. In this work we perform similar sensitivity analysis for a case of multiple earthquakes, i.e. for the case of probabilistic seismic hazard assessment (PSHA) and loss estimations. Taiwan Island has been chosen as the test case for this study because of relatively high seismicity and previous experience in earthquake hazard modelling, which can be used as the source of necessary data and for comparison of results. Seismic hazard model has been constructed and probabilistic seismic hazard and loss analysis has been performed using Monte Carlo technique.

2. GROUND MOTION CORRELATION

It has become common practice to separate the total ground-motion aleatory variability into two independent components, namely, the earthquake-to-earthquake (between-earthquake) variability and the site-to-site (within-earthquake) variability. The between-earthquake variability results from event-specific factors that have not been included in the predictive model. The within-earthquake variability is determined mostly by peculiarities in the propagation path and local site conditions,

The ground-motion parameter Y at n locations during m earthquakes is represented by

$$\log Y_{i,j} = f(e_i, p_{i,j}, s_{i,j}) + \eta_i + \varepsilon_{i,j} \quad (1)$$

where e_i denotes variables that are properties of the earthquake source; $p_{i,j}$ are the properties of propagation path; $s_{i,j}$ are the properties of site location j during earthquake i; and f is a suitable function that describes the dependence of the mean value of ground-motion parameter $\overline{Y}_{i,j}$ on the magnitude, distance, local site conditions, etc. The random variables η_i and $\varepsilon_{i,j}$ represent the between-earthquake and within-earthquake components of variability (independent and normally distributed with variances σ_η^2 and σ_ε^2), respectively. The value of η_i is common to all sites during a particular earthquake i, and the value of $\varepsilon_{i,j}$ depends on the site. Assuming the independence of the two random terms, the total aleatory variance σ_T^2 is given by $\sigma_T^2 = \sigma_\eta^2 + \sigma_\varepsilon^2$.

The between-earthquake correlation of earthquake ground motion, or the similarity of ground-motion variability during different earthquakes, is determined by the relation between the components of variability (Wesson and Perkins 2001):

$$\rho_\eta = \sigma_\eta^2 / \sigma_T^2 = \sigma_\eta^2 / (\sigma_\eta^2 + \sigma_\varepsilon^2) \quad (2)$$

At the same time, two close sites may exhibit correlation of ground-motion residuals during an earthquake due to the commonality of wave paths (within-earthquake site-to-site correlation), which depends on the site separation distance Δ. The site-to-site (or spatial) correlation function $\rho_\varepsilon(\Delta)$ is usually represented as

$$\rho_\varepsilon(\Delta) = \exp(a\Delta^b), \quad (3)$$

where a and b are the region-dependent coefficients. The so-called "correlation distance" R_C may be considered a characteristic of the correlation (Wang and Takada 2005). The correlation distance shows the site-to-site distance for which the correlation coefficient $\rho_\varepsilon(\Delta)$ decreases up to 1/e = 0.368. For earthquake i and site j, the total correlation in $\varepsilon_{i,j}$ values is the following (e.g. Park et al. 2007):

$$\rho_T(\Delta) = \rho_\eta + \rho_\varepsilon(\Delta)(\sigma_\varepsilon^2 / \sigma_T^2) \quad (4)$$

.

The modern ground-motion attenuation equations (e.g. New Generation Attenuation models, NGA) allow the recognition of the between-earthquake correlation, because the equations include specification of the between-earthquake and within-earthquake components of variability (e.g. Douglas 2003, 2006; Abrahamson et al. 2008). The site-to-site correlation should be empirically evaluated for a given area. A dense observation of records from numerous earthquakes is necessary for analysis of the site-to-site correlation structure; therefore, such correlations investigated only for areas of dense strong-motion network: California, Japan and Taiwan (see review of recent studies in Sokolov et al. 2010). Analysis of the site-to-site correlation in Taiwan, which has been performed by Sokolov et al. (2010), revealed that the correlation structure is highly dependent on the local geology (see Figure 1), as well as on peculiarities of the propagation path (azimuth-dependent attenuation).

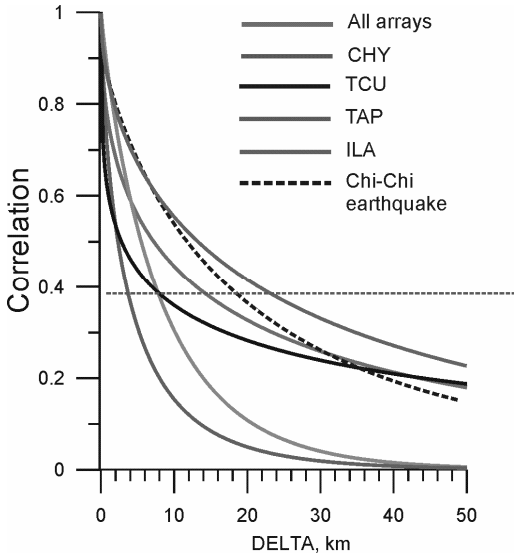

Figure 1. Site-to-site intra-event (spatial) correlation functions $\rho_\varepsilon(\Delta)$ estimated for particular strong-motion arrays in Taiwan using the data from moderate-to-large earthquakes ($M_W > 6.0$) in Taiwan (Sokolov et al. 2010). CHY array – thick sediments; TCU array - stiff soils in extended hilly areas; TAP array - triangular asymmetric alluvium-filled Taipei basin; ILA array - Quaternary alluvial Ilan basin. The data from all arrays were used for the case of the Chi-Chi earthquake. Red dashed line show the level of 1/e = 0.368.

3. ESTIMATION OF SEISMIC HAZARD

3.1 The Approach

In this work we applied the Monte-Carlo approach (e.g. Ebel and Kafka 1999) for seismic hazard and loss assessments. This approach, as it has been stated by Bommer and Crowley (2006), is consistent with the real nature of ground-motion variability. The large numbers of earthquake scenarios that are compatible with the seismicity model are triggering to sample the magnitude and spatial distribution of seismicity, as well as the distribution of ground motion for each event as defined by the aleatory variability. Each scenario generates a random combination of input parameters from their respective distributions, giving one possible model solution. This process is repeated many times, generating alternative model solutions. As the number of iterations increases it is possible to estimate the probability distribution function of the model solution. The approach

is suitable as a method for studying correlated hazard or so-called 'joint hazard' at various points of spatially distributed systems, (e.g. Rhoades and McVerry 2001).

The seismic source model describes as completely as possible, both spatially and temporarily, the process of earthquake occurrence in a region. The Monte Carlo process is used for generation of synthetic catalogues. Each synthetic catalogue represents a version of what could occur in the way of earthquakes in that region in the next years that would be consistent with past behaviour. Each epicenter within the source zone is determined randomly accepting that any location within the source zone has an equal probability of being the epicenter of the next earthquake. The depth of the given earthquake source is also generated randomly. The magnitude value is determined randomly against the magnitude-frequency distribution for that source zone.

For each generated event in the synthetic earthquake catalogue, ground-motion parameter at selected sites is calculated using (a) the appropriate ground-motion prediction equation and (b) two random draws from the standard normal probability distribution: the between-earthquake variability for the earthquake and the within-earthquake variability at each site (Bommer and Crowley 2006; Crowley and Bommer 2006). For a given earthquake, the influence of the between-earthquake variability will be the same through the region of interest, whilst the influence of the within-earthquake variability will be different at each site. The spatial correlation is also considered. From observation of the seismic effect of a very large number of simulations, probabilities can be calculated by merely counting the number of results exceeding a critical value.

3.2 The Input Data

Tectonic setting and seismicity of Taiwan are described in detail elsewhere (see, for example, review in Tsai et al. 1987; Campbell et al. 2002; Cheng et al. 2010). In this study we considered only crustal seismicity (earthquake depth less than 35 km) and we accepted the source zonation scheme given by Loh and Jean (1997) (Figure 2). Seismicity in each zone was analyzed separately to determine the magnitude frequency parameters in the form of linear Gutenberg-Richter law. Obviously, it is not possible to assume that parameters of seismicity sharply change at borders of the zones and a smoothing procedure is applied. A uniform distribution for earthquake depth has been accepted in calculations.

The ground motion-prediction equation for the calculation was used in the following form, which was recently proposed for Taiwan (Sokolov et al. 2010):

$$\ln PGA = -3.07 + 0.83M_W - 1.33\ln[R + 0.15\exp(0.54M_W)] + 0.0023R \pm \sigma_T \quad (5)$$

where PGA is measured in units of g, and R is the hypocentral distance in km. In our analysis we jointly consider both the components of aleatory variability (between-earthquake and within-earthquake) and the site-to-site (spatial) correlation. The total standard deviation σ_T is considered as a magnitude-dependent quantity assuming. gradually decreasing σ_T from 0.66 (M_W 5.0) to 0.50 (M_W 8.0).

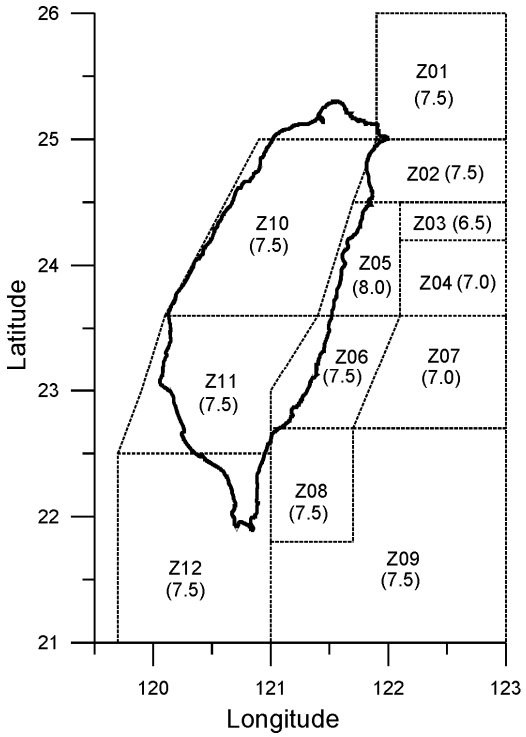

Figure 2. Source zonation scheme (Loh and Jean 1997). Values of maximum magnitude are shown in parentheses.

3.3 Modelling of Correlated Ground Motion

The following models of spatial correlation are applied (see also Sokolov and Wenzel 2010). First, we used the following values of between-earthquake correlation $\rho_\eta = \sigma^2{}_\eta / \sigma^2{}_T$: 0.09, 0.31, and 0.50. The correlation distances R_C, which characterize the spatial correlation (equation 3), vary from 5 km to 30 km. The accepted ranges of between-earthquake correlation and spatial correlation may be treated as reliable because they correspond to the observed values (see review in Sokolov and Wenzel 2010). We also consider the extreme cases, where all the variability is between earthquakes (all-between, $\sigma_\varepsilon = 0, \rho_\eta = 1.0$); where all the variability is within earthquakes (all-within, $\sigma_\eta = 0, \rho_\eta = 0.0$); and a case of spatially uncorrelated ground motion (no-spatial), for which coefficient of spatial correlation $\rho_\varepsilon(\Delta)$ equals to zero for all separation distances Δ > 0 km, and $\rho_\varepsilon(\Delta) = 1$ for Δ = 0 km. The all-between case corresponds to application of conventional PSHA (Cornell 1968), in which the ground-motion variability is implicitly assumed to be entirely between-earthquake component (e.g. Bommer and Crowley 2006).

When modeling the correlated ground-motion field, in addition to the median value $\overline{Y}_{ij}$, we need to generate the standard normal variates (errors) of η_i and $\varepsilon_{i,j}$.

The dependence structure among the variates is described by the total correlation coefficients (equation 4) and the correlation matrix Σ. The correlation matrix Σ is defined as follows:

$$\Sigma = \begin{pmatrix} 1 & \rho_{12} & \cdots & \rho_{1k} \\ \rho_{21} & 1 & \vdots & \rho_{2k} \\ \vdots & \vdots & \vdots & \vdots \\ \rho_{k1} & \rho_{k2} & \cdots & 1 \end{pmatrix} \quad (6)$$

where ρ_{ij} is the correlation coefficient calculated for the sites separated by a distance Δ. Descriptions of the procedure for generation of *k*-site random field of ground-motion error values that are spatially correlated may be found in many sources (e.g. Johnson 1987; Park et al. 2007). The generation consists of the following steps. First, a vector of independent standard normal variates **U**= [U_1, U_2, …., U_k] with standard deviation σ_T, or **U** ~ $N_k(0, \sigma_T^2)$, is generated. Then, a correlation matrix Σ is constructed and a Cholesky decomposition is applied to represent the correlation matrix Σ as the matrix product of matrix **B** and its transposition $\mathbf{B}^T$, i.e., $\Sigma = \mathbf{B}\,\mathbf{B}^T$. The required vector **X** is obtained as **X=BU**. These X_j values are added to the median ground-motion term $\overline{Y}_{ij}$ to obtain a realization of spatially correlated ground motions. Figure 3 shows examples of modeled ground-motion residuals for two models of spatial correlation.

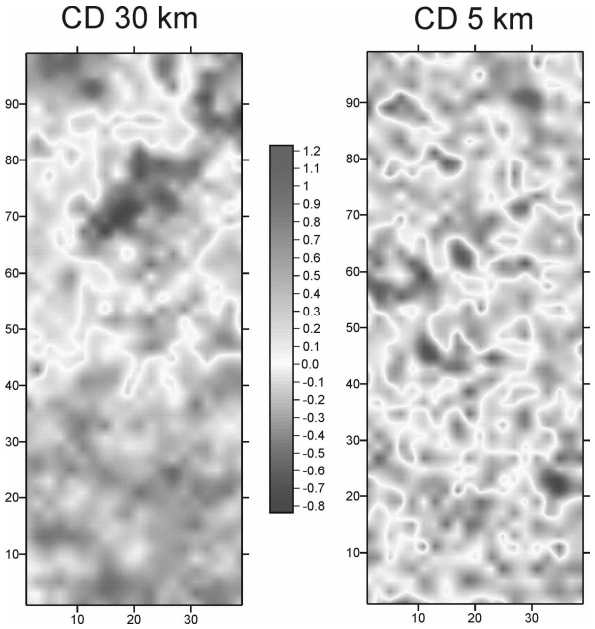

Figure 3. Examples of distribution of spatially-correlated ground motion residuals (natural logarithm of g – acceleration of gravity) modeled for two values of correlation distance (CD)

3.4 Results of Probabilistic Seismic Hazard Assessment

Monte Carlo technique was used to generate 1000 stochastic 2000-year catalogues of earthquakes with magnitudes $M_W \geq 4.75$; each catalogue contains more than 17500 events. One ground motion random field (PGA) was generated for each earthquake using the selected correlation model. The hazard rates, i.e., the annual probability of exceedence of PGA values at the individual sites were computed from the statistics of the simulated earthquakes. Figure 4 shows PGA map for 475-year return period (i.e. 10 % probability of exceedence in 50 years) and hazard curves for particular sites – large cities: Taipei, Taichung, Hualien, Chiai, and Taitung.

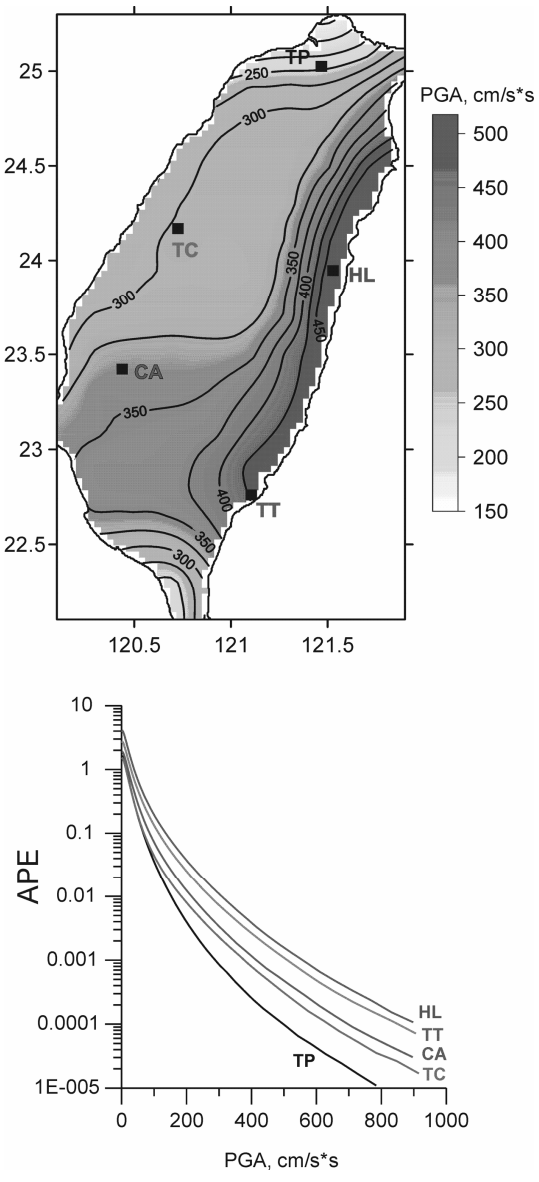

Figure 4. PGA scheme for return period of 475 years. The hazard curves (annual probability of exceedence of PGA values) are shown for sites Taipei (TP); Taiching (TC), Hualien (HL), Chiai (CA), and Taitung (TT).

The PSHA map, which is based only on the regional sources, reveals that the hazard level increases from the northwest to the southeast and southwest; the hazard is highest along the eastern coast of Taiwan. Our results show a good agreement with the previous assessments, which were performed using the Cornell's (Cornell 1968) approach (e.g. Sokolov et al. 2001; Campbell et al. 2002; Cheng et al. 2007, 2010).

Some applications require assessing the probability that a specific event will occur during certain condition at least once or that several such events will occur simultaneously. For example, there may be an interest in knowing whether the vulnerable elements of a lifeline network (e.g. bridges, local substations of power supply network, etc.) are likely to be simultaneously affected by shaking of sufficient strength to disable them or at least one element will be damaged causing the failure of the system (e.g. Rhoades and McVerry 2001; McVerry et al. 2004). To analyze such cases, we considered a few models of sites distribution with different distances between the sites. An example is shown in Figure 5a.

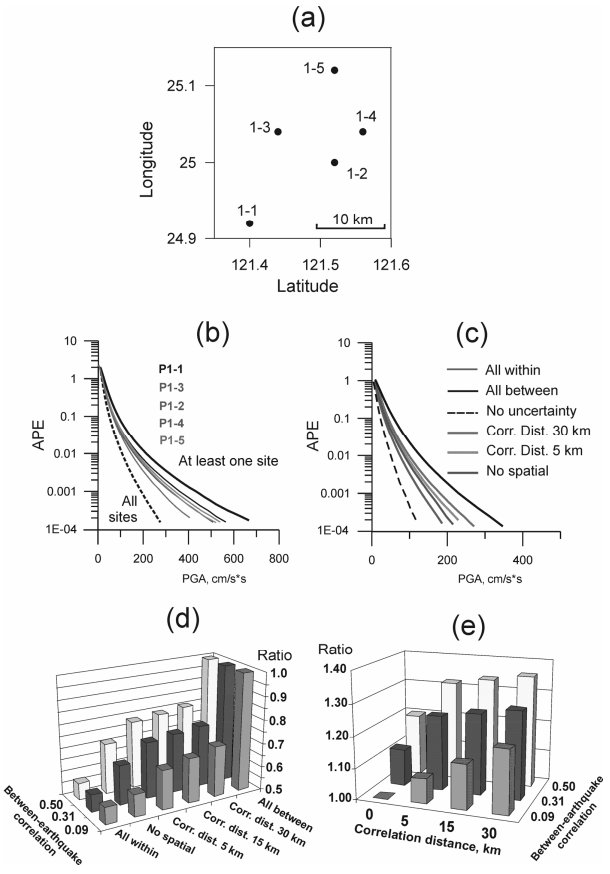

Figure 5. Analysis of joint hazard, Taipei area (low hazard). (a) The model of sites distribution. (b) Comparison of hazard curves, between-earthquake correlation $\rho_\eta = 0.31$. (c) Joint exceedence, influence of spatial correlation, $\rho_\eta = 0.31$. (d, e) Relative influence of the correlation components on joint exceedence. The base value (*see text*) corresponds to Ratio = 1.0.

The examples of hazard curves, i.e. the annual probability of exceedence of a given PGA threshold for the considered sites separately, for at least one site, and for all sites simultaneously (joint hazard), are shown in Figure 5bc (Taipei area). As can be seen from Figure 5b, the return period for joint exceedence (all sites) is larger than the return periods for the individual sites. At the same time, the return periods for the individual sites are larger than the return period for the at least one exceedence. The assumptions of all-between-earthquake (ABE) variability and all-within-earthquake (AWE) variability, depending on the case of interest, provide upper and lower bound estimates (see also Rhoades and McVerry 2001; McVerry et al. 2004). For at least one exceedence, the relative changes between the bound estimates, i.e. ratios AWE / ABE, do not exceed 20 %, while for joint exceedence the difference between the bound estimates vary between 80 % and 100 % (Figure 5d).

Influence of the spatial correlation, parameters of which vary within considered realistic ranges, is shown in Figure 5c. The influence may be characterized by relative changes of ground-motion parameter (PGA) for particular annual probability of exceedence (APE), or by changes of APE for particular PGA threshold, when varying the correlation components. Here we used the first variant (same APE, changes of PGA) and analyzed the changes comparing with a base value, which corresponds to the case of smallest considered between-earthquake correlation ($\rho_\eta = 0.09$) and spatially uncorrelated ground motion ($R_C = 0$ km, no-spatial).

For the at least one exceedence, the changes in characteristics of between-earthquake correlation ρ_η and the site-to-site correlation $\rho_\varepsilon(\Delta)$ reveals only a slight influence on the PGA estimations for particular annual probability of exceedence. When considering joint exceedence, variations in the correlation distances R_C , as well as variations in the between-earthquake correlation ρ_η , would considerably change the PGA estimations (Figure 5e).

On one hand, the combined effect of variations in the correlation components depends on return period (annual probability of exceedence), i.e. the relative changes increase with the increase of return period. On the other hand, the relative impact of the particular correlation component taken alone (i.e. only between-earthquake correlation or only site-to-site correlation) is the largest in the case of the smallest correlation coefficient of the other component.

As expected (see also McVerry et al. 2004), a set of closely located sites is characterized by the higher frequency of joint exceedence of a given PGA threshold than a set with relatively large distance between sites. In general, the probability of at least one exceedence is approaching the probability of joint exceedence, while the distance between considered sites is decreasing. However it should be noted that this effect has been observed in our study for the case of areal source zones.

3. ANALYSIS OF LOSS AND DAMAGE

For loss analysis we selected the areas of 10 km x 10 km at the location of Taipei (low hazard) and Hualien (high hazard) cities (see Figure 4). The areas were divided into cells of 1 km x 1 km and the random values of ground motion parameter were calculated for the centers of the cells. On one hand, the increase of resolution (or the decrease of the cell dimensions) would increase the calculation time. On the other hand, the dimensions of a cell should be much lower than the smallest considered correlation distance (R_C 5 km) in our analysis. Bal et al. (2010) analyzed the influence of the geographical resolution of the exposure data on the variability of loss estimations. They showed that the results of loss estimation are relatively insensitive to the spatial resolution of the building stock for exposure at grid sizes less than 2 km x 2 km. It has been supposed that all cells contain the same number of hypothetical buildings, which are typical for Taiwan (Liao et al. 2006), namely: steel-braced frames of four to seven stories.

In this study, we use the methodology, which is based on fragility functions (e.g. HAZUS, FEMA 2003), for loss estimation. A fragility function defines the exceedence of a damage state for a given level of ground shaking. Five damage states are considered: None, Slight, Moderate, Extensive and Complete. The probability of being or exceeding a damage state DS_i is modelled with a cumulative lognormal distribution- Details of the procedure, definitions and assumptions are described in Sokolov and Wenzel (2010).

The development of damage-loss functions for various types of structures is a demanding task. Such conversions have been performed using the regional damage ratio models based either on (a) Modified Mercalli intensities that were calculated directly (McVerry et al. 2004) or estimated from the PGA values (Molas et al. 2006), or on (b) pseudo-spectral acceleration (Park et al. 2007; Goda and Hong 2008). To minimize the effects of errors in the estimation of the replacement cost, we did not consider the conversion of damage to monetary loss. The mean cost ratio (MCR) was calculated in our study by integrating the results of calculation for every particular building.

Examples of loss exceedence curves, i.e. the annual probability of exceedence (APE) of a given mean cost ratio (MCR) threshold, are shown in Figure 6a. The assumptions of all-between-earthquake (ABE) and all-within-earthquake (AWE) variability provide upper and lower bound estimates of MCR values. The difference between the estimates depends on level of hazard and on annual probability of exceedence (return period). For example, the results obtained for low hazard area (Taipei) and for return periods less that 300 years showed a negligible difference between the extreme variants of correlation. For return period 475 years, the difference (ratio ABE / AWE) is about 1.60 for the Taipei area (low hazard) and 1.90 for the Hualien area (high hazard). Obviously, the ratio should depend also on the type of considered constructions (e.g. seismic design level).

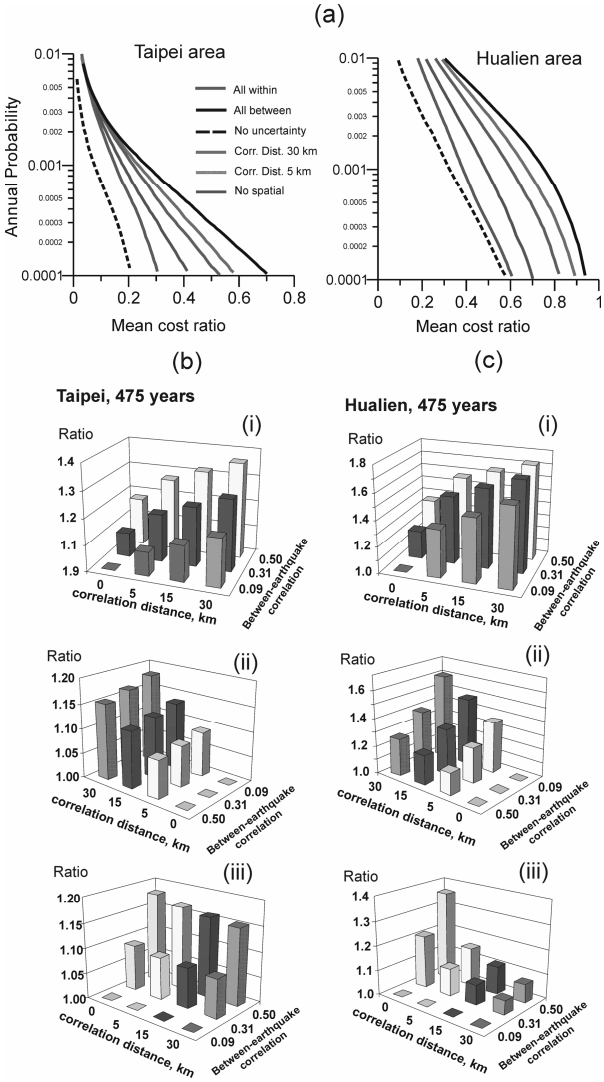

Figure 6. Mean damage ratio, influence of correlation components. (a) Loss exceedence curves, between-earthquake correlation $\rho_\eta = 0.31$. (b, c) relative influence of the correlation components. (i) combined influence; (ii) influence of spatial correlation; (iii) influence of between-earthquake correlation.

The MCR values estimated for particular return periods may vary over wide ranges when considering different characteristics of the between-earthquake correlation and the spatial correlation. Figures 6b and 6c show quantitative description of the MCR variations relative to the base values. First (Figure 6bc-i), the base value has been assigned to the smallest considered between-earthquake correlation ($\rho_\eta = 0.09$) and spatially uncorrelated ground motion (R_C = 0 km). The variations in the loss estimations due to a combined influence of the between-earthquake correlation and the spatial

correlation may be as high as 35% for area of low hazard (Taipei) and 75% for area of high hazard (Hualien).

Second, we separately compared the variations of loss estimations caused by to spatial correlation $\rho_\varepsilon(\Delta)$ alone (Figure 6bc-ii) and by to between-earthquake correlation ρ_η alone (Figure 6bc-iii). On one hand, the relative impact of the particular correlation component taken alone (i.e. between-earthquake correlation or site-to-site correlation) also depends on the level of hazard, i.e. the impact is larger for the high-hazard area (Hualien) than that for the low-hazard area (Taipei). On the other hand, the relative impact of the particular correlation component is the largest in the case of the smallest correlation coefficient of the other component.

As the example, let us consider Hualien area, return period 475 years (Figure 6c). The full-scale variations in the between earthquake correlation (i.e. ρ_η from 0.09 to 0.5) would increase the MCR values by 35 % in the case of no spatial correlation (R_C = 0 km) and by less than 10 % in the case of considerable spatial correlation (R_C = 30 km). Correspondingly, the full scale variations in the spatial correlation (i.e. R_C from 0 km to 30 km) would increase the MCR values by almost 60 % in the case of smallest between-earthquake correlation ($\rho_\eta = 0.09$) and by 22 % in the case of largest between-earthquake correlation ($\rho_\eta = 0.5$).

We also analyzed the case when it is necessary to estimate probability (return period) that several critical elements of a network (e.g. bridges) would be damaged simultaneously (joint damage) or at least one element would be damaged causing the failure of the system. For this purpose, we considered a system of three bridges located within the high-hazard territory (Hualien area). Two models of location of the bridges were constructed, which are characterized by different distances between the bridges (Figure 7a), namely: the model B1, distances vary from 10 km to 14 km; the model B2, distances vary from 2.1 km to 2.3 km.

The classification of typical bridges in Taiwan is given by Liao and Loh (2004), and we used the Type 4C bridge (Table 1 in Liao and Loh 2004). The damage level was accepted as equal to or greater than 20% of the replacement cost (damage ratio 0.2). The expected time of bridge outage for this damage level (extensive damage) is between 3 weeks and 3 months (Mander 1999). Details of the procedure, definitions and assumptions are described in Sokolov and Wenzel (2010). Note that here we did not consider uncertainties arising from the damage factor (Stergiou and Kiremidjian 2006) and correlated damage states conditioned in ground motion (Lee and Kiremidjian 2006).

Figures 7b and 7c show estimations of return periods for the cases when at least one bridge will be damaged (Figure 7b) and all bridges will be damaged simultaneously (Figure 7c). For at least one damaged bridge, the possible variations (within realistic range) in the correlation components may be neglected. When considering joint damage (Figure 7c), variations in the correlation distances R_C, as well as variations in the between-earthquake correlation ρ_η, would considerably change the estimations of return period. The assumptions of all-between-earthquake (ABE) variability and all-within-earthquake (AWE) variability provide the lower and the upper bound estimates. The relative changes between the bound estimates, i.e. ratios ABE / AWE are about 14 times and 18 times for the models B1 and B2 correspondingly. As expected, the system of closely located bridges (model B2) is characterized by the smaller return period of joint damage than the system (model B1) with relatively large distance between sites.

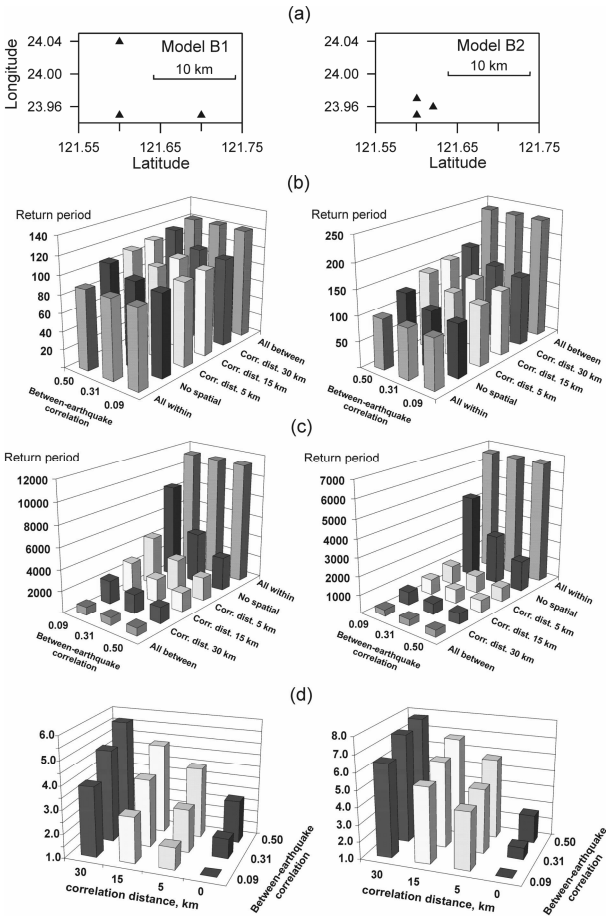

Figure 7. Analysis of joint damage for a set of bridges (Hualien area) considering influence of the correlation components. (a) The models of bridges distribution. (b) Damage of at least one bridge. (c) Damage of all bridges (joint damage). (d) Influence of the correlation components on return period of joint damage.

The relative influence of the correlation components on the return period of joint damage (Figure 7d) has been analyzed by comparison of the estimations with the base value, which corresponds to the case of the smallest considered between-earthquake correlation ($\rho_\eta = 0.09$) and spatially uncorrelated ground motion (R_C = 0 km). On one hand, the realistic full-scale variations in the

correlation components may lead to considerable alterations (up to 6-8 times) in estimations of return period. On the other hand, the site-to-site correlation plays more important role in the estimations than the between-earthquake correlation, especially for the case of closely located bridges (model B2). Thus, when analyzing joint damage for a set of closely located critical elements of a network, the possible variations in the between-earthquake correlation may be neglected if the spatially correlated ground motions are used.

3. CONCLUSIONS

A model for probabilistic seismic hazard and loss estimation using Monte Carlo approach has been developed for Taiwan region. The model is based on previous experience in earthquake hazard modeling in the region. The framework has been used for sensitivity analysis of the impact of variation of characteristics of ground-motion correlation components on probabilistic estimates of seismic loss and damage for extended objects (hypothetical portfolio) and critical elements (e.g. bridges) of a network. It has been recently found that, on one hand, consideration of a realistic correlation model of seismic excitation is especially important in seismic loss estimation and that, on the other hand, the parameters of ground-motion correlation may vary over wide ranges.

The results of the modeling show that the proper consideration of (a) the between-earthquake correlation and (b) the parameters of spatial correlation is essential for the estimation of seismic losses for distributed portfolios. Both types of ground-motion correlation affect the probability of joint damage of critical components and the characteristics of loss distribution for a portfolio. The peculiarities of the influence were analyzed and are described in literature. In our work, we showed that, on one hand, the impact depends on level of hazard and probability level of interest (return period), and that, on the other hand, the relative influence of each type of correlation is not equal. Obviously, characteristics of the analyzed portfolio or parameters of critical elements of a network (e.g. seismic design level of construction and mutual location of elements) may be of considerable importance.

Thus, supporting and extending the conclusions and recommendations made, for example, by Rhoades and McVerry (2001) and Goda and Hong (2008), we should emphasize the following. If information on correlation models is not available, first, it is necessary to obtain upper and lower bound estimates by assuming the extreme characteristics of correlations (the perfect correlation and the uncorrelated ground motion). Second, if the difference between the bound estimates cannot be neglected, one should make correspondent assumptions about the correlation based on reported models and results. However it is necessary to bear in mind that the spatial correlation of ground motion, in principle, depends on the chosen ground motion model. On the other hand, the correlation structure depends on the local geology as well on peculiarities of the propagation path (azimuth-dependent attenuation) (e.g. Sokolov et al. 2010). Thus, a single generalized model of spatial correlation may not be adequate for large areas.

We realize, of course, that there are several limitations of our study. Our findings have been obtained using the areal model of seismic zones without consideration of influence of linear (fault) sources. Proximity to the active faults may considerably affect the results of hazard and loss estimation. We did not consider epistemic uncertainty in all inputs to the assessment, which usually is incorporated using the logic tree approach. The damage analysis in our study was based only on peak ground acceleration, and it included some arbitrary assumptions about the parameters of fragility curves. Obviously, for practical calculations requiring the estimation of the absolute values of loss, these simplified assumptions have to be reconsidered.

Abstract: Prediction of the response spectra for the strong motion on seismic bedrock based on an attenuation relationship is very important for the earthquake mitigation and the nuclear power plant safety. So far, since the data are rarely derived on seismic bedrock, it remains many difficulties to develop an attenuation relationship on seismic bedrock directly. In this study, we have developed a response spectra database on seismic bedrock include the following data: (1) Data directly estimated from the recordings derived at the vertical array at KiK-net stations at which the bottom seismograph is located on seismic bedrock with Vs over 2km/sec; (2) Recordings derived at hard rock sites in RK-NET and dam sites; (3) Near source data estimated using the substructure model and an equivalent linear method for records at K-NET and KiK-net sites. Based on this database, we developed a new attenuation relationship for response spectra on seismic bedrock, including the near source records. This paper presents the preliminary results of the development of the attenuation relationship.

1. INTRODUCTION

Prediction of the response spectra for the strong motion on seismic bedrock based on an attenuation relationship is very important for the earthquake mitigation and the nuclear power plant safety. So far, since the data are rarely derived on seismic bedrock, it remains many difficulties to develop an attenuation relationship on seismic bedrock directly.

In this study, we develop a response spectra database on seismic bedrock include the following data: (1) Data directly estimated from the recordings derived at the vertical array at KiK-net stations at which the bottom seismograph is located on seismic bedrock with Vs over 2km/sec; (2) Recordings derived at hard rock sites in RK-NET and dam sites; (3) Near source data estimated using the substructure model and an equivalent linear method for records at K-NET and KiK-net sites. Based on this database, we develop a new attenuation relationship for response spectra on seismic bedrock, including the near source records. This paper presents the preliminary results of the development of the attenuation relationship.

2. DATA

We choose 28 earthquakes, with Mw over 5.5 and 3 or more records per event on hard rock are obtained, to establish the new attenuation relationship for response spectra on bedrock, among the 47 events we collected. There are 13 crustal earthquakes, 6 inter-plate earthquakes, and 9 intra-plate earthquakes in the database. Table 1 show the earthquakes used in this study. The moment magnitude ranged from 5.5 to 8.3. Figure 1 shows the histogram of the earthquake type and plot of moment magnitude vs. the focal depth.

The strong motion data used in this study are derived at stations in KiK-net, K-NET, and F-NET by National Research Institute for Earth Science and Disaster Prevention (NIED), RK-NET by Central Research Institute of Electric Power Industry (CRIEPI), and the dam observation stations by Japan Commission on Large Dams (JCOLD), National Institute for Land and Infrastructure Management (NILIM) and the Miyagi prefecture. Only the data recorded or estimated on hard rock are used.

For the strong motion derived by KiK-net, the stations at which the bottom seismograph located on the bedrock where Vs >2km/s are selected for estimating the strong motion on bedrock. Generally, the strong motion observation system at stations in KiK-net is a vertical array observation system, at each station, seismograph installed both on the ground surface and on the bottom of the borehole. In this study, the stations at where the bottom of the borehole reaches the bedrock with shear wave velocity over 2 km/sec are selected as the candidate stations for the

estimation of strong motion. For the purpose, we firstly identified the properties of the soil materials in the borehole by fitting the transfer function defined as the ratio of the Fourier spectra of the seismic wave recorded at ground surface and the bottom of the borehole. Then the strong motions on bedrock are estimated from the records on ground surface of the borehole. Almost all the records from KiK-net are derived by using this method. Figure 2 shows the example of the result of the identification of material of the borehole and the estimated strong motion on seismic bedrock.

Finally, for the 28 target earthquakes, 521 records on bedrock are derived. For the near source area, however, since the data derived are not sufficient, 27 records with a fault distance under about 20km are used by evaluating the site effects between the seismic bedrock and ground surface based on an equivalent linear method, while the velocity structure are derived from the database by NIED.

In the database, the distance definitions used in this study are fault distance and the equivalent hypocentral distance (EHD). In this paper we only show the results for horizontal component and fault distance

Figure 3 shows the distribution of M_w and fault distance of the records in our database. From this figure, many near field strong motion can be confirmed in our database

3. REGRESSION MODEL

3.1 Attenuation model for deep earthquake

Midorikawa and Ohtake (2002) proposed a model with a different attenuation rate for shallow and deep earthquake. For understanding the physical base of the above model, we performed a numerical simulation to check the attenuation rate for shallow and deep earthquake. The simulation is summarized as follows.

(1) *Method*: a 2D FDM is used for the simulation. Simulation model is designed as a 300km in horizontal direction (X axes) and 90km in vertical direction (Z axes), divided by meshes with size of 0.1km by 0.1km. The velocity structure used in the simulation is JMA2001 model, which is a standard model used to determine source location of the earthquakes occurred in Japan. Figure 4 shows the distribution of Vp and Vs of JMA2001 model.

(2) *Target earthquake*: An Mw6 reverse earthquake is assigned as the target earthquake. Depths of the earthquakes are set to 10km, 20km, 50km and 70km. a simple triangle source function with a duration of 1 sec is used in the simulation. Seismic waves are calculated at receivers with distances ranged from about 10km - 280km.

(3) *Results*: Figure 5 shows the attenuation rate of PGV for the four scenario earthquakes. From the figure, the different attenuation rates at far stations are confirmed between the shallow earthquakes (focal depth of 10km and 20km) and the deep earthquakes (50km and 70km). This result suggests the different attenuation rate should be included in the regression model.

3.2 Model used in this study

As discussed above, the following model is adopted as the regression model in this study. For coefficient of C and k, since no sufficient data for the estimation, we adopt the values used by Si and Midorikawa (1999).

$$
\begin{aligned}
&\log SA(T) = b(T) + g(X) - kX + \varepsilon(T) \\
&b(T) = a(T)M_w + \sum d_i(T)S_i + h(T)D \\
&g(X) = \left\{ \begin{array}{l} -\log(X + C);\ D \le 30km \\ 0.6\log(1.7D + C) - 1.6\log(X + C);\ D > 30km\ \&\ X \ge 1.7D \end{array} \right\} \\
&C = 0.0055 \cdot 10^{0.5M_w},\ T < 0.5s \\
&= 0.0028 \cdot 10^{0.5M_w},\ T \ge 0.5s \\
&k = 0.003,\ T < 0.5s \\
&= 0.002,\ T \ge 0.5s
\end{aligned}
\qquad (1)
$$

Where, SA(T) shows GMTRotI50, an average response spectra proposed by Boore et al. (2006) for horizontal components, and response spectra for vertical components. X shows fault distance or EHD. D shows the focal depth, S_i is a category variable, shows the earthquake type defined as crustal, inter- and intra-plate earthquake, the same as that used in Si and Midorikawa (1999). In this paper, we only show the results for GMTRotI50 and the fault distance.

4. RESULTS

We performed a two-step regression analysis. Firstly b (T) is decided; then regression on a (T), d_i (T), and h (T) simultaneously. For the periods longer than 5s, only the earthquakes with Mw over 6 are used. The weighting schemes are as follows: 8 for distance ≤ 25km; 4 for ≤50km; 2 for ≤ 100km. For events: 8 for No. of records ≥ 30;4 for ≥ 20; 2 for ≥ 10.

Figure 6 shows the coefficient derived in this study. From the figure, a (T), the coefficients of Mw increase with period T, and the coefficients d_i (T) for intra-plate generally decrease with T, these represents the common knowledge about the effects of seismic source on ground motion, implicating the results are reasonable. The coefficient of focal depth, h (T), varies in the range of 0.003 to 0.009, also show reasonable results by comparing with the previous studies, e.g., for PGA or PGV.

Figure 7 shows the comparison of the most important coefficient a (T), with recent previous studies. From the figure, the results in this study show almost the same values as the others, e.g., Uchiyama and Midorikawa (2006), Kanno et al. (2006). This implicated that, the results in this study are reasonable.

Figure 8 shows examples of the predicted response spectra by using our new model. The response spectra are calculated under the following condition: a crustal event, at a fault distance of 20km; Mw of the target earthquakes are 6, 7 and 8. From the results, it can be confirm that, (1) the amplitudes increase with Mw; (2) corner frequency increases with Mw too. Generally the predicted response spectra are considered as reasonable.

5. CONCLUSIONS

In this study, we construct a database of response spectra on seismic bedrock. Based on the database, we derived a new attenuation relationship of response spectra on bedrock. The standard deviation is considerable small. Comparison with other studies show our results are consistent with the recent previous studies, implicating our model is reasonable.

Acknowledgements:

The authors acknowledge supported by the Research Found from an incorporated administrative agency, Japan Nuclear Energy Safety Organization. The strong motion data is provided by the KiK-net, K-NET and F-NET by NIED, RK-NET by CRIEPI, Dam records by JCOLD, NILIM, and the Miyagi prefecture. Figures are plotted by Plots. Part of the regression analysis is performed using the R language. The authors thank Professor Tatsuo Ohmachi, Dr. Yoshiaki Shiba, Dr. Shojiro Kataoka, Dr. Changjiang Wu, Dr. Hiroyuki Yamada for their fruitful suggestion. The thanks also go to Akihiro Sawaii, Toshio Kuriyama, Dr. Reiko Tajima and the other colleagues in KKE for their great help.

ON THE EFFECTIVE EARTHQUAKE EARLY WARNING SYSTEMS FOR BOTH DISTANT AND NEAR EVENTS

Yutaka Nakamura

President, System and Data Research, Tokyo, JAPAN
Visiting Professor, Dept. of Built Environment, Tokyo Institute of Technology, Yokohama, JAPAN
yutaka@sdr.co.jp

Abstract: This paper describes the truly effective early warning systems with simulated results for disaster prevention against distant and near events. And the role of national or public organizations in earthquake disaster prevention will be discussed.

1. INTRODUCTION

It is clear that the basic countermeasure against earthquake strong motion is to reinforce buildings and other structures. However, even enough counter-measured facilities against expected strong motion un-expecting accidents may be occurred. Against the un-expecting accidents, the earthquake early warning system, *UrEDAS*, Urgent Earthquake and Detection and Alarm System, was developed 25 years ago. At first the system was adopted for the Seikan under-sea-tunnel as an earthquake information system in 1988, and then fully operated for safety of the Tokaido Shinkansen from 1992. After that we are developing and improving our systems on the experiences of the Kobe earthquake and etc., as the technical innovation group for the EEW, Earthquake Early Warning. As the results of our activities, *FREQL*, Fast Response Equipment against Quake Load, was developed. At the start of the *UrEDAS* operation, the processing time of warning was three seconds after the P-wave detection. Now the processing time of *FREQL* is shortened to 0.1 second in minimum. This shortened processing time makes possible to issue a quick alarm over one second leading for large motion against even an under earthquake. Although this time margin is very short, it is expected that significant effects will be generated for facilities operated under the ultimate situation as the bullet train or the elevator system of high-rise buildings. The ultimate EEW system as *FREQL* is useful for rescue activities just after the earthquake damage to prevent the second disaster by large aftershocks.

In 1992 Nakamura's Group of *RTRI*, Railway Technical Research Institute, proposed a project of *UrEDAS* network with 2000 stations not only for earthquake disaster prevention, but also for working as a node of communication network when natural disaster occurred. In 1992, TV news of NHK, Nihon Hoso Kyoukai (Japan Broadcasting Corporation) announced that a trial operation of EEW information service for Tokyo metropolitan area with UrEDAS information will start in 1993. But this project was not realized mainly because of objection of *JMA*, Japan Metrological Agency. *JMA* started the similar project in 2005 using a system developed by themselves. In this paper, not only the EEW of Japan, but also the present state of the information for earthquake disaster prevention will be described.

2. CONCEPT OF EEW

There are two kinds of earthquake alarms as illustrated in **Figure 1**. One is the "On-Site Alarm" which is an alarm based on observations close to the objects to be warned. The other one is the "Front Alarm" which is an alarm based on observations near the epicentral area, which is then used for the warning in possible damage areas away from the epicenter. Because the latter alarm concept requires the use of communication networks, it is also sometimes called

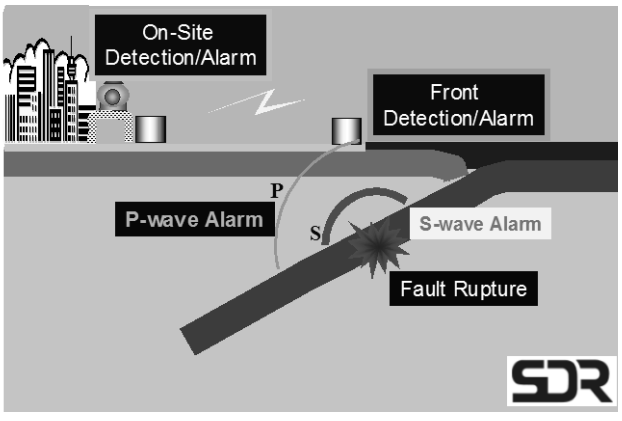

Figure 1 Concept of an EEW system

"Network Alarm". Both alarm types described can make use of two different triggers, also called "alarms". One is the trigger/alarm exceeding a preset level, the so-called "S-wave Alarm" or "Triggered Alarm"; the other one is the trigger/alarm during the preliminary motion, the so-called "P-wave Alarm".

3. *UrEDAS*

The idea of disaster mitigation by the EEW depends on the progress of science and technology during 19 and 20 centuries. Earthquake is a vibration caused by the results of the crust destruction. Although the earthquake prediction obviously brings numerous benefits to the disaster prevention, this kind of destructive phenomena is a stochastic phenomenon and is impossible to predict its occurrence with enough accuracy and reliability applicable to disaster prevention. Instead of the prediction the EEW is close up for disaster prevention.

The idea to minimize the direct effects of earthquakes by developing an early warning system was first published by Dr. J. D. Cooper (1868) with the aim of earthquake disaster prevention in San Francisco. It is interesting for me that he describes the idea of EEW based on the failure of the Japanese earthquake prediction method using a magnet at an earthquake in 1868. After Cooper various similar ideas has been proposed, but Cooper's and the other ideas were never realized and then basically forgotten.

About 100 years after Dr. Cooper's publishing, independently a similar idea was born from an idle talk at a tea time of an university laboratory. This is the detection system before 10 seconds for Tokyo metropolitan area proposed by Dr. Hakuno et al (1972). At the same time, many institutions and agencies including *JMA* started to research a possible EEW based on the existing automatic earthquake observation system consisting of a network of many monitoring stations.

JNR, Japanese National Railways, had also started to research possible EEW based on the same concept as *JMA*, while Nakamura at the *RTRI* of *JNR*, started to develop a different concept in 1979, using only a single station. He completed the prototype *UrEDAS*, pronounced "Yuredasu" meaning "shaking begins" in Japanese. This was the first actual P-wave detection and alarm system worldwide and was published in Nakamura (1984).

The main *UrEDAS* functions are the estimation of magnitude and location, vulnerability assessment and issuing warnings within a few seconds using initial P-wave motion at a single station. Unlike other automatic seismic observation systems, *UrEDAS* does not have to transmit the observed waveform in realtime to a remote processing or centralized system and is therefore comparatively simple. *UrEDAS* calculates parameters such as back azimuth, predominant frequency for magnitude evaluation and vertical to horizontal ratio for discrimination between P and S waves, using the amplitude for each sample in realtime. These calculations are processed in realtime without storing waveform data. The amount of processing of *UrEDAS* is almost constant regardless of whether or not an earthquake is occurring, so the number of computational processes does not increase in the event of an earthquake. Then UrEDAS does not cause any system down after big earthquake.

UrEDAS can issue its alarm based on the *M-Δ* diagram in **Figure 2** immediately after the earthquake detection. The *M-Δ* diagram is derived from past damage experience to JNR facilities and equipment and aids in decreasing the number of false or needless alarms. This kind of alarm is referred to as the *M-Δ* Alarm. *UrEDAS* can also assist in decisions to safely restart train operations based on the detailed earthquake parameters.

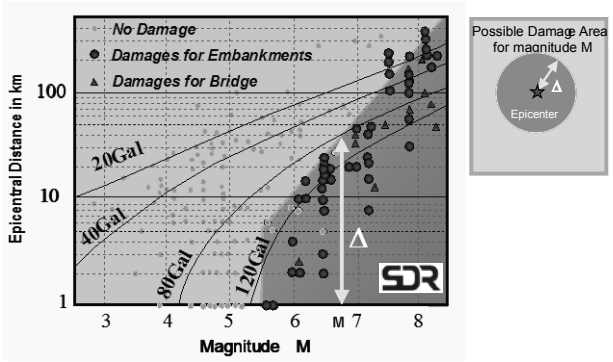

Figure 2 M-Δ diagram

After an initial testing period, the development of *UrEDAS* for routine use was completed and trial operations for the protection of the Shinkansen line, the bullet train, in central Japan were carried out commencing in 1990. These trials led to the implementation of some additional capabilities and functionality of *UrEDAS*. In 1992, *UrEDAS* started routine operations with full functionality for the Tokaido Shinkansen line (Nakamura, 1996). These *UrEDAS* issue a P-wave warning with a processing time of just three seconds after detecting the P-wave.

Other organizations, such as *JMA*, continued their research and development but without implementing operational systems. This made *JNR* the only agency to implement an operational and functioning actual warning system in the 20th Century.

4. THE 1995 KOBE EARTHQUAKE AND *Compact UrEDAS*

After the 1995 Kobe earthquake, it was recognized that an even shorter warning time would lead to even more effective realtime disaster mitigation. To achieve this, *UrEDAS* was developed further with the aim of being able to issue warnings within about one second after the detection of a damaging earthquake. The resulting system was the *Compact UrEDAS* which became available in 1997 (Nakamura, 1998) and commenced routine operations for the Tohoku, Joetsu and Nagano Shinkansen lines in 1998.

In contrast to *UrEDAS* which estimates the destructiveness of the earthquake from the earthquake's parameters, *Compact UrEDAS* derives this from the earthquake motion directly 'in realtime' and then issues the

alarm, if required. To estimate earthquake dangerousness, the power density *PD* (W/kg) of the earthquake vibration is calculated from the inner product of the acceleration vector $\boldsymbol{a}$ (cm/s^2) and the velocity vector $\boldsymbol{v}$ (cm/s). As this value is a large number, it is normally expressed in terms of the Destructive Intensity (*DI*) defined as the logarithm of absolute value of this inner product (*LPD*, logarithm of the power density) as Eq. (1). The concept of *DI* is illustrated in **Figure 3**.

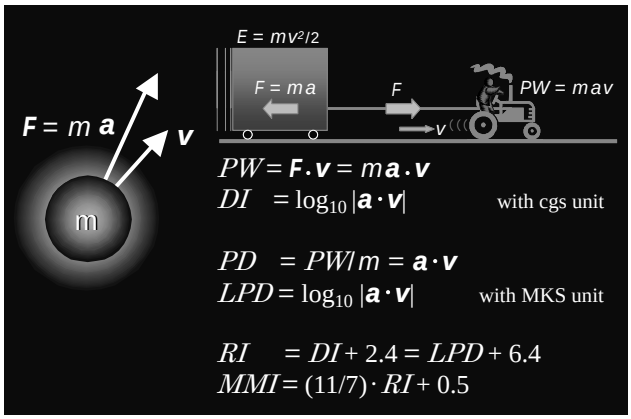

Figure 3 Relationship between various earthquake

$$DI = \log |\boldsymbol{a}\cdot\boldsymbol{v}| = LPD + 4.0 \qquad (1)$$

The maximum value of *DI* during an event, DI_{max} relates to the earthquake damage and is similar to the instrumental intensity scale of *JMA*, I_{JMA}, with the constant difference of 2.4, and corresponds to *MMI*, the Modified Mercalli Intensity. These indices are referred as *RI*, Realtime Intensity, and *MMI*, respectively.

$$RI = DI + 2.4 \qquad (2)$$
$$MMI = (11/7)RI + 0.5 = (11/7)DI + 4.27 \qquad (3)$$

I_{JMA} can only be calculated after earthquake termination according to its artificial definition without physical background. Contrary to this, *DI* is defined as the logarithm of Power Density multiplied by a constant. Power Density is a physical variable related closely to earthquake damage. *DI* can be calculated in realtime and its value increases immediately after the P-wave arrival. Because *DI* is sensitive to the P-wave arrival, it can be used to define a P-wave alarm. **Figure 4** shows the change of *RI* as a function of time with the acceleration waveform and the change of *SI*, Spectral Intensity. *RI* is more sensitive than both, the acceleration and *SI*, because the value of *RI* increases drastically at the P-wave detection, about one second prior to the other indices.

When the P-wave arrives, *RI* increases dramatically, followed by a further but slower increase until the arrival of the S-wave, by which time it reaches its maximum, called RI_{max}. The *PI*-value is defined as the maximum *RI* within *t* seconds after P-wave detection. This *PI*-value seems to be applicable as a trigger for the P-wave alarm. Furthermore, it is possible to estimate RI_{max} from the *PI*-value approximately.

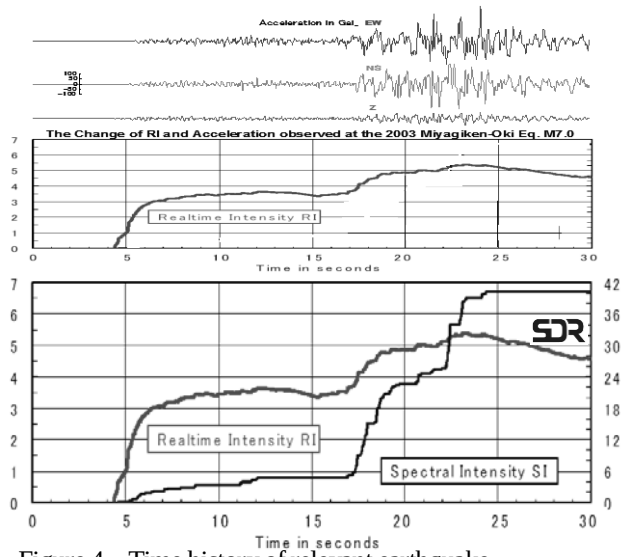

Figure 4 Time history of relevant earthquake

Because each facility has its own withstanding intensity level, each customer can determine the *PI*-value as the trigger of the P-wave alarm. In other words, with the continuous observations of *RI*, an earthquake alarm can be issued efficiently and the damage can be estimated reliably. In fact, the *PI*-value with its physical meaning of power related to destructiveness and dangerousness of the earthquake can thus be used for a P-wave alarm as realized in the *Compact UrEDAS* and *FREQL* (explained later in detail).

The function of the *Compact UrEDAS* is to issue an early warning for the area close to the instrument based on the risk of the detected earthquake motion, which is different from the alarm from the *UrEDAS* to the area of possible damage based on the estimated location and magnitude of the detected earthquake. The target area of the *UrEDAS* alarm is about 200 km around the location of the instrument, while that of the *Compact UrEDAS* alarm is only about 20km around the instrument. Thus, to maximize the effectiveness of the warning system, an ideal strategy is to use the *UrEDAS* (front alarm or network alarm) to respond to more distant large earthquakes and use the *Compact UrEDAS* (on-site alarm) to respond to nearby earthquakes.

5. EXAMPLE OF A SUCCESSFUL EEW BY *Compact UrEDAS*

The derailment of one Shinkansen train during the 2004 Niigata-ken Chuetsu Earthquake (M6.8) impressively demonstrated the effectiveness and benefits of the early warning system for Shinkansen train operations. The fact that there were no fatalities or injuries to the passengers and crew of the train is clearly a result of the availability of the early warning system. The circumstances and course of events of the derailment are described in the following. **Figure 5** shows a summary and timeline of the events.

The train line is built on many viaducts, and two of them with different characteristics are joined at 300m from

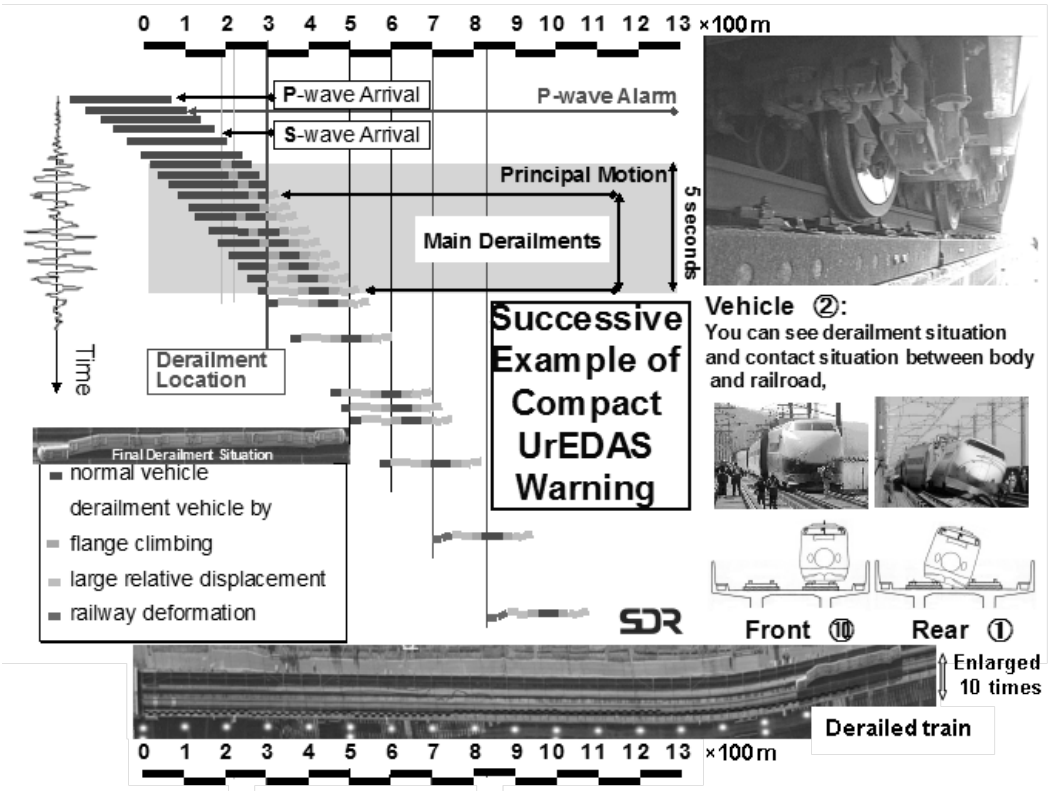

Figure 5 The Shinkansen Derailment during the 2004 Niigata-Ken Chuetsu Earthquake

the tunnel exit including the snow-shade (the 300m point hereafter). The earthquake effects on these viaducts were different from each other. When the train passed the 300m point, it is likely that the train derailed, because the joints in the rail tracks underwent different displacements.

The power supply to the train was interrupted by the P-wave alarm of the *Compact UrEDAS* installed at the substation (SS), 11km from the epicenter of the earthquake. The alarm was triggered about 2.5 seconds before the arrival of the S-wave at the location of the train. The large motion started one more second after that. So the P-wave alarm preceded the onset of the large motion by about 3.5 seconds. Without the automatically initiated emergency breaking triggered by the alarm the train would have arrived at the 300m point earlier and more vehicles would have passed that point during the large motion. With the very real possibility of the rails buckling while the train passed over them at great speed, this most probably would have caused a much more serious derailment destroying the rails completely which then might well have led to the train overturning.

If this happened to the lead vehicles, it could have been as catastrophic as the accident of the German ICE (InterCity Express) high-speed train in 1998 (Wikipedia). Consequently, although the derailment could not be prevented, this certainly illustrates the usefulness of the warning system impressively.

A subsequent simulation of the alarm behavior of a *FREQL* system using the recorded waveform showed that the train would have received the P-wave alarm another 0.8 seconds earlier, if a *FREQL* had been installed in Shin-Kawaguchi SS, because the *FREQL* would have issued the P-wave alarm already 0.2 seconds after the P-wave detection.

There are several more examples of successful warnings by *UrEDAS* or *Compact UrEDAS* in 1995, 2003, 2005 and as detailed in Nakamura and Saita (2007).

6. *JMA*'S EEW

In about the Year 2000, *JMA* started research on a single site detection system with the Railway Technical Research Institute. Their system concept was basically similar to the ideas behind the *UrEDAS*. However, in contrast to the *UrEDAS* which is a direct realtime system, the *JMA* development adopted an intermittent processing system by determining the necessary parameters using stored waveform data of several seconds duration to fit the estimated function. As such, *JMA*'s centralized system gathered information of each site and re-processed it using the stored information from many sites, and then issued an alarm, if necessary.

Therefore, *JMA*'s EEW can be regarded as a network-type alarm system that requires a normally functioning telecommunications network. Except for the cases of extremely deep earthquake events, the combination of processing time and telecommunication time (the time it takes for the observations to reach the central system) is too long to issue a meaningful alarm for the possible epicentral damaged area before the large earthquake motion from a nearby earthquake or an epicentral earthquake starts.

Therefore, this system is unable to issue a warning before the onset of the large earthquake motion at the damaged area. In some cases, the warning was even issued after termination of the earthquake motion. In the case of the 2008 Iwate-Miyagi-Nairiku Earthquake, for instance, it was impossible for the system to issue the warning for the damaged area.

7. ULTIMATE EEW SYSTEM: *FREQL*

The functions of *UrEDAS* and *Compact UrEDAS* were combined which not only reduced the size and weight of the system, but also improved its functionality. This development was completed in 2005 and given the name *FREQL*. In Japanese, *FREQL*, pronounced "furekkuru", means "wave coming". *FREQL* shortened the processing time required to issue an *UrEDAS* /P-wave alarm - based on the estimated earthquake parameters from three seconds (for *UrEDAS*) to one second. The previously minimum time for issuing a P-wave alarm based on the dangerousness of the detected earthquake motion by the *Compact UrEDAS* of one second was improved by the *FREQL* to just 0.2 seconds and further to 0.1 seconds in 2009. This enables *FREQL* to issue an alarm before a large earthquake motion even in the case of the epicentral area.

FREQL is not only very valuable in the detection of the initial quake, but is also used during rescue operations after the main shock by detecting, and warning for possible aftershocks. For instance, the Tokyo Fire Department Hyper Rescue Team pulled out a small child from underneath debris from a land slide during the 2004 Niigataken-Chuetsu Earthquake. After that they had contacted us for using *FREQL* to keep the safety of the rescue staff during the high risk of aftershocks. Based on their request, a portable version of the *FREQL* was developed in 2005, improving the system's capabilities further and making it more compact.

The Hyper Rescue Team examined *FREQL* not to cause false alarm because of the working heavy equipments. And also functional examination with the high quality three dimensional shaking table made skeptic person understand that *FREQL* should be useful for earthquake disaster prevention.

The portable *FREQL* is now in use by many fire departments nationwide, even accompanying international disaster rescue teams, such as to the 2006 Pakistan Earthquake and the 2008 Sichuan Earthquake, see **Figure 6**.

Figure 6 FREQL used by Japanese International Rescue Team at the Sichuan Earthquake

RI: Realtime Seismic Intensity.

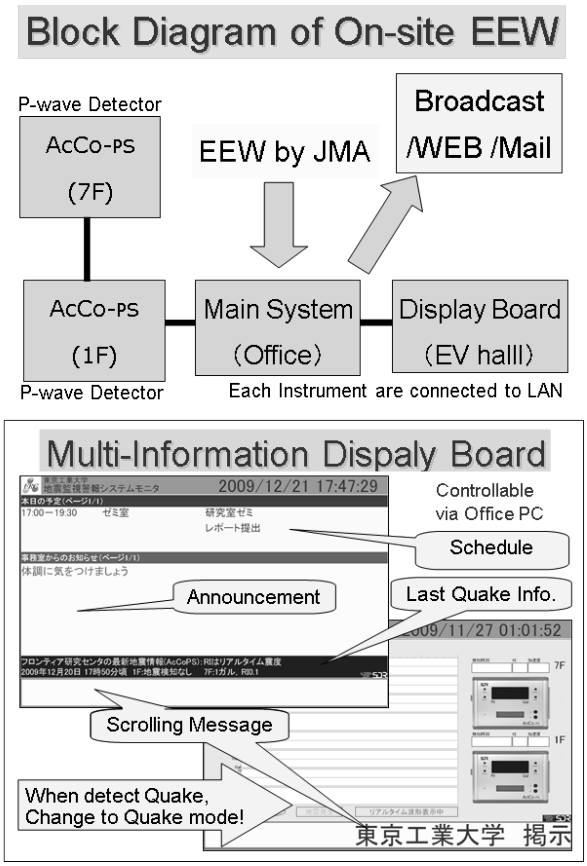

Figure 8 Block diagram of On-site EEW in Suzukakedai Campus of Tokyo Tech.

Rescue teams involved in the aftermath of the 2008 Iwate-Miyagi-Nairiku Earthquake also benefited greatly from the portable *FREQL*.

FREQL were used also in some private railway companies in Tokyo metropolitan area for EEW, and are testing now in a nuclear power plant, semiconductor facilities and so on. We expect in near future *FREQL* will be actively involved in plants and worksites to mitigate earthquake damage.

The alarm processing time of EEW Systems explained above is shown in **Table 1** and **Figure 7**, is the comparison of each EEW's functions.

Tokyo Institute of Technology has started operation of unique earthquake information system integrated with a display board. Normally this system shows general campus information with recent earthquake observed information. And if *AcCo-PS*, P-wave warning device with *FREQL* function, detects an earthquake, this system shows waveform and *RI* and *PGA* with frequency range between 0.1 Hz and 5 Hz (*5HzPGA*), see **Figure 8**.

8. SIMULATIONS OF *FREQL* ALARM

In this section simulated examples will be presented for damaged earthquakes; big near event, near event and huge distant event.

8.1. A Big Near Event

The 2008 Iwate-Miyagi-Nairiku Earthquake, M7.2 and 8 km depth, was occurred in north-east of Japan at 14th June 2008, around 8:43 of local time. This earthquake caused severe damage in the epicentral area, yet *JMA*'s EEW system was unable to issue an alarm before the start of shaking in the damaged area within approximately *25* km of the epicenter. **Figure 9** shows the time of the actual alarms issued by *JMA*'s EEW and compares them with alarms which an on-site *FREQL* system would have been able to issue, based on a simulation using the recorded waveforms. The depth of this earthquake was approximately 8km below the surface. The alarm from *JMA*'s EEW was issued *3.5* seconds after the event detection to the primary customer and one second later to the public, which is equivalent to about *10* seconds after the earthquake occurrence. Although the timing of the alarm in this case was faster than the averaged processing time of *5.4* seconds (see Figure 7), the

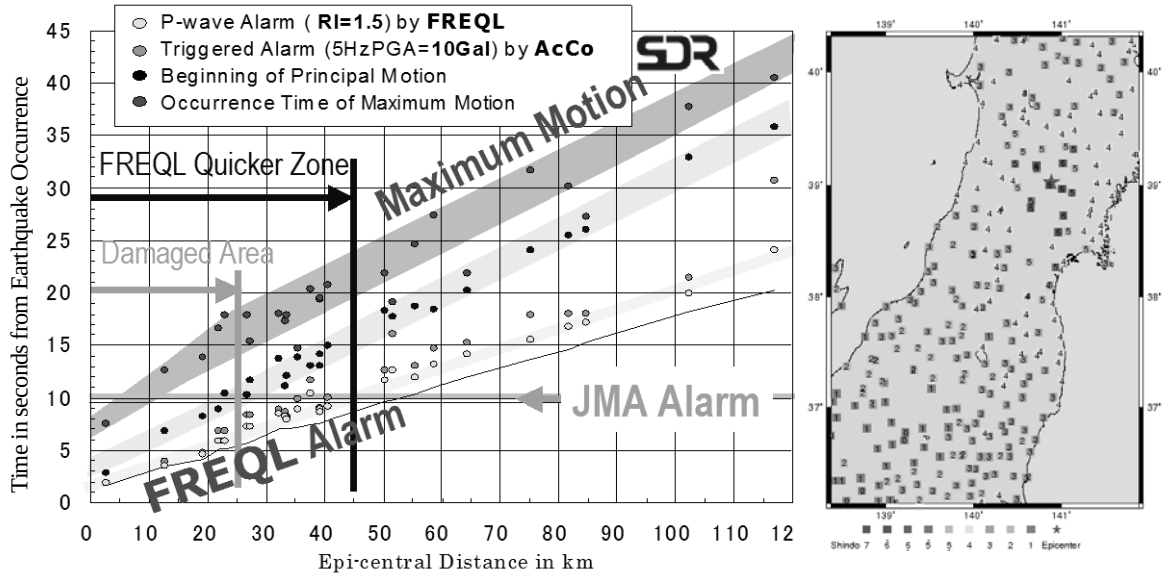

Figure 9 Comparison of EEW timing between JMA and FREQL/AcCo for the 2008 Iwate-Miyagi-Nairiku Earthquake

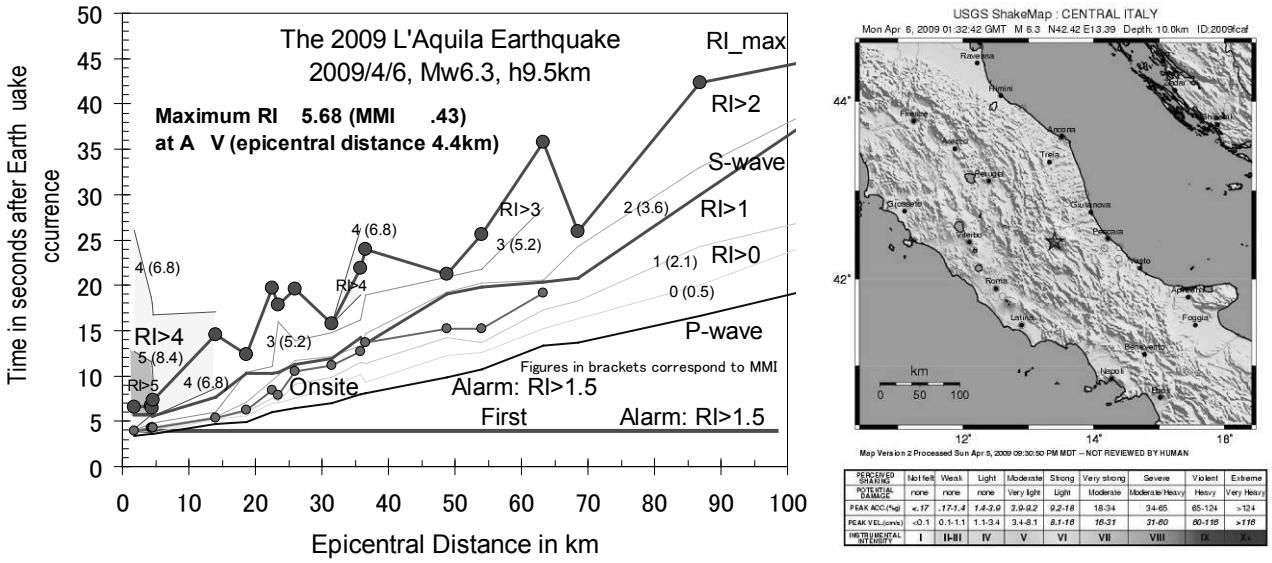

Figure 10. Timings of P wave arrival, FREQL warning, S-wave arrival and Maximum motion arrival: RI means Realtime Seismic Intensity; figures in brackets are corresponding to MMI.

warning was still only delivered after the beginning of the strong motion. In contrast to this, *FREQL* is expected to issue an alarm *0.2* seconds after the P-wave detection in the damaged area, i.e. the time margin before the beginning of the strong motion is several seconds, even at the epicenter itself.

In general, one can safely state that the on-site alarm issued by the *FREQL* is faster than that issued by *JMA*'s EEW within an area of about *50* km from the epicenter. For epicentral distances over *50* km, the on-site EEW of the *FREQL* is issued more than *10* seconds before the onset of strong motion. The average processing time of *JMA*'s EEW is *5.4* seconds, but to transmit the information from the detecting site to the processing center and the warning to the user will take some additional seconds. Typically, the transmitting time from the detecting site to the processing center, and from there to the users is estimated to be a total of around two seconds, increasing the time difference between receiving the warning from *JMA* and from *FREQL* even more. The experience of the 2008 Iwate-Miyagi-Nairiku Earthquake confirms this finding for locations with over 100km of epicentral distance. Until today, there has been no example where *JMA*'s EEW was able to effectively be used for disaster prevention by means of early warning

8.2. A Near Event-1

The 2009 L'Aquila Earthquake, M6.3 and 9.5 km depth, was occurred in central Italy at 6th April 2009. This earthquake caused severe damage in the epicentral area.

Figure 10 shows a result of simulation for the 2009 L'Aquila earthquake using strong motion records. According to this figure, FREQL was expected to get a few seconds as a leading time at even epicentral area. It is very short time, but during the leading time people could be evacuate into some sturdy desk before falling down the floor or the ceiling. It is needless to say that the most important measure is to build the structures enough earthquake-proof. Even after the reinforcement against the earthquake, because there is still risk on the falling objects, the repeated emergency drills are essential to acquire the image of the damage situation after the earthquake for the reasonable countermeasures. Anyway there is no system to issue the earthquake alarm quicker than on-site FREQL, so it is advisable to take proper countermeasures without exaggerating the effect of EEW.

8.3. A Near Event-2

The 2010 Jiansian Earthquake, M6.4 and 23 km depth, was occurred in mountain area of southern Taiwan at 4th March 2010, 8:18:52.14 of local time, according to the *CWB*, Central Weather Bureau. **Figure 11** shows distribution map of seismic intensity *RI* and *5HzPGA*. The strong motion was observed at the plane area apart from epicenter and damage was occurred in this area. This interested phenomenon was strongly reflected by the amplification of the sedimentary

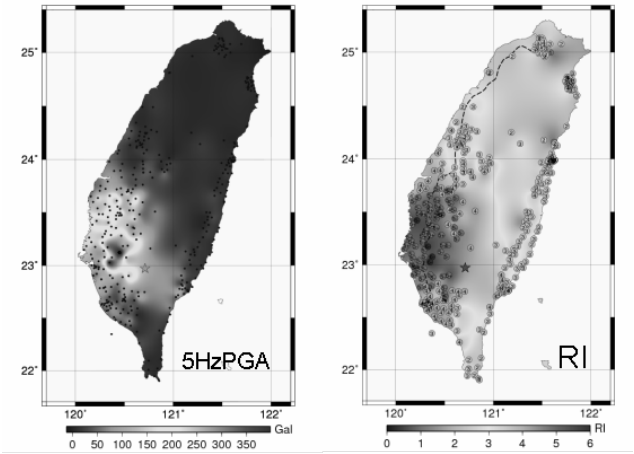

Figure 11 Distribution of Realtime Seismic Intensity and 5HzPGA of the 2010 Jiansian Earthquake, Taiwan

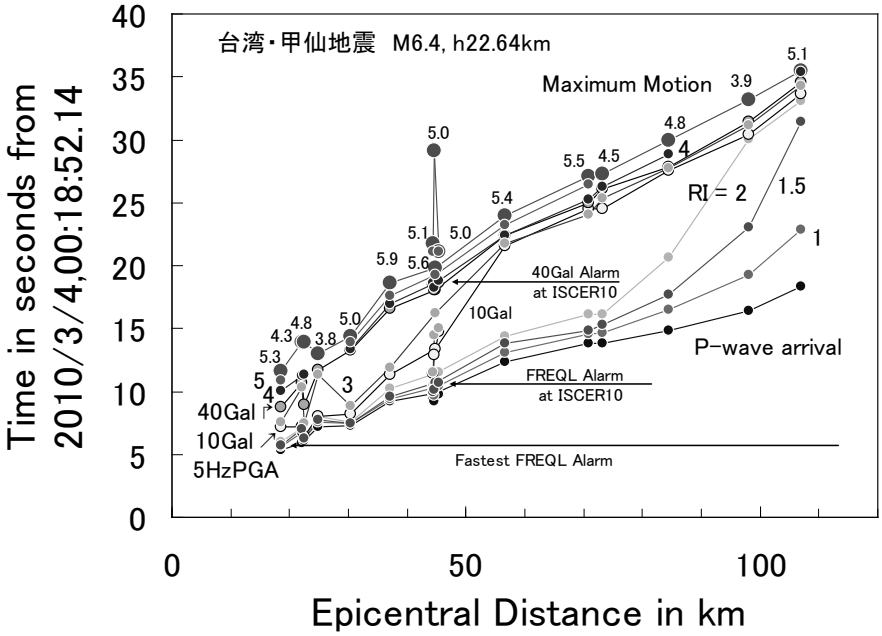

Figure 12 Simulation Result of FREQL Alarm for the Jiansian Earthquake

surface ground on the plane. In the area a running Taiwan Shinkansen train with 300km/h was derailed, but no injured passenger and no damage to the structures.

Figure 12 shows a simulation result of *FREQL* alarm using strong records of the *CWB* with changing of the *RI*. The 40 Gal alarm, which is a triggered alarm over 40 Gal of 5HzPGA, was issued at 8:19:10 to the derailed train. *FREQL* alarm should be issued at 8:19:02, 8 seconds earlier than the 40 Gal alarm. *FREQL* alarm issued *0.8* seconds after P wave detection proceeding to the strong motion with over *7* seconds. It is clear that the *FREQL* alarm proceeding to the strong motion with over three seconds at even the focal area.

8.4. A Huge Distant Event

A huge earthquake, Mw 8.8 and 47 km depth, with tsunami was occurred along the coastline of Chili in 27th February 2010, 3:34 of local time. **Figure 13** shows a simulated result using the waveform data set of Chili University. According to this the strong motion over *5* of *RI*, correspond to *8* of *MMI*, were maintained several tens seconds even at several *100* km apart from epicenter. This is the property of a huge earthquake of almost M_w *9*. The on-site alarm by *FREQL* in focal area will be issued just after P wave detection. In the area far from the epicenter, the on-site alarm by *FREQL* will be delayed from P wave detection. But the leading time proceeding to the strong motion over *4* of *RI*, correspond to *7* of *MMI*, were estimated as follows; over *7* seconds for the focal area and several tens seconds for distant area. Of course the leading time of a network alarm by *FREQL* will be longer, but the on-site alarm by *FREQL* will be present enough leading time needless communication facilities which often broken at big disaster occurrence.

9. WHAT INFORMATION IS REQUIRED FOR EARTHQUAKE DISASTER MITIGATION?

From the operational side, there are three pieces of information relevant to realtime earthquake assessment:

(1) an early warning before the onset of the strong shaking for the area of certain damage,
(2) information before the shaking starts about the area that will not be damaged, and
(3) a precise and detailed estimate of the location and extent of the area where serious damage can be expected.

The most important issue for public agencies is to have a reliable assessment as listed in Item (3) above, so that rescue activities in the damaged areas can be initiated immediately. For the public agencies it is impossible to deliver information as under Item (1) due to the long processing and communication times. Only on-site early warnings can deliver that information. In general, the early warning can only be used to trigger individual or locally based social group help or action. Governmental assistance will mainly focus on the rescue work in the seriously damaged areas evaluated by information as under Item (3). Information as under Item (2) has no relevance to damage, and is unnecessary information for disaster prevention. For most events, unfortunately, *JMA*'s EEW seems usually only capable to deliver information as under Item (2).

The warning must be delivered rapidly and be accompanied by information for a rational response to the event. The information as under Item (3) above is essential to decide on such actions. It is important to receive rapid and

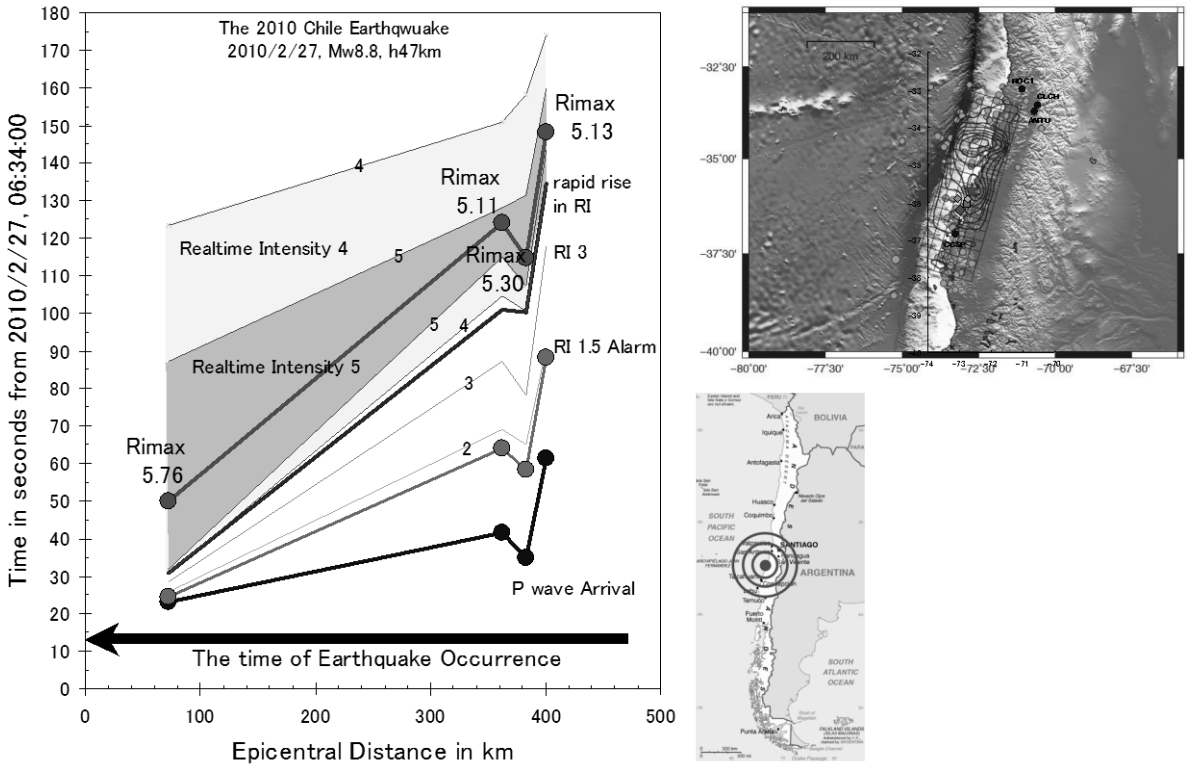

Figure 13 Simulation Result for the 2010 Chile Earthquake of Mw 8.8

accurate earthquake information from organizations such as JMA in Japan, but it is also important not to restrict the delivery of the information as under Item (3) from other organizations, such as local universities or Institutions.

As mentioned above, the best possible earthquake assessment (made in realtime) is essential information to specify the extent and location of the seriously damaged area, to enable the implementation of immediate and appropriate emergency response directly after the event. While earthquake observation systems designed for scientific research must be able to determine the exact location of the events, *UrEDAS* has deliberately been designed to estimate the earthquake parameter only in an approximate way to be able to issue the warning and the required response action in the shortest possible time.

Public organizations should deliver information on the earthquake parameters not only for the main shock but also for aftershocks as soon as possible. However, from the viewpoint of earthquake disaster prevention, it is more important to deliver accurate earthquake information as quickly as possible rather than to deliver a "late" early warning. For the most appropriate and quick response after the earthquake, the "actual observed" seismic motion as intensity, not an estimated value, is the most important information because the degree of damage can be estimated from it.

10. PROBLEMS IN THE DELIVERY OF EARTHQUAKE WARNINGS BY THE NATIONAL AUTHORITIES

If only one authority can issue warnings, all organizations and the general public must rely on it. This leads to the general public, as well as organizational managers develop the habit of waiting for the information from the authority instead of using some reasonable self-management for protection and mitigation. On the other hand, if other organizations are also permitted to issue warnings, all involved must be aware of that they do this on their own risk and must take full responsibility for their warnings and possible consequences.

If issuing warnings is based on a law or regulation, organizations and individuals responsible for issuing warnings develop a strong tendency to wait with the warning until the last moment (which may be too late). On the organizational level, promulgation of such warnings might be slowed down for fear of reprisals or bad reputation.

In Japan, this trend is quite obvious in the ways in which tsunami warnings or cautions are given. By law, only *JMA* is permitted to issue tsunami information in the form of an official tsunami warning. However, as it is commonly seen on TV news in Japan, the source of such tsunami information is not clear and in most cases, the accuracy of the information on which the warning is based is doubtful. This situation can lead to a considerable lack of reliability with many false warnings and cautions, commonly know as the "crying wolf syndrome".

It became very obvious that an *M7* class earthquake causes catastrophic damage especially in the area close to the epicenter. Although *M7* class earthquakes are quite common in Japan, it is a potentially fatal flaw in the warning system that the *JMA*'s EEW cannot issue a timely and accurate estimate of the large motion in the catastrophically

damaged area. If the early warning for the large motion is delayed too long (for whatever reason) it becomes meaningless.

For *M8* class events (which occur statistically once every several tens of years in Japan), the *JMA*'s EEW seems to be capable to issue a warning with a useful time margin for the strong motion. Yet such a warning is only useful, if it is readily available for the damaged area more than *50* km from the epicenter. This, however, might not be the case, because in such a serious situation it is quite possible that the information is lost or delayed by problems in the communication system. In contrast, an on-site alarm system is, by definition, not exposed to these problems and can issue a warning or alarm before the onset of the large earthquake motion.

On-site alarm equipment such as the *FREQL*, is capable to issue the alarm in as short a time as *0.1* seconds after the P-wave and can thus issue the warning before the onset of the large earthquake motion, even for locations close to the epicenter. If then a local FM radio station would broadcast the *FREQL* information, there would be a time margin for preventative action within the damaged area. Unfortunately, after December 2007, there is a hesitation for implementing of such a system because it might violate a law restricting the authority to issue warnings to *JMA*.

11. CONCLUDING REMARKS

Realtime earthquake warning was initially aimed at disaster prevention for the train system in Japan, but is by now used in many other environments as well. To be of wide-ranging benefit, the time margin of the warning must be very short on a time scale of seconds to enable quick action by the general public, such as to seek shelter (like under a sturdy desk) or to evacuate immediately to a pre-determined safety zone. The disaster prevention activity must be based on the actual seismic motion in the surrounding area, not an estimated one or one for some other location.

It is an open question whether or not an appropriate earthquake early warning system is in place in Japan today. Clearly, there has not been much discussion about this issue until today. It seems that the (so far futile) attempt to develop a reliable earthquake prediction system is getting much more attention than the fact that an effective and reliable earthquake early warning system is a reality and readily available.

It is clear that the primary preventative action by the people at the time of the earthquake is to keep away from places where they could be hit by falling or loose objects. To be able to do this obviously requires a timely and immediate warning to be issued.

The earthquake information including warning is not effective for disaster prevention to be provided exclusively as a national project. A warning cannot prevent the possible collapse of structures, but it can most definitely assist people evacuating from collapsing facilities. A prompt and reliable earthquake warning should become part of the daily life of the people in Japan. National organizations should be able to specify the area of expected catastrophic damage accurately and initiate rescue operations without delay based on information from responsible and capable organizations in realtime.

Acknowledgment:

The author wishes to thank Tokyo Fire Department for their cooperation in the implementation the systems: *FREQL*-based early warning system. The simulation described in this article used the waveform data from K-NET and KiK-net of NIED, National Institute of Earth Science for Disaster Prevention, Dr. Kai-Wen Kuo of the Central Weather Bureau of Taiwan and Mr. Jerry Li of Taiwan High Speed Rail Corporation. I wish to express my sincere thanks to all individuals that contributed to this paper.

Abstract: An evaluation of the seismic response of structures using SRSND simulator developed for compute damage ratio in terms of repair cost on housing at Pisco is presented. The simulator consider the implementation of a simple algorithm for compute the seismic response of a building base on material, story height, state of conservation of the building and irregularities. The damage is compute by comparison with a damage matrix based on test results and also post quake survey developed after Pisco quake on Pisco city. Also fragility curves results for the same city has been developed by the authors and is used as comparison parameter for evaluation of the SRSND simulator results. Good agreement between both results has been found. Therefore confidence in the use of the simulator as a tool to predict losses on cities after a quake is shown.

1. INTRODUCTION

On the estimation of seismic risk analysis of cities, there are different parameters used as output of the process. The more likely used is the damage cost or the cost of reposition of the damage structures. Other parameters are the probability of damage for deterministic type of structure, the amount of collapse housing by material type and others. The evaluation of each of the output parameters need the evaluation of probability approach or empirical regression analysis based on damage survey after the event. Each of these results is linked with earthquake acceleration on a characteristic soil. Therefore, the evaluation of the seismic response of a building and the determination of the damage level need the knowledge of the soil condition, probable acceleration on the site, material influence, number of stories of the building, basic geometry and other input parameters.

In this paper a seismic response simulator with damage level estimation (Simulador Respuesta Sísmica y Nivel de Daño SRSND in Spanish) is presented. This simulator is used as a tool to predict the cost of reposition for a damage level as a consequence of an input acceleration of the ground. The development of the simulator, the input data on for the model and the parameters used on the quake response are presented. Then the validation if the model is performed by comparison with field survey results and also fragility curves developed from the survey of Pisco city after August 15th 2007 earthquake.

2. ESTIMATION OF SEISMIC RESPONSE

For the estimation of the seismic response on an approximate method is developed based on the peak ground acceleration of the soil where the structure has been build. For that purpose seismic hazard of the location is used as a first input. Next a catalog of building types that represent the study zone is needed. Therefore a field survey for typify the buildings must be developed. On the survey several variables are consider: seismic demand acceleration, material of the building, number of stories, structural predominant system, state of conservation, irregularities of plant, height and shape. Then we use the methodology propose by Miranda, that use a series of βi index to produce the seismic response based on a product of βi by the spectral displacement (Sd) for the predominant period of the building, divided by the height of the building(H), to reproduce the maximum inter story drift during an earthquake:

$$\left(\frac{\Delta\delta_j}{h_j}\right)=\frac{\beta_1\beta_2.\beta_3\beta_4}{H}S_d$$

The index β1, is an modal participation factor approximation given as a function of the story number:

$$\beta_1=\frac{3N}{2N+1}$$

The index β2, is a ratio between the approximate maximum drift (calculate as SDOF system) against the drift on real system:

$$\beta_2=\frac{\max\left(\frac{\Delta\delta_j}{h_j}\right)}{\left(\frac{U_r}{H}\right)}$$

The index β3 is the reatio between the force response (F^x) with the over resistance of the structure (F) formulated as a function of the assign ductility (μ) for the type of structural system:

$$\beta_3 = \frac{U^x + \Delta U^x}{U} = \frac{F^x.\mu}{F}$$

The index β4 produce an approximation of the ratio between the inelastic drift and the elastic drift that provide an approximate measure of the ductility:

$$\beta_4 = \frac{\varphi_{inelastic}}{\varphi_{elastic}}$$

The estimation of the period of the structure is the base for this diagnosis, which is extremely dependant of the type of building and number of stories. Therefore the drift in each story can be approximate and by comparison of drift limits based on experimental approach, the estimation of damage level using a damage matrix will produce the reposition cost of the building.

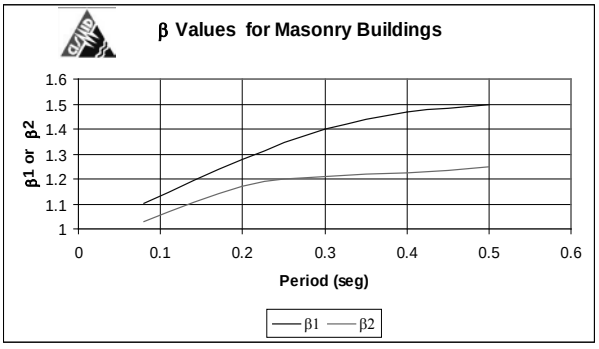

Figure 1: Values of β1 and β2 parameters

This procedure has been automated in our SRSND simulator to provide under a seismic scenario the estimation of the damage level of a city. For the βi values, multiple analysis of typical houses and ductility consideration has been calibrated with test results. Figure 1 shows the values of β1 and β2 for masonry buildings. Figure 2 presents the values of β3 factor as function of the period of the structural system considering assigned ductility (μ) of 6. Figure 3 presents the values of for β4 as function of the assigned ductility.

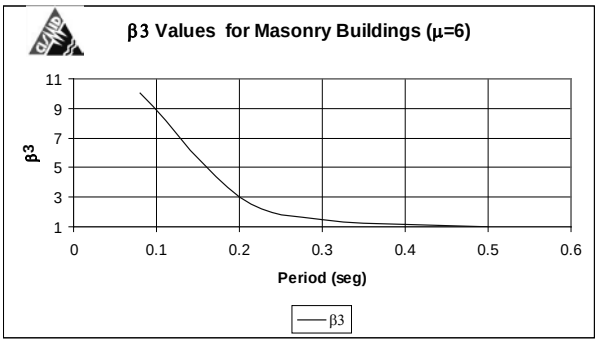

Figure 2: The β3 factor

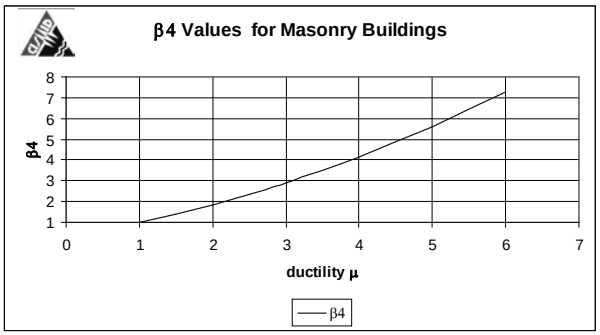

Figure 3: The β4 values as function of ductility

After the evaluation of the seismic response, the damage level can be computed using the following matrix:

Drift (Δδj/hj)	Damage Level	Occurrence
1/2000-1/1000	Non damage	none
1/800	Light damage	Initial crack
1/350	Severe damage	Diagonal open
> 1/200	Collapse	Non

3. VALIDATION OF SRSND WITH PISCO QUAKE FIELD SURVEY

On August 15th 2007 an earthquake of magnitude 8.0 Mw, stroke the south coast of Peru with epicenter at Latitude -13.49° and Longitude: -76.85° with depth of 26 Km. located 74 Km. west of Pisco city. The quake kill 593 persons, with 1,291 injured, and 48,208 collapse houses, and near 90,000 affected houses.

The authors with the support of professors and students of the Faculty of Civil Engineering of the National University of Engineering carried out a field survey on the Pisco city involved in the present report with the financial aid of Inter-American Development Bank (IDB) and World Bank (WB). Pisco city is located on the coast. However the damage characterization depends of the demand and also the site conditions where different kinds of soil profiles were found.

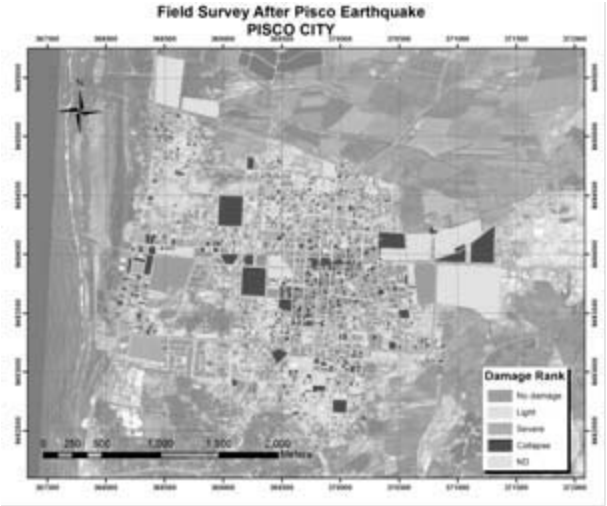

Figure 4: Results of Damage Survey in Pisco

Pisco has areas of soft soil represented by a mix of sand with gravel with high level of humidity and also a middle soil with gravel and compact sand. A campaign was developed to study Pisco city, to implement the damage characterization, and record the data on a GIS system.

Figure 4 presents the damage survey in Pisco city performed by CISMID. Here the red color represents the collapsed structures, in orange the severe damage buildings, in yellow slight damage and light green non damage structures.

Using the field survey data, the simulator SRSND performed the risk analysis results in terms of reconstruction cost using the damage matrix. Figure 3 and Figure 4 have a good agreement, showing that the simulator can emulate the response of the buildings and provide the cost of reconstruction.

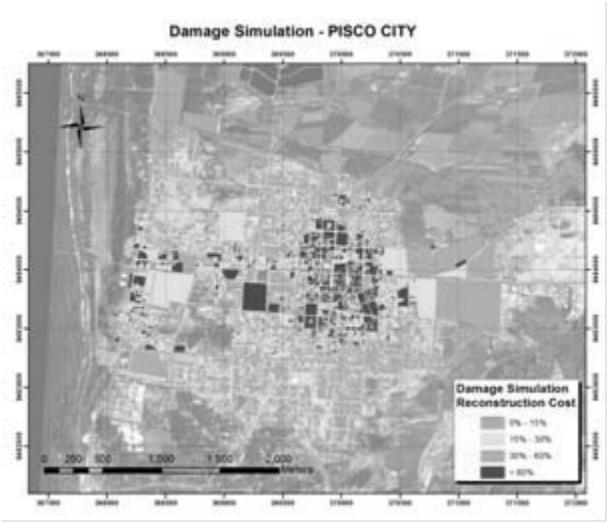

Figure 5: Damage simulation in terms of reconstruction cost

4. FRAGILITY CURVES FROM SURVEY DATA AND VALIDATION OF SRSND

In order to know the fragility of the structural systems damage under Pisco earthquake an analysis of the survey data has been performed in order to compute the probability of damage under an assigned peak ground acceleration. We must mentioned that one of our limits was the difficulty to have a representative soil profile during the quake, because the few records of after shocks and also the few stations that record these events.

Figure 6 shows the results of field survey on Pisco City, by damage for each type of material used in the city. From the total of adobe buildings, 82% collapsed, following by quincha buildings with 65% of collapse. Masonry buildings suffer less from the strike of the quake (slight damage and non damage) with 70% of them without high demand.

If we consider the total of buildings of Pisco city, Figure 7 presents the percentage considering the total number of the buildings. The adobe buildings that collapsed in the city represents 15% of the total and the masonry buildings that collapsed represents 10.7% of the total of housing.

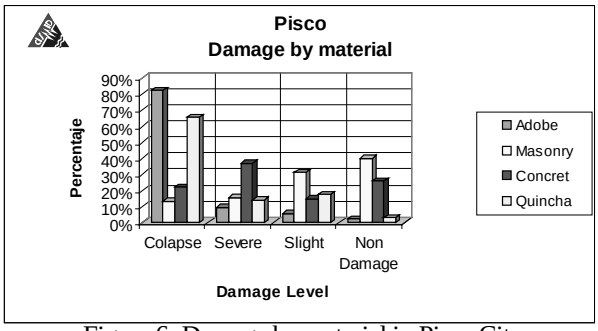

Figure 6: Damage by material in Pisco City

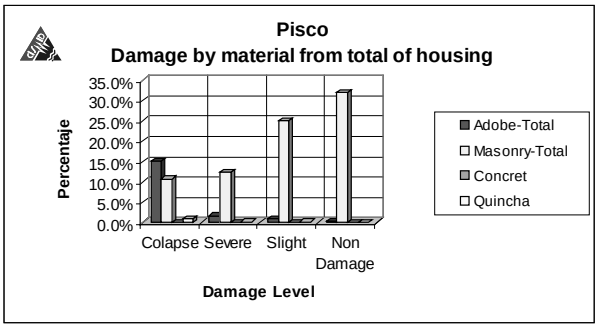

Figure 7: Damage related with total

In Pisco city the adobe structures suffer more than other materials. Also masonry buildings had less damage than the adobe but collapse in this case are more related with the soil profile and demand acceleration during the earthquake.

Mainly in Pisco city soil profile presents three big groups of peak ground acceleration: 0.42g, 0.462g and 0.588g. Under these demands buildings will experiment a probability of damage. Correlating these accelerations with the data of survey, soil profile and also material type we developed fragility curves for adobe structures and masonry structures, presented in Figure 8.

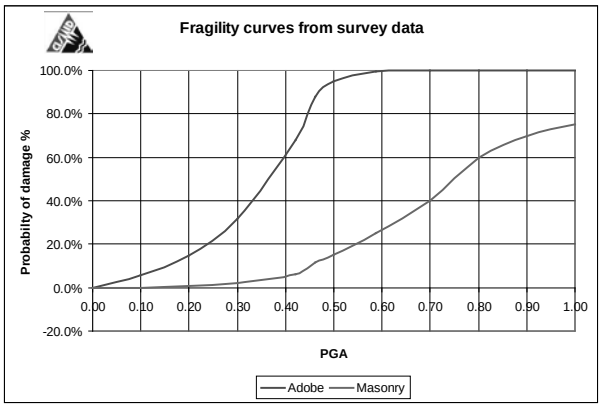

Figure 8: Fragility curves for adobe and masonry

Using these curves the probability of damage of each building can be computed. Then the results show that three groups were generated: 3118 buildings had less than 10% of probability of damage. Among 5193 buildings have a damage probability between 10 to 30 %, and 1866 buildings

have a damage probability over 60%. This last situation means collapse and cost of reposition is 100%.

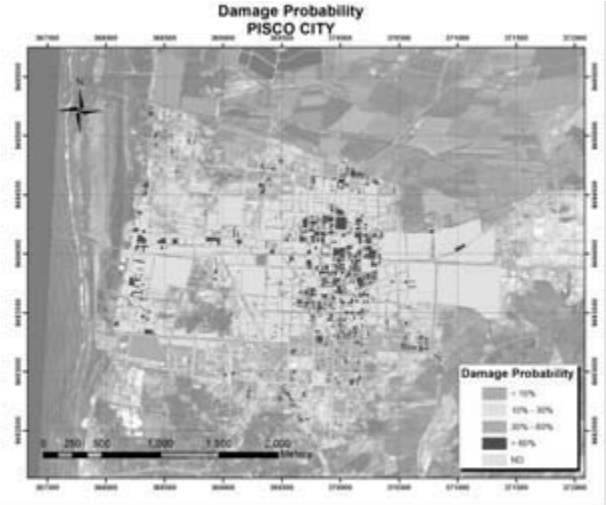

Figure 9: Damage Probability from Fragility Curves

Figure 9 presents the results of the damage probability in each building of Pisco city, considering the fragility curves presented in Figure 8. Here is possible to see the agreement with the SRSND and also the field survey results. These verified the simulation performed by SRSND and also validate the use of the developed fragility curves from survey and soil profile data.

5. CONCLUSIONS

- A simulator for the seismic response of buildings using survey data and approximation parameters βi has been presented. The simulator perform an approximate methodology based on a SDOF system that used the predominant period of the building to compute the seismic response and damage level.
- To compute the earthquake response the spectral displacement must be computed using the predominant period. Then with the use of the same parameter, the constant βi are computed for an assigned ductility. Curves for each parameter are introduced for the case of masonry buildings.
- For validation of the SRSND simulator a comparison with the damage survey after Pisco earthquake was performed. Here a good agreement among colors on Figure 4 and Figure 5, give a trustable results from the simulation
- Also survey results after Pisco earthquake is presented. Mainly the damage due to the earthquake in Pisco City has been caused by the soil conditions that may amplify the seismic waves, on building materials, like adobe, that have a bad behavior against seismic forces and construction quality that do not comply with the standards.
- As a consequence of 15/8/2007 Pisco quake, damage on housing occurs at Pisco, were the most damage construction system was the adobe walls house with 82% of collapse in Pisco.
- Masonry housing experiment less damage than adobe due to the confinement of the walls, with only 10% of collapse in Pisco.
- It is evident the correspondence between the damage levels and the soil conditions; therefore, soil profile of urban areas constitutes a very important tool for city planning and reconstruction plans.
- Damage levels were presented in a matrix related with drift values. These values can be correlated with the type of damage and also with the cost of retrofit its damage. It means the cost of restoration.
- It is demonstrated that even in a case of a strong ground motion if the masonry buildings are built following the national standards they do not collapse, given as result the safety of their occupants.

Abstract: To evaluate the seismic vulnerability of an urban area it is necessary to know the type of buildings or the actual land use over it. The development of building inventory is costly and time consuming, therefore, in Peru only few municipalities may have the capacity to develop such a kind of work. In this paper it is discussed the use of high resolution images to infer the type of social class and consequently the type of house or building typified by its major characteristics, based on two characteristics: the number of pools and the concentration of vegetation that exist in each block of the area under study.

1. INTRODUCTION

Peru is located in a seismic prone area and the development of the cities are so fast and do not pay attention to the regulation on building constructions, so it is of interest to study the type of building on urban area to know their vulnerability in case of an extreme earthquake. One of the main data source to assess the type and condition of the building are the census or inventory data that is developed for the local governments. In most of the municipalities in Peru there is not a policy to develop this kind of data, not only because of lack of economic resources but also because the absence of technical people that can understand the problem and conduct this work. Therefore it is necessary to develop a methodology to carry out a fast inventory of buildings and to recognize their vulnerability against earthquakes. Recently high resolution imagery is becoming more accessible, not only because price, but also because multiple satellites are observing the earth surface constantly given a rich source on information about the land use. Lima city is characterized by people of different social classes; these social classes may indicate the type of building where they live, in terms of quality and if they followed the regulations during the construction of the building. Low class people generally they construct their houses by themselves, as they can and without following the regulations of the National Building Code.

In this study it is proposed to used high resolution satellite imagery to recognize the social class of the people by identify some characteristics of their houses like pools and greenness and thus to classify the vulnerability of the urban area. Finally the land information is integrated with PRISM sensor data to identify areas that are built over important slope to evaluate also hazard of these area.

2. UMBRELLA PROJECT

This research is under the project "Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru" the purpose of this project is to developed technologies and measures for prediction and mitigation of earthquake/tsunami disasters caused by large-magnitude inter-plate earthquakes occurring off the coast of Peru.

This project is divided into five active groups. Group 1 will research on seismology and geotechnical issues, and give the final response of the soils. Group 2, will study the source, effects and countermeasures of tsunamis produced by an earthquake. Group 3, will identify the most typical building problems and will propose retrofitting methods or will give some advises to improve the actual building code. Group 4, will develop methodologies to identify the land use, by using the satellite imagery and integrating all the information in a GIS platform to assess the risk of the building as well as to develop a methodology for fast assessment of the damaged area by an earthquake or tsunami. Finally, Group 5 will take the entire group's output and will disseminate this knowledge and propose policies for a sustainable development of the population. This project is under the support of Japan International Cooperation Agency, Japan Science and Technology Agency, Peruvian International Cooperation Agency. And the institutions directly involved in this study are the Chiba University and Tokyo Institute of Technology, from the Japanese side and the Japan Peru Center for Earthquake Engineering Research and Disaster Mitigation, National University of Engineering, from the Peru side.

3. STUDY AREA

The area of study is the district of La Molina in Lima Peru. This district has a population of approximately 130000 habitants. This district is very special in Lima Metropolitan area, because here it can be found people of different social classes and therefore different construction type and building quality. Another issue in this district is that it is growing very fast and the new developed urban area is taking place on terrain with important slope. Because soil conditions, buildings in this district have suffered of important damage in past earthquakes, therefore it is important to know the type of building that are built on this area. In Figure 1 it can be seen the location and extension of La Molina district, that is located in the middle east of Lima. Although this is a district with relatively good economical resources, the situation of the cadastral information is still in the beginning stage that is why it is necessary to use another source of information to evaluate and assess the type of buildings.

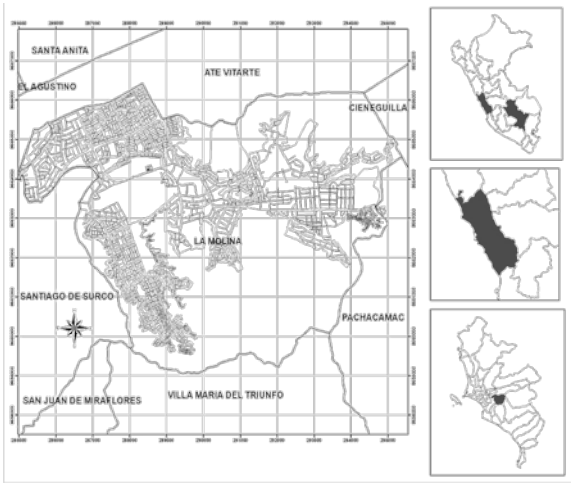

Figure 1. District of La Molina in Lima, Peru.

4. DATA CHARACTERISTICS

The date used in this work is the multispectral Worldview 2 which major characteristics are shown in Table 1.

Table 1. Worldview 2 scene characteristics.

Characteristic	Value
Acquisition date	March 11, 2010
Number of bands (M – P)	8 – 1
Rows/Columns (M – P)	4031/5463 – 16124/21852
Bits per pixel	16
Spatial resolution	2.0 m MS/0.5 m PAN
Wavelength (nm):	
- Coastal (Band 1)	- 427 nm
- Blue (Band 2)	- 478 nm
- Green (Band 3)	- 546 nm
- Yellow (Band 4)	- 608 nm
- Red (Band 5)	- 659 nm
- Red edge (Band 6)	- 724 nm
- NIR 1 (Band 7)	- 831 nm
- NIR 2 (Band 8)	- 908 nm

As we can see in Table 1 the number of multispectral bands that are included in one image is good enough to detect many materials over the earth surface. This advantage is taken as the base for the analysis. In this research Worldview 2 images were selected instead of Ikonos (Cook et. al., 2000) images because two reasons: first: there is a better resolution 0.50 m vs. 0.60 m, and second spectral resolution in case of Worldview 2 has more sensibility as it can be seen in Figure 2.

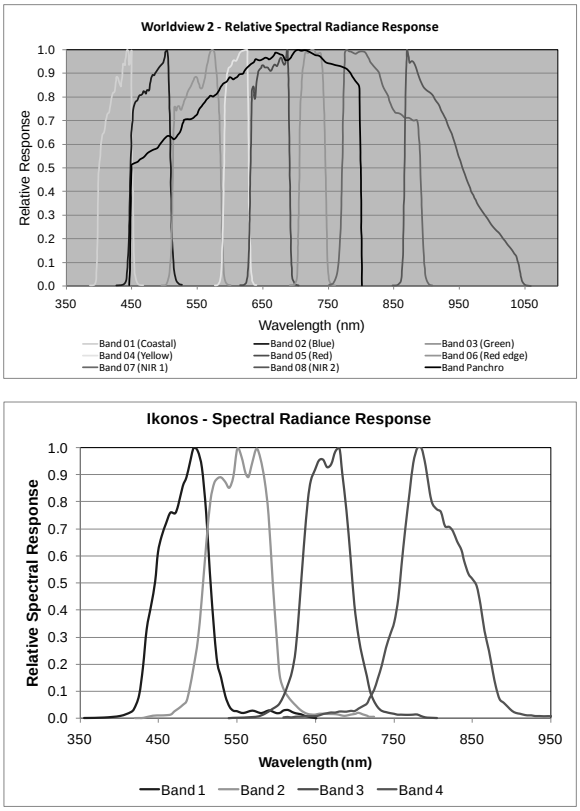

Figure 2. Spectral response comparison between Worldview 2 and Ikonos images.

5. METHODS AND PROCEDURES

To assess the seismic vulnerability of an urban area can be done by evaluating of housing census data, but it has the drawback that that method cannot be generalized, one approach based on contextual analysis of image and GIS data is presented by Ebert et al (2008) where an approach based on proxy variables that were derived from high resolution optical and laser scanning data was applied, in combination with elevation information and existing hazard data social class we investigate the location of swimming pool within an urban area. Another approach for building inventory is presented by Dutta et. al (2005) where very high resolution satellite optical data from Quickbird satellite with object-oriented classification scheme was used for an overall

accuracy of 85% in detailed classification of urban land cover.

In La Molina district it can be found different types of land use depending on the social classes. As it is shown in Figure 3, high social class area (a) has an important green area and important features are the pools inside of the lot, middle class area (b) has also important green area but no pools, and low class area has few vegetation and no pools. Therefore if pools and vegetation can be detected in an automatic manner we could infer the type of social class in the area and as consequence the social vulnerability of it.

(a) (b) (c)

Figure 3. Difference between land use in La Molina.

For mage classification exits a bunch of methods, mainly classified into two big groups: unsupervised and supervised methods. One of the methods of supervised classification is described by Mohd et. al. (2007) the Spectral Angle Mapper (SAM) this is a physically-based spectral classification that uses an n-dimensional angle to match pixels to training pixel area. The algorithm determines the spectral similarity between two spectra by calculating the angle between them, treating them as vectors in a space with axes equal to the number of bands. Smaller angles represent closer matches to the training pixels.

Luc et. al. (2005) depicts how to obtain the angle between two spectra that are being compared. In Figure 4 it can be seen, in a three bands dimension space, if spectral angle (θ) is small then the tested (t) and reference (r) spectral vectors are similar. In Eq. 1, we can see the numerical calculation, where the angle θ is a kind of correlation value between two samples in an n-dimensional spectral space.

$$\theta = \cos^{-1}\left(\frac{\sum_{i=1}^{n} t_i r_i}{\sqrt{\sum_{i=1}^{n} t_i^2 \sum_{i=1}^{n} r_i^2}}\right) \qquad \text{Eq. 1}$$

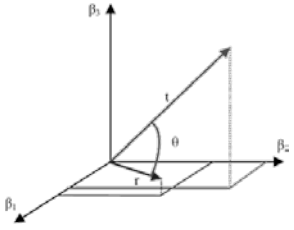

Figure 4. r reference spectra vector, t spectra vector to be compared, θ spectral angle .

Pixels that are in pools are selected as trained pixels. Pixels were selected over the image, and their spectral response was analyzed. Figure 5, shows how the pixels were selected and the average of the digital number of these pixels.

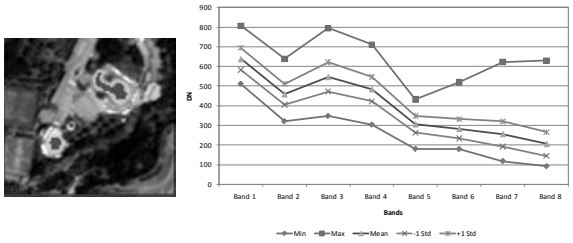

Figure 5. Trained pixels and their spectral response.

Another parameter that was used is the NDVI to detect the concentration of vegetation in the area.

6. RESULTS

The SAM method for classification gave good results and the pools could be detected, the number of pools in one block where automatically counted and the image was transferred to GIS map and then classified by this number.

Additionally, the NDVI also was calculated and the number of pixels that represent vegetation where counted in each block.

Figure 6 shows the thematic map considering the number of pools by block, it can be seen that there are some areas where the number of pools is considerable given areas of high class. In Figure 7, is presented the thematic map representing the concentration of vegetation in each block, high concentration of vegetation indicates high class, while very low concentration may indicate low class.

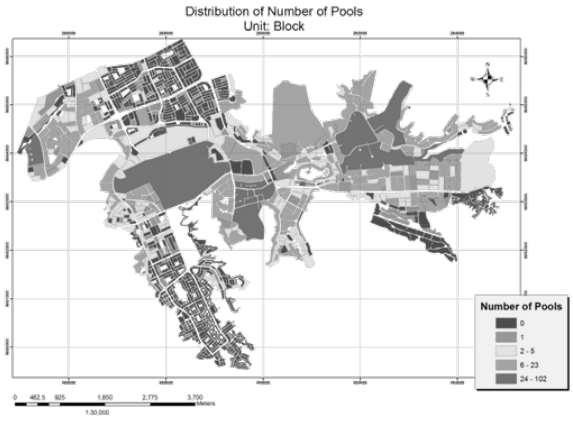

Figure 6. Classified map indicating the number of pools by block.

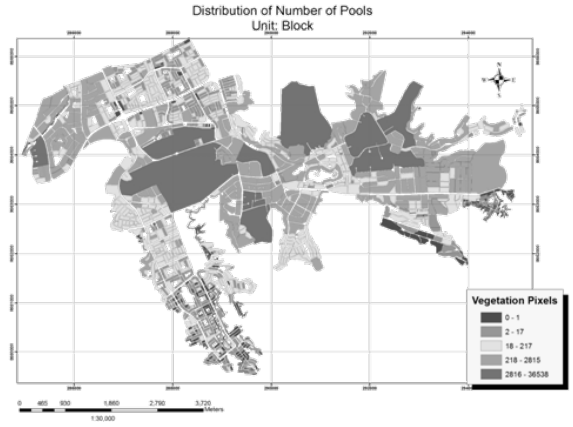

Figure 7. Classified map indicating the number of vegetation pixels by block.

Also it was conducted a field survey for verification of the results given good agreement with the two indexes. In Figure 8, it can be seen that for different type of land use it is possible to correlate the number of pools and the NVDI.

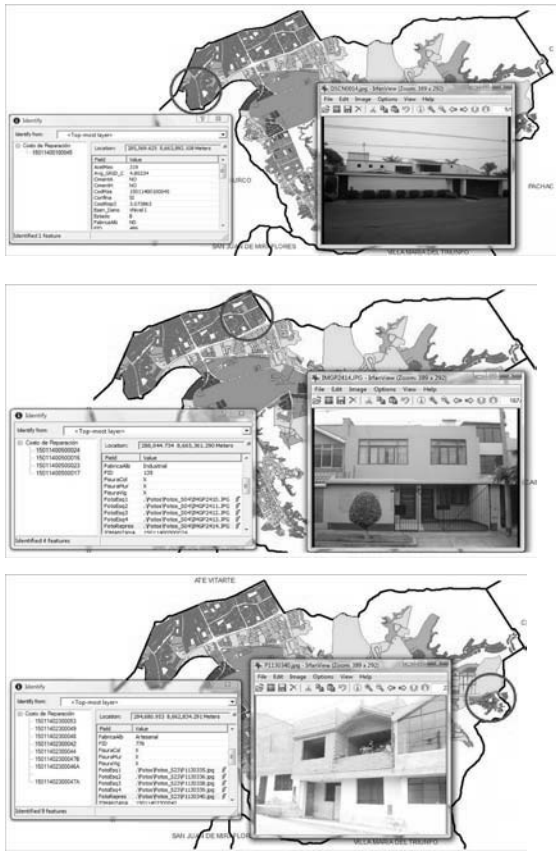

Figure 8. Field survey of different sectors.

3. CONCLUSIONS

It can be shown that from satellite information it can be inferred the type of social class based on two characteristics of the urban area: the number of pools and the concentration of vegetation. While the number of pools and the concentration of vegetation is high it is and indicative that the social class of the people who live there is high and therefore their houses may be well constructed, while on the other side where pools do not exist and the vegetated area is minor may indicate a social class where the construction of the houses may have not follow the standards and therefore their seismic vulnerability could be considerable.

Abstract: In order to estimate the building damage distribution of the 2006 Central Java, Indonesia earthquake, a procedure of pixel-based damage detection is applied to the optical satellite images observed before and after the earthquake. The satellite FORMOSAT-2 images with the resolution of 2m are used. The comparison of the images shows that the digital numbers in severely damaged area in the post-event image is higher those in pre-event image. In the analysis, the pixels of the image are classified into vegetation, bare ground and built-up areas. The damaged areas are detected by differential of the digital numbers in the built-up areas. The estimated damage distribution is validated by comparing with the GIS building damage data obtained by the field survey. The result shows that the severely damaged areas are well detected by the analysis. In the densely vegetated area, however, the damage is underestimated because the buildings are obscured by trees.

1. INTRODUCTION

In a destructive earthquake, man-made structures such as buildings and infrastructures would be severely damaged over a wide area. As basic information for early-stage recovery activities, it is necessary to identify the damage distribution as soon as possible after an earthquake. Since remote sensing can easily capture the real world from the air at a time, the remote sensing technology is a promising tool for early damage assessment and has been applied in various post-earthquake activities (Rathje and Adams, 2008). For rapid damage identification, it is important to develop a computer-based image analysis to automatically or semi-automatically detect damaged areas from satellite images.

Pixel-based image analysis is one of the major change detection techniques from remote sensing data (Lunetta and Elvidge, 1998). In pixel-based change detection, each pixel is assigned to "change" pixel or "non-change" pixel based on the characteristics of the pixel between two-date images. The technique had been also applied to detect earthquake damage (e.g., Kohiyama and Yamazaki, 2005). In these damage detection studies, difference and/or correlation of digital number (DN) or edge intensity between the pre- and post-event images is used. The areas where these indices are significantly changed after the event are extracted as damaged areas.

There would be two factors of false detections in the pixel-based change detection. The one is that difference of projection direction of buildings and their shadows between two images may produce lots of false detections when using the images whose observation angles such as off-nadir angles are different each other. The other is that change detection for whole pixels in the images may produce not only the change related to earthquake damage but also non-earthquake change (e.g., seasonal vegetation change). For the former factor, the use of images whose off-nadir angles are same may reduce such false detections. For the latter factor, false detections would be reduced by extracting built-up areas in advance and detecting changes only from the built-up areas.

For more accurate automatic damage identification, a procedure of pixel-based damage detection is proposed in consideration of the two problems shown above and applied to optical satellite images observed before and after the 2006 Central Java, Indonesia earthquake. The satellite FORMOSAT-2 images with the spatial resolution of 2m are used because the satellite observes with constant off-nadir angle. To accurately detect the damage of buildings, pixels of the images are firstly classified into three categories; vegetation, bare ground and built-up areas. The damage areas are estimated by the differential of DN in the extracted built-up areas between the pre- and post-event images. The detected damage distribution is validated by comparing with the building damage data obtained by field survey.

2. CHARACTERISTICS OF SATELLITE IMAGES

The destructive earthquake in Java Island, Indonesia occurred at 05:54AM on May 27, 2006 (M_W6.3) caused severe damage in the central Java province. The epicenter

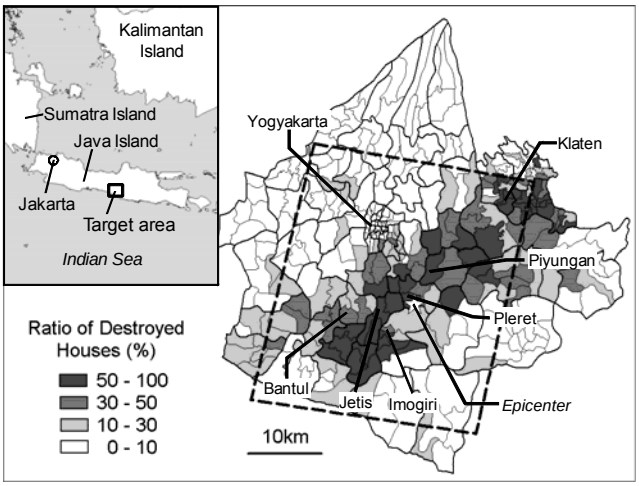

Fig. 1 Target Area with Village-level Damage Ratios

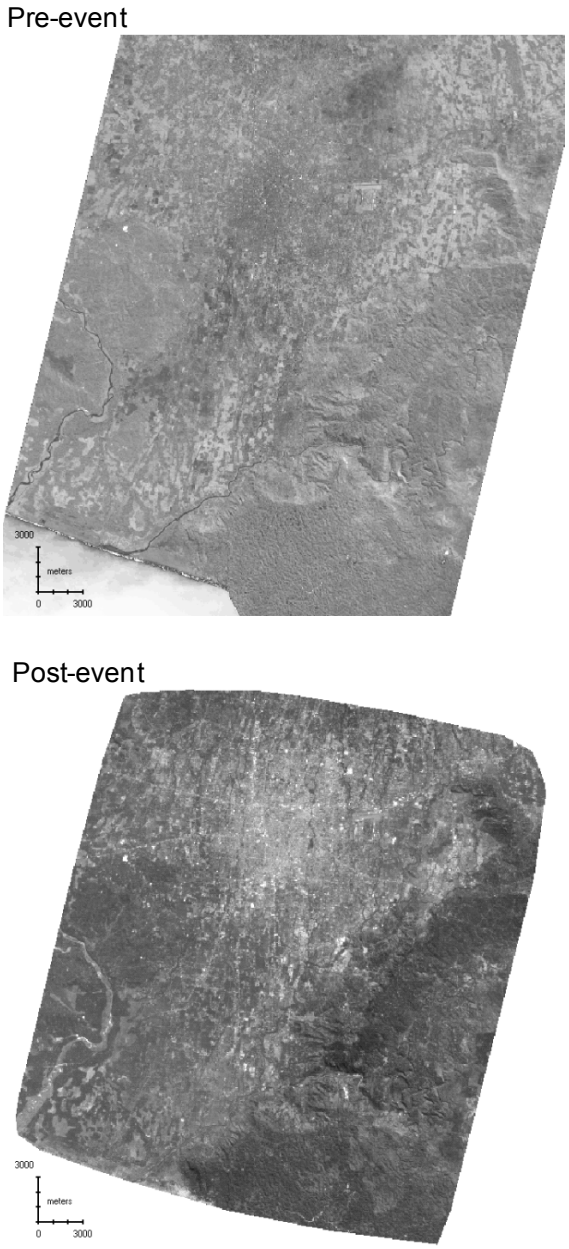
of the earthquake is located in 15km southeast from Yogyakarta, a major city of the central Java. The number of deaths and injured people was approximately 5,700 and 37,000, respectively. The number of destroyed buildings was more than 300,000. The monetary loss was about 3 billion US$ (Karnawat et al., 2008).

Figure 1 shows the location of the epicenter and distribution of ratio of destroyed houses by village-level damage statistics compiled by the regional governments approximately one month after the earthquake (IFRC, 2006). The damage ratio is higher than 50% not only in the epicentral areas such as Prelet and Jetis but also in the northeastern areas about 30km far from the epicenter such as Klaten. The dotted square in Fig. 1 shows the target area of this study.

Figures 2 show the pre- and post-event satellite images used in this study. The FORMOSAT-2 images observed before and after the earthquake are used. The pre- and post-event images were observed in May 18 and June 11, 2006, respectively. The panchromatic image is used as the pre-event image because multi-spectral image was not acquired in the target area before the earthquake. The panchromatic and pan-sharpened images from the multi-spectral image are used as the post-event image. The spatial resolution of the images is 2m.

Figures 3 (a) and (b) show the close-ups of the pre- and post-event panchromatic images in severely damaged area. According to the field survey by Architectural Institute of Japan (2007), about 90% of the residential houses are severely damaged in the settlement located at the central part of the image. Figure 3(c) indicates a cross-section of the DN of the images along the dotted line in the figures. In the severely damaged area, the DN in the post-event is remarkably higher than that in the pre-event. The collapsed buildings produce lots of rubble piles such as wall bricks on the surface ground. Since the reflectance of brick is higher than that of roof tile (Miura et al., 2007), the difference of the reflectance of the materials results the differential of the DN. Therefore, the differential of the DN between the images is used to detect the building



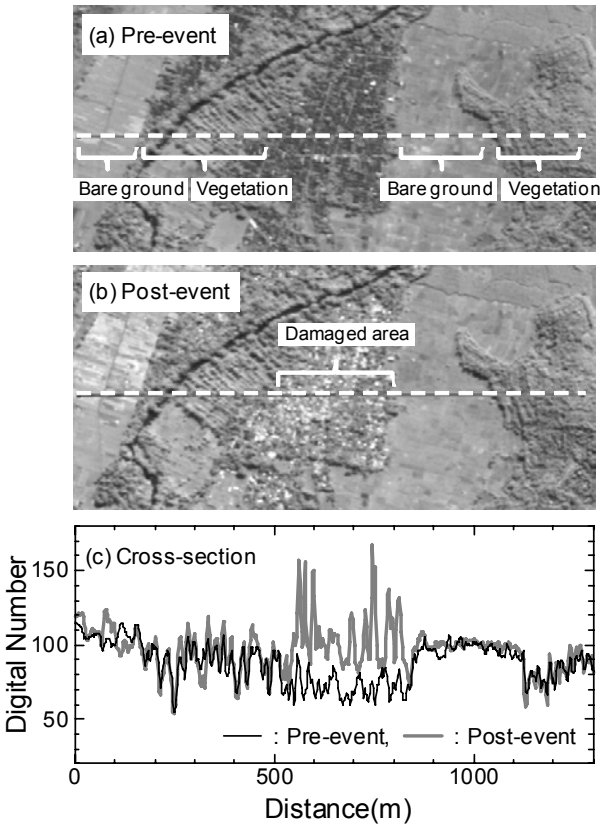


Fig. 2 Comparison of Pre- and Post-event Images

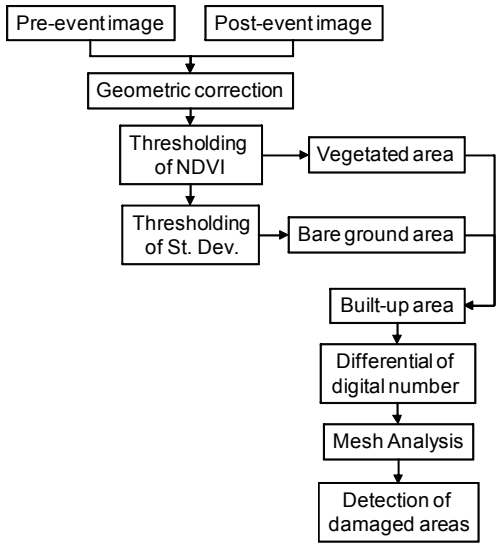
damage areas in this study.

3. DAMAGE DETECTION

Figure 4 shows the flowchart of the damage detection procedure employed in this study. In order to detect building damage in built-up areas, the pixels of the images are classified into vegetation, bare ground and built-up areas. First, vegetated areas are extracted by thresholding of NDVI (Normalized difference vegetation index) calculated from post-event pan-sharpened image. NDVI is defined as the difference in pixels between near infrared band image and red band image divided by their sum. A higher NDVI indicates a higher density of green leaves in a pixel. Figures 5 (a) and (c) indicate the distribution and the

Figs. 3 Comparison of Pre- and Post-event Images



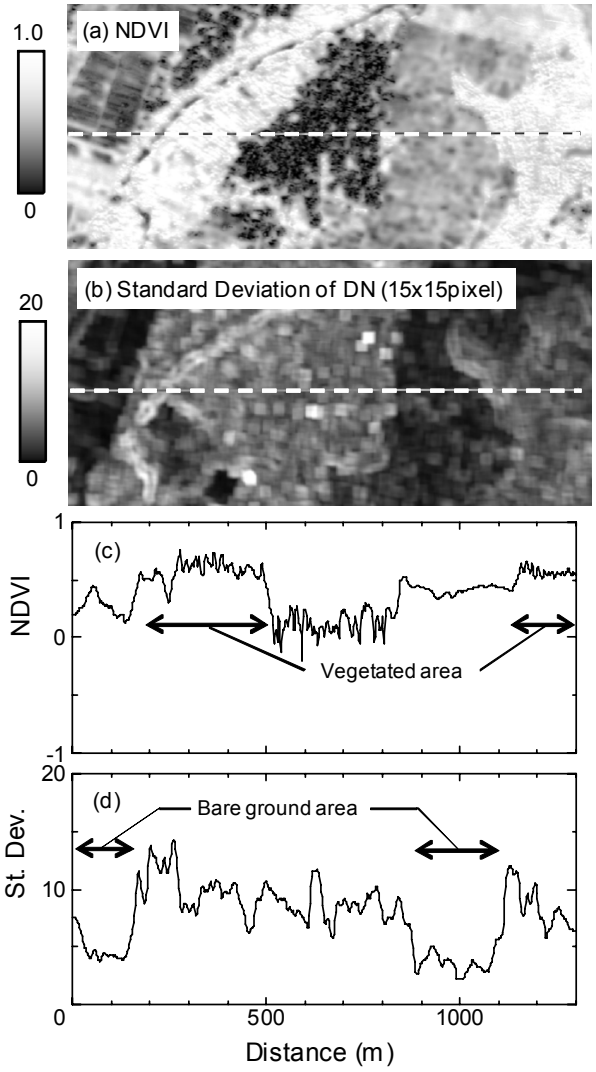


Fig. 4 Flow of Damage Detection

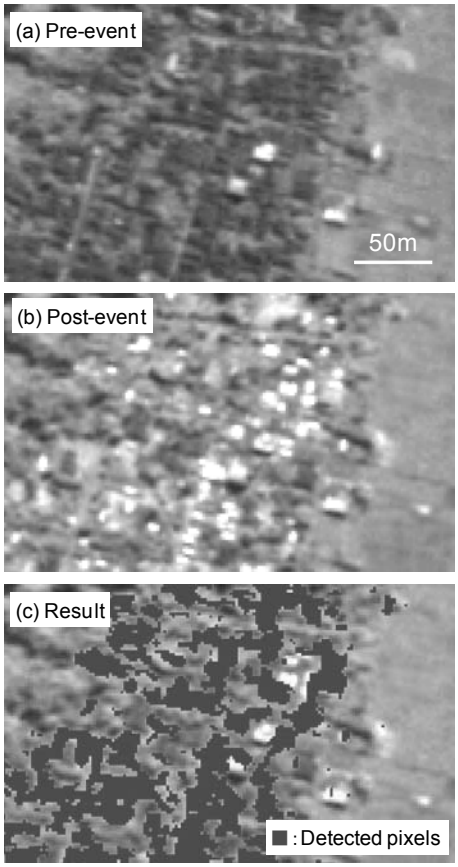
cross-section of NDVI in the area shown in Figs. 3. The threshold value of NDVI is selected by comparing the distribution of NDVI and the vegetated area. In this study, the pixels whose NDVI is higher than 0.4 are classified into vegetated areas.

Second, bare ground areas are extracted by thresholding of standard deviation (SD) of the DN in a windowed area calculated from pre-event panchromatic image. Because

Figs. 5 NDVI and SD Images



homogeneous materials such as soil are uniformly distributed in bare ground, the variation of the DN in bare ground areas is lower than that in built-up areas. The SD that is one of the texture indices is used to extract the bare ground areas. By considering that the size of buildings in the target area is from 5 to 30m and the size of bare ground is from several tens to hundreds meters, the window size for the calculation of the SD is determined at 30x30m (15x15pixels). Figures 5 (b) and (d) indicate the distribution and the cross-section of the SD. The threshold value of SD is selected by comparing the distribution of the SD and the bare ground areas. The pixels whose SD is lower than 6.0 are classified into bare ground areas.

Finally, built-up areas are extracted by subtracting the vegetated areas and bare ground areas from the whole area. The differential of the DN in the built-up areas is calculated and the thresholding is applied to the differential. From the comparison of the difference image and the distribution of damaged areas, the pixels whose differential of the DN is larger than 20 is extracted as the damaged areas. Figures 6 shows the distribution of the detected pixels. Red pixels

indicate the detected pixels, showing the damaged area is well detected in the analysis.

The detected pixels would correspond to rubble piles produced from collapsed buildings. This indicates that the severely damaged or collapsed buildings can be detected but moderately and slightly damaged buildings cannot be detected by the image analysis.

In order to identify the extent of the detected pixels, the number of the detected pixels is evaluated by 200m-mesh map. Figure 7 shows the distribution of the detected areas. Figure 8 shows the distribution of damage ratios of destroyed houses calculated from the village-level damage statistics (IFRC, 2006). In the epicentral area such as Pleret and Jetis whose damage ratio is more than 70%, many pixels are well detected by the image analysis. Also in the northeastern area such as Klaten that are severely damaged, many pixels are detected as damage. On the contrary, in the southern area such as Pundong and Bambang Lipuro, the number of the detected pixels is rather smaller while the area is also severely damaged according to the damage statistics.

Figs. 6 Result of Damage Detection

4. VALIDATION

In order to quantitatively evaluate the result of the damage detection, the estimated damage distribution is compared to building-by-building damage data obtained in field surveys by Gadjar Mada University in Yogyakarta. The data includes the location of building, building use, structure, material of roof, number of floors and damage level (Kerle, 2010). The damage is classified into three categories; Collapse/Heavy damage (Collapse), Moderate damage and Slight damage. About 50,000 buildings in the epicentral area were investigated. Approximately 95% buildings of the surveyed buildings are one-story residential buildings. Almost 65% of the buildings are classified into collapse, 15% and 20% are classified into moderate and slight damage, respectively.

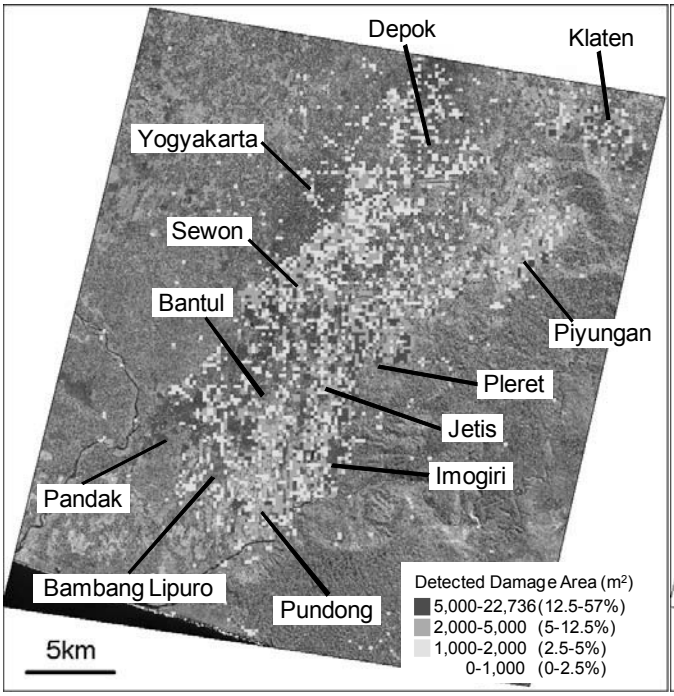


Fig. 7 Distribution of Detected Pixels

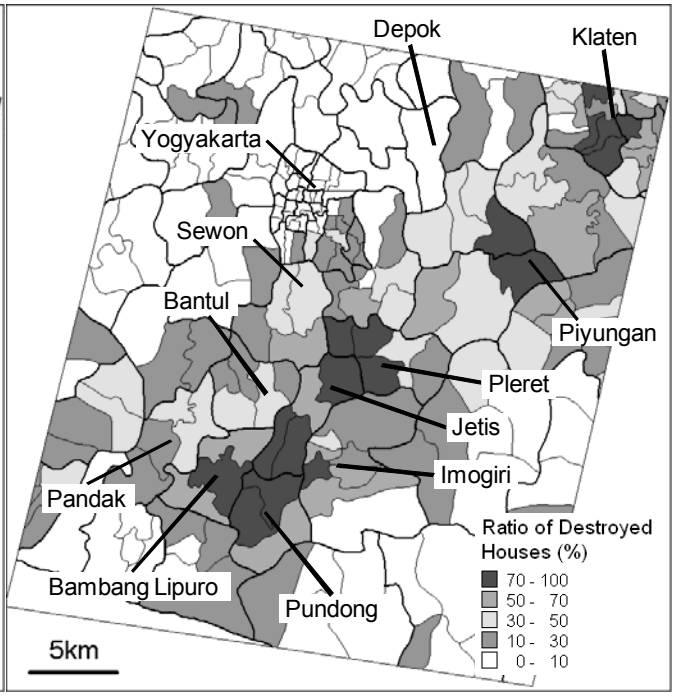

Fig. 8 Village-level Damage Distribution

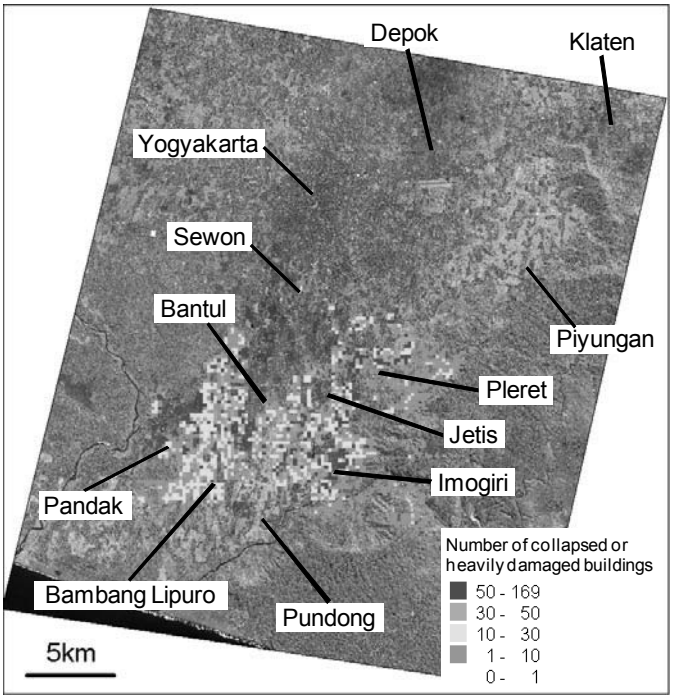
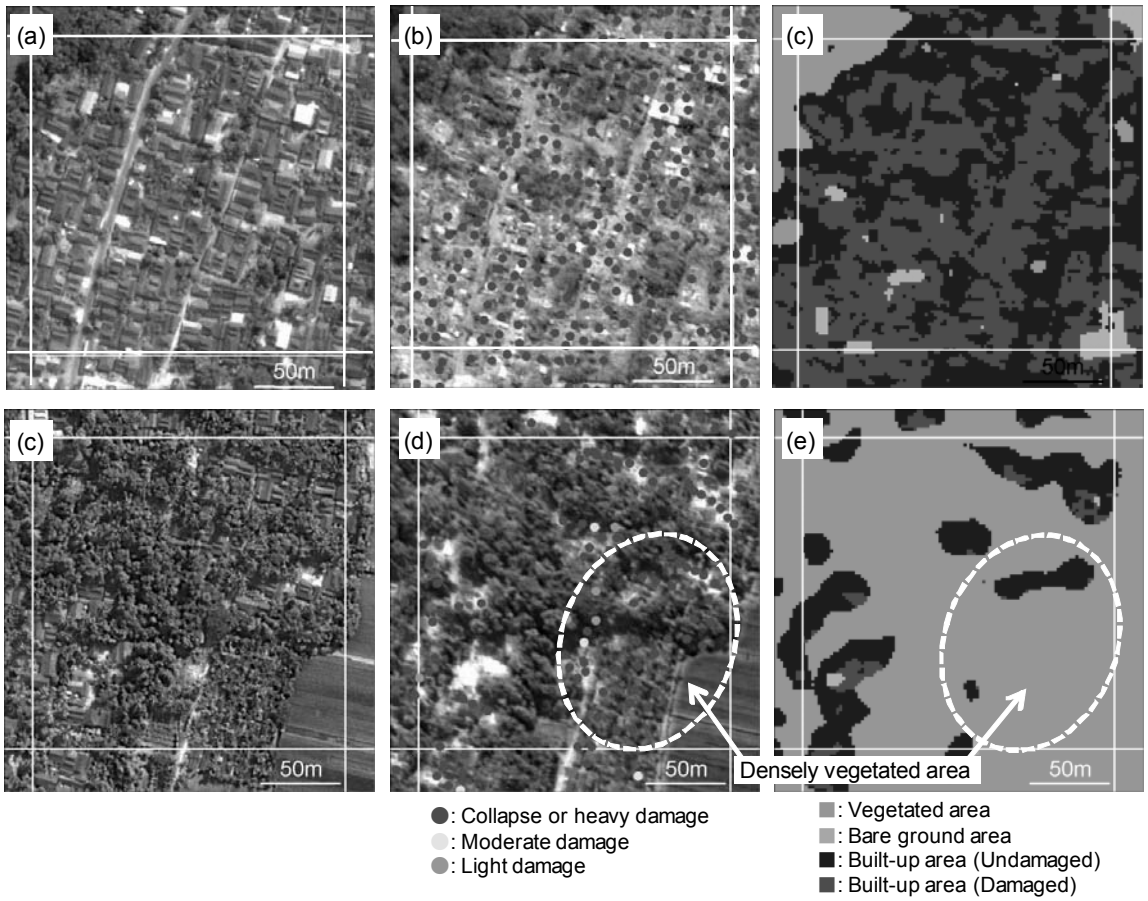
From the comparison of the damage data and the actual building distribution in satellite images, the survey was conducted for settlement-by-settlement and unsurveyed settlements are situated in next to the surveyed settlements. In the surveyed settlements, almost all the buildings seem to be investigated. Since the size of the settlements is usually more than 200m, the damage rate can be properly evaluated by 200m-mesh map. Figure 9 shows the distribution of the number of collapsed buildings obtained in the field surveys. The data covers Prelet, Jetis, Imogiri, Bantul and does not cover Yogyakarta and Klaten.

Figures 10 (a), (b) and (c) show the close-ups of the pre-, post-event image and the damage detection in a built-up area. The damage data is illustrated by points in Fig. 10(b). Red, yellow and green points represent collapsed, moderately damaged and slightly damaged buildings, respectively. In Fig. 10(c), red, blue, orange and green pixels represent damaged, undamaged, bare ground and vegetated areas, respectively. In this mesh, about 170 buildings are collapsed and the damaged areas are almost successfully detected by the image analysis. Figures 10 (c)-(e) show the close-ups in a vegetated area. While many buildings are collapsed in the dotted circle in the figure, the damaged areas are mis-detected and classified into vegetated areas by the image analysis. As





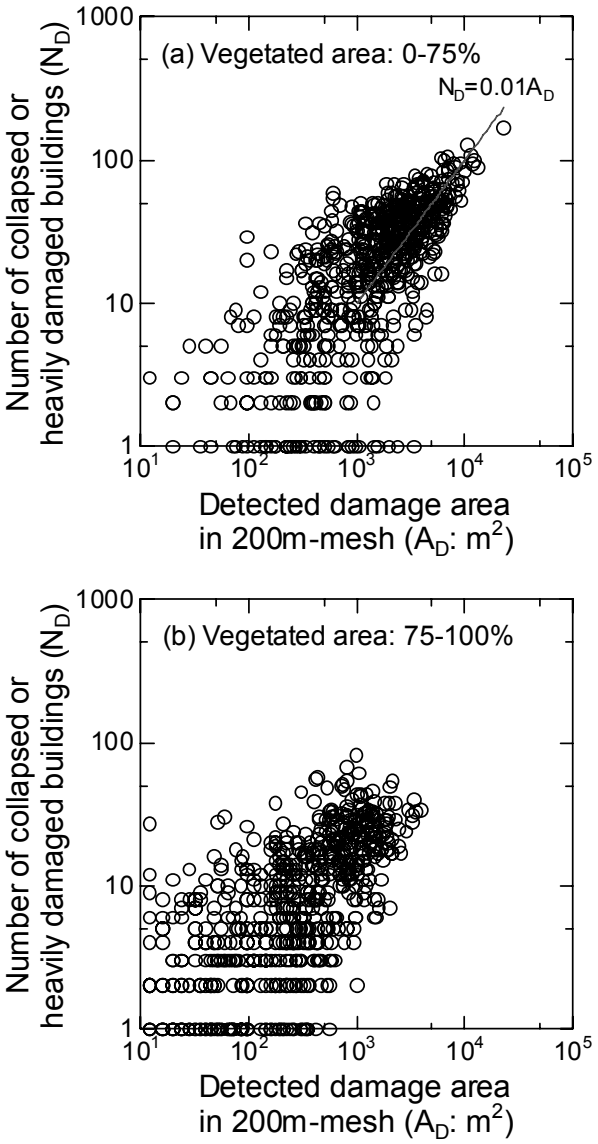


Fig. 9 Distribution of Collapsed Buildings by Field Survey

Figs. 10 (a) Pre-event, (b) Post-event, (c) Result of Damage Detection in Built-up Area
(c) Pre-event, (b) Post-event, (c) Result of Damage Detection in Vegetated Area

Figs. 11 Relationship between Detected Area by Image Analysis and Number of Collapsed Buildings

shown in the images, most of the area is covered with vegetation such as trees. Since the building roofs are obscured by trees in the densely vegetated areas, it is difficult to identify the damaged buildings from the satellite image. The dense vegetation might be a cause of the underestimation of the damage.

If the detected pixels represent collapsed buildings, the detected areas should be proportional to the product of number and size of the collapsed buildings. Since the data for building size is not available, the relationship between the damage area detected in the image analysis and the number of the collapsed buildings in each 200m mesh is examined. As shown in Figs. 10, since the damage in vegetated areas might be underestimated, the relationships are examined by considering the percentage of vegetated areas in each mesh.

Figures 11(a) and (b) show the relationships for the meshes whose percentage of vegetation is (a) less than 75% and (b) more than 75%, respectively. The correlation of the relationship is clearer observed in the less vegetated areas such as Fig. 11(a) than in the densely vegetated areas such as Fig. 11(b). Approximate line of the relationship is plotted in Fig. 11(a). From the approximate line, average detected area per a collapsed building is estimated to 100 square meters. The average size of residential buildings in the target area is about 5 to 10 meters. The detected area per a collapsed building is a little bit larger than the average size of a building because the detected areas may include rubble piles scattered around the buildings.

5. CONCLUDING REMARKS

Image analysis for building damage detection is applied to the pre- and post-event FORMOSAT-2 images to estimate the damage distribution of the 2006 Central Java, Indonesia earthquake. In the damage detection, built-up areas are firstly extracted from the images. The damaged areas are estimated from the differential of the DN in the built-up areas. The comparison of the estimated damage distribution and the building damage data by the field survey indicates that severely damaged areas are well detected although the damage is underestimated in the densely vegetated areas.

Abstract: This paper presents the results of a field survey conducted by the authors after the 2010 Chile earthquake. The authors visited the affected area about a month after the earthquake. The GIS datasets for the damage levels of buildings in Talca and the tsunami-inundated areas in Talcahuano, Dichato, and Constitución are constructed in this study, and a series of fundamental analyses are performed using a digital elevation model (DEM). Further, the usefulness of satellite images captured after the earthquake to detect damaged buildings in Talca is discussed using the GIS datasets constructed in this study.

1. INTRODUCTION

The 2010 Chile earthquake occurred off the coast of the Maule Region of Chile on February 27, 2010, at 03:34 local time (06:34 UTC) with a magnitude of 8.8 on the moment magnitude scale. The epicenter was offshore from the Maule Region, approximately 335 km southwest of Santiago, the capital of Chile, and 105 km north-northeast of Chile's second largest city, Concepción. It is reported that a severe ground motion with the Modified Mercalli Intensity (MMI) scale of VII was felt widely in Chile and that the extensive damage was caused by the ground shaking and tsunami (USGS, 2010). The total economic loss estimates range from USD 15 to 30 billion, which correspond to 10% to 15% of Chile's real GDP (Bray and Frost 2010). According to the report on the scene, the actual death toll was 486 as of March 8, 2010, and approximately 370,000 homes were damaged.

The authors visited the affected area about a month after the event as part of an international research project "Enhancement of earthquake and tsunami disaster mitigation technology in Peru" (Yamazaki *et al.* 2010), which is under the research program "Science and Technology Research Partnership for Sustainable Development (SATREPS)" (JST 2008) supported by the Japan Science and Technology Agency (JST) and the Japan International Cooperation Agency (JICA). The lessons learned from the 2010 Chile earthquake are expected to apply to the earthquake disaster mitigation technologies in Peru because the two countries have common regional tectonics and social surroundings.

Three teams of Japanese and Peruvian researchers were dispatched by the SATREPS project to carry out field surveys. In this paper, the results of the field survey performed by Damage Assessment Group and Disaster Mitigation Plan Group are presented. The spatial damage data, topographical maps, and satellite images provided by different institutions are compiled by the geographical information system (GIS), and the primitive analyses are conducted to reveal the characteristics of the tsunami-inundated areas in view of elevations and damage incidents to adobe and unreinforced masonry buildings, which are also widely seen in Peru.

2. OUTLINE OF FIELD SURVEY

The authors arrived in Santiago on April 2, 2010. We drove to Concepcíon the next day and visited the tsunami-affected areas of Talcahuano, Dichato, and Constitución. We moved to Talca on April 7 and left Santiago on April 8. Before leaving, we visited Valparaíso and Viña del Mar. Figure 1 shows the locations of the cities that we visited during the survey.

Figure 2 shows the route of our field survey in Santiago

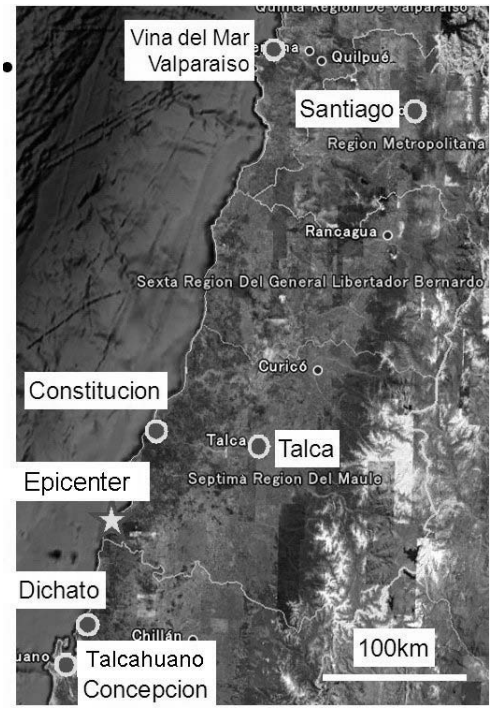

Figure 1 Locations of cities visited by the authors

Figure 2 Survey route and field photos in Santiago—April 2, 2010

and some field photographs. The route was recorded by a portable GPS device during the survey and the location of the photo shooting could be identified as the location data were embedded in the Exchangeable Image File Format (EXIF). An RC building with 20 stories constructed in 2003 suffered from shear failures in columns and walls at the first and the second stories. A collapsed highway bridge and an

Figure 3 Survey route and field photos in Concepcíon—April 4, 2010

Figure 4 Survey route and field photos in Dichato—April 5, 2010

RC building with the collapsed first floor were found. The locations of these sites are also shown in the survey route in Fig. 2.

Figure 3 shows the survey route in Concepcíon. An RC

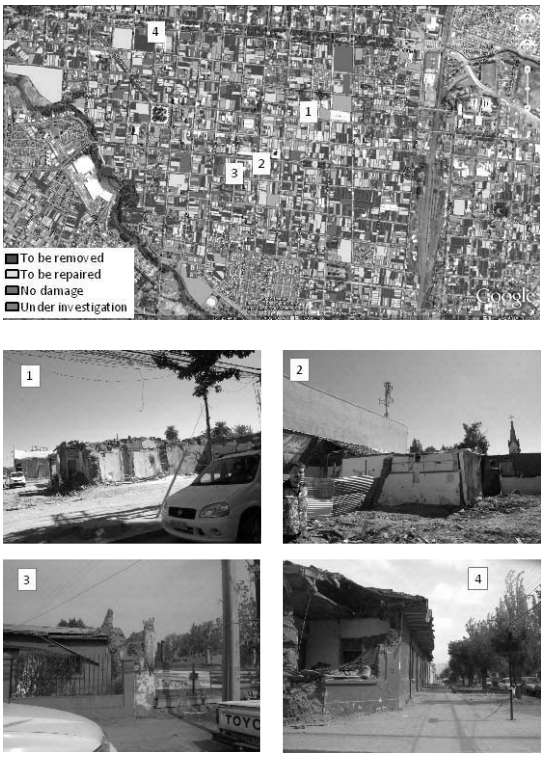

Figure 5 GIS file to show the damage levels of buildings in Talca and locations of field photos

building with the damaged middle floor was found at the site numbered 1. An RC building with 15 stories had collapsed completely at the site numbered 2. The road bridges collapsed at sites 3 and 4. The temporary bridge girder was constructed two days after the earthquake at site 3. Although the photos are not shown in this paper, the adobe and unreinforced masonry constructions were severely damaged in the urban area.

Figure 4 shows the survey route in Dichato. It is reported that more than 80% of the built-up area in Dichato suffered from tsunami (Humboldt State University Preliminary Tsunami Survey Team, 2010). As shown in the field photos, the buildings collapsed because of the tsunami waves. A ship was conveyed against the river flow because of the tsunami and eventually found at site 3.

3. CONSTRUCTION OF GIS FOR BUILDING DAMAGE AND TSUNAMI-INUNDATED AREA

3.1 Building Damage GIS in Talca

Talca is the capital of both Talca Province and Maule Region. Its population is approximately 200,000, and it is approximately 250 km south of Santiago and 60 km northwest of the epicenter of the 2010 Chile Earthquake. According to USGS (2010), Talca was affected with a severe ground motion with the MMI scale of VII.

During our survey, we interviewed officials from Maule Regional Office to investigate the damage of buildings. As a result of our interview, an image file that shows the damage levels of buildings was provided. The polygons, which

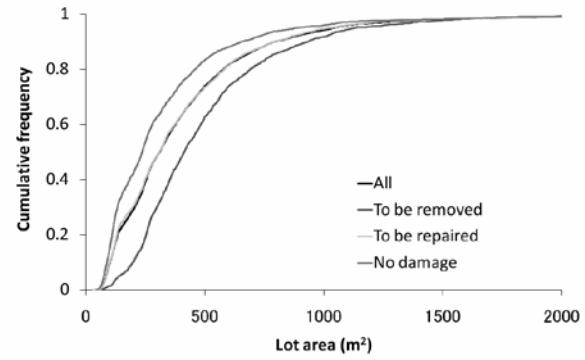

Figure 6 Cumulative frequencies of the areas of building lots with respect to the damage level

indicate the building lots, are classified into four levels, namely, to be removed, to be repaired, no damage, and under investigation. It should be noted that the image file was compiled with the damage dataset as of March 31, 2010.

In this study, the location of the image file was established in terms of map projections. The satellite image and road data presented in Google Earth were employed as a base map to georeference the image file. Then, the image file was converted to a GIS file with polygons to identify the damage levels of buildings. Figure 5 shows the developed GIS file presented by Google Earth and some field photos to show the examples of damaged buildings.

In all, 5617 polygons were projected to the map coordinate system. 1559 (27.8%), 1872 (33.3%), and 1864 (33.2%) buildings were classified as to be removed, to be repaired, and no damage, respectively. The typical construction types in Talca are adobe and unreinforced masonry buildings, which are primarily used for older constructions with 2–4 stories (dating back to before the 1960s–70s). Modern buildings that were designed according to the current codes suffered minor, repairable damage, while a large number of adobe and unreinforced masonry constructions suffered significant damage (MCEER, 2010).

Figure 6 shows the cumulative frequencies of the areas of building lots with respect to the damage level. The mean of all the georeferenced areas was approximately 430 m^2 and was almost equal to that of the areas associated with the buildings to be repaired. The mean of the lot areas of the buildings to be non-damaged was approximately 340 m^2, which was considerably smaller than that of the buildings to be removed. On the basis of the results, it has been speculated that the newer buildings are constructed in relatively small lots; however, the construction periods are not available at this moment.

Recent advancements in remote sensing technologies and their applications have made it possible to use remotely sensed imagery for estimating the damage distribution due to natural disasters. Among them, high-resolution optical satellite imagery, which has become available in the last decade, has made satellite remote sensing more useful in disaster management since even the damage status of individual buildings can be identified (Saito *et al.* 2004, Yamazaki *et al.* 2005). Figure 7 compares the pre- and

(a) Pre-event (Jan. 1, 2008)

(b) Post-event (March 10, 2010)

(c) GIS data

Figure 7 Comparison between pre- and post-event satellite images to detect affected buildings

post-event high-resolution optical satellite images with the GIS dataset shown in Fig. 5. As for the pre- and post-event images, the image captured by QuickBird on January 1, 2008, which is presented in Google Earth, and that captured by WorldView-2 on March 10, 2010, are employed in this study. A comparison of the pre- and post-event images revealed that some of the affected buildings could be visually detected, but not all the damaged ones could be identified appropriately. Since the post-event image was captured with the large off-Nadia angle (40.3°), the quality of image is not sufficient for visual damage inspection. Moreover, the number of affected buildings whose roofs had completely collapsed is small in Talca. Hence, it can be concluded that the damaged buildings in Talca are difficult to be detected through visual damage inspection using satellite images.

3.2 Development of GIS for Tsunami-Inundated Area

Various institutions released the maps to show the damage distribution at their Web sites after the 2010 Chile earthquake. The tsunami-inundated areas interpreted from satellite and aerial images were published by National Office of Emergency of the Interior Ministry (ONEMI) of Chile

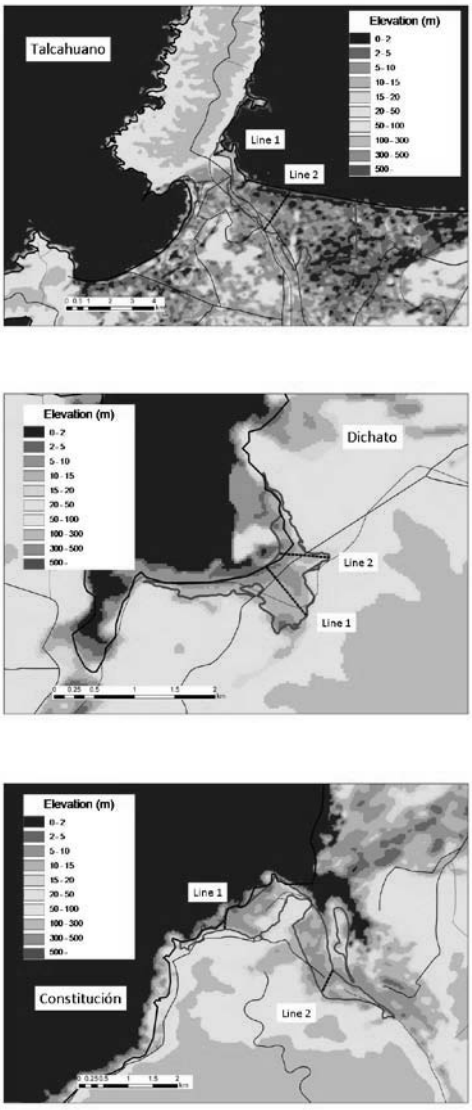

Figure 8 Tsunami-inundated areas in Talcahuano, Dichato, and Constitución

(SNIT 2010). On the basis of the maps, the number of affected buildings and that of causalities were estimated.

In this study, the tsunami-inundated areas were projected onto a map coordinate system, and the topographical conditions were evaluated in terms of the elevation. The inundated areas in Talcahuano, Dichato, and Constitución were converted to the GIS data and compared with the digital elevation model (DEM). The DEM employed in this study is the ASTER Global Digital Elevation Model (GDEM) developed by the Ministry of Economy, Trade, and Industry (METI) of Japan and the United States National Aeronautics and Space Administration (NASA) (ERSDAC 2009). The ASTER GDEM is a highly accurate DEM covering all the land on earth with the spatial resolution of 30 m.

Figure 8 shows the tsunami-inundated areas in Talcahuano, Dichato, and Constitución and the distributions of the elevation derived from the ASTER GDEM. The elevations in the inundated areas are lower than 20 m on the

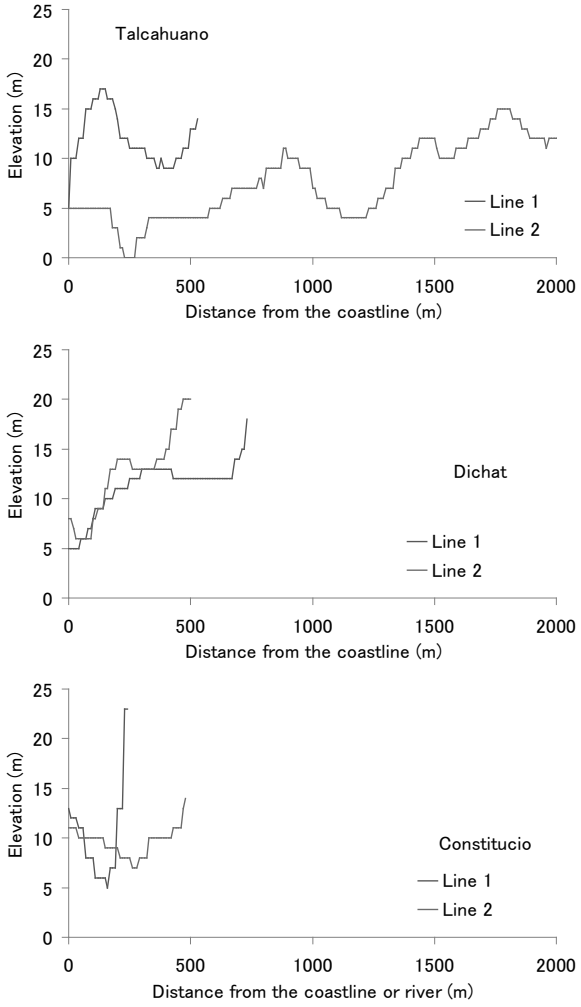

Figure 9 Elevations along the transverse lines set in Fig. 8

whole except for a certain area in Constitución. As shown in the figure, we set the two traverse lines in each inundated area. The elevations were extracted along the two lines. The extracted elevations are illustrated in terms of the distance from the coastline in Fig. 9. As for Line 2 in Constitución, the elevations are presented with respect to the distance from the Maule River. The relatively low elevations and slow grades result in long travel distances of the tsunami wave. According to Line 2 in Talcahuano, the tsunami wave could travel approximately 2000 m from the coastline. Line 1 in Constitución was assigned to identify the surveyed site by Imamura *et al.* (2010). According to their report, the tsunami runup height was 28.3 m at the site. Since the DEM used in this study is a global dataset that consists of 30-m grid cells, the elevation at the site is estimated to be approximately 23 m. The slope is estimated to be approximately 67% and is almost equivalent to that reported by Imamura *et al.* (2010), which is 63.5%.

As shown in Fig. 10, the inundation depth was measured at several sites in the three cities. The inundation depth along the beachfront street in Talcahuano was larger than 150 cm, but a depth of 55 cm was observed in its bystreet (site 4). Figure 11 summarizes the measurements in the three cities. The inundation depth is presented with

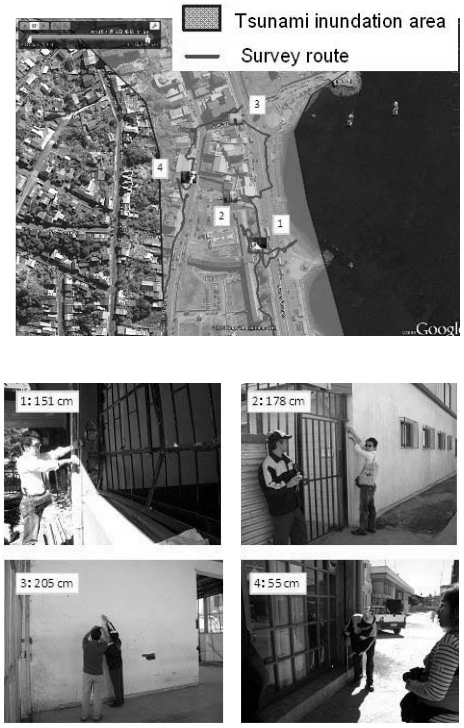

Figure 10 Measurement of tsunami inundation depth in Talcahuano

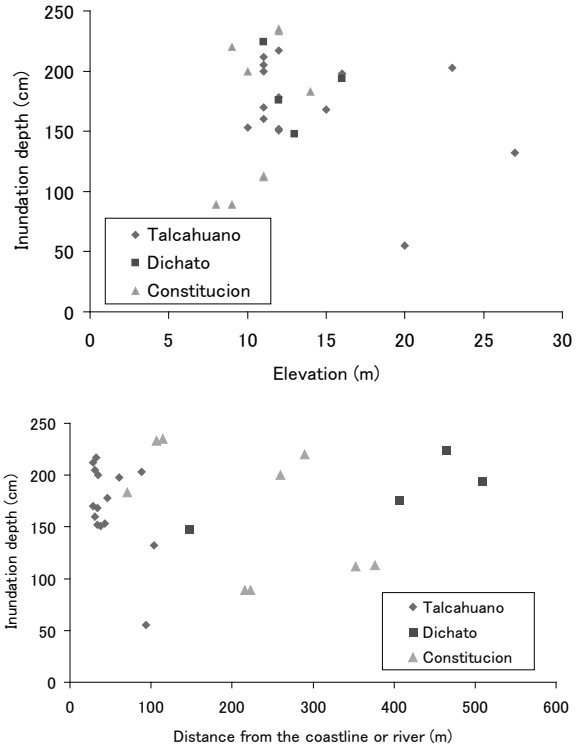

Figure 11 Summary of the measurement of tsunami inundation depth

respect to the elevation and the distance from the coastline. As for the results in Constitución, the records are shown with respect to the distance from the Maule River. A clear tendency is not seen in the relationship between the tsunami inundation depth and the elevation. The recorded depth in

Talcahuano and Constitución decreased with an increase in the distance from the coastline or the river; however, this tendency is not seen from the records in Dichato because of the insufficient number of measurements.

4. CONCLUSIONS

In this paper, the results of a field survey conducted after the 2010 Chile earthquake by the authors during April 2–8, 2010, are presented. The GIS dataset for the building damage in Talca was developed by establishing the location of the image file in terms of map projections. The usefulness of high-resolution satellite images to detect the building damage in Talca was investigated with the aid of the constructed GIS dataset. Moreover, the tsunami inundation maps published by ONEMI were georeferenced, and the characteristics of the inundated areas were evaluated in view of the elevation.

According to the relationship between the building damage levels and the lot areas, the mean of the areas associated with the non-damaged buildings was the smallest, while the mean of the areas associated with the buildings to be removed was the largest. In Talca, modern buildings that were designed according to the current codes suffered minor, repairable damage, while a large number of adobe and unreinforced masonry constructions, which were built in the 1960s–70s, suffered significant damage. On the basis of these circumstances, it has been speculated that the newer buildings may be constructed in relatively small lots; however, the construction periods are not available at this moment. According to the results of a visual damage inspection using pre- and post-event satellite images, it was concluded that the damaged buildings in Talca could not be appropriately detected because of their damage patterns and the quality of the post-event satellite image.

A comparison of the georeferenced tsunami-inundated areas with the elevations obtained from the ASTER GDEM revealed that the elevations in the inundated areas were lower than 20 m on the whole except for a certain area. A clear tendency was not seen in the relationship between the tsunami inundation depth and the elevation. The recorded inundation depth in Talcahuano and Constitución decreased with an increase in the distance from the coastline or the river.

These findings of our field survey after the 2010 Chile earthquake will be expanded in the earthquake and tsunami disaster mitigation technology in Peru through the SATREPS project.

Abstract: A new data logger is developed to use for microtremor and strong motion measurement. Especially, to know the deep structure, we need to handle microtremors in low frequency range: that is, lower than 1 Hz. In this frequency range, not only power of microtremors is very small, but the sensitivity of sensor is generally critical. A data logger with very low noise and high resolution is required for this purpose. Of course, we can find very expensive systems with high performance in noise and resolution, though, they are not so suitable for the microtremor survey, usually. We, thus, introduce some traditional but new features and complete a new system. Basic performances of the new systems are examined and discuss the aplicability to the observations in fields.

1. INTRODUCTION

To know deep ground structure, microtremor surveys are carried out. For this purpose, we need precise information with respect to phase for surface waves (for example, Okada (2003), Matsushima and Okada (1990), Morikawa *et al.* (2004)). Generally speaking, the power of microtremors in low frequency range is definitely smaller than ones in high frequency range. The sensor sensitivity, however, is very low in low frequency range and the S/N (signal-to-noise ratio) of analogue circuit is very bad because of 1/f noise, which is called sometime pink noise. This means that we have many difficulties to observe precisely microtremors in low frequency rawnge to apply them to the estimation of deep ground structure.

Recently, many kinds of small sensors are provided and many of them works based on sophisticated feedback system. They usually announce that they have flat response to very low frequency range, sometimes to DC (direct current, that is, 0 Hz). They have some analogue circuit for feedback system, thus, they cannot escape from the 1/f noise, especially, as signal level is very low.

To avoid the problems relating to 1/f noise, we may use a moving-coile-type (MC-type) sensor, which has classical and simple system. Because MC-type sensor does not have any noise caused by power supply and analogue circuits: this means 1/f noise free. If we use MC-type sensors, we can concentrate to develop a data logger with very low noise. Of course, we have to consider the high output impedance of MC-type sensors, but we may keep still advantages over feedback-type sensors, which is contaminated by the noise from analogue circuits in sensors.

Considering the above situations, we have tried to develop a new data logger with very low noise and high dynamic range, using three analogue-to-digital converter (ADC) for one singnal. Recently, the cost of ADC is decreased drastically for consumer use, thus, we can possibly complete this products with low costs. We discuss the performance of our new data logger: especially, the noise level in low frequency range.

2. BASIC CONCEPTS FOR DESIGN

Generally, a MC-type velocity sensor has enough sensitivity to vibration whose period is ten times to the natural period of its pendulum. Thus, the target performance of our data logger is set that it can keep enough S/N against microtremors with ten times longer period range than the natural period of a sensor.

For a MC-type velocity sensor, the response in longer period range than natural period of sensor decrease in 6 dB/oct. in a case where its damping ratio is set 0.7. This means that the sensitivity of sensor is half at twice period of natural period and about 1/10 of sensitivity at ten times of period. For example, in a case where we have a sensor with sensitivity of 1V/kine (kine = cm/s) and with natural period of 0.5 seconds, its sensitivity is only 0.1

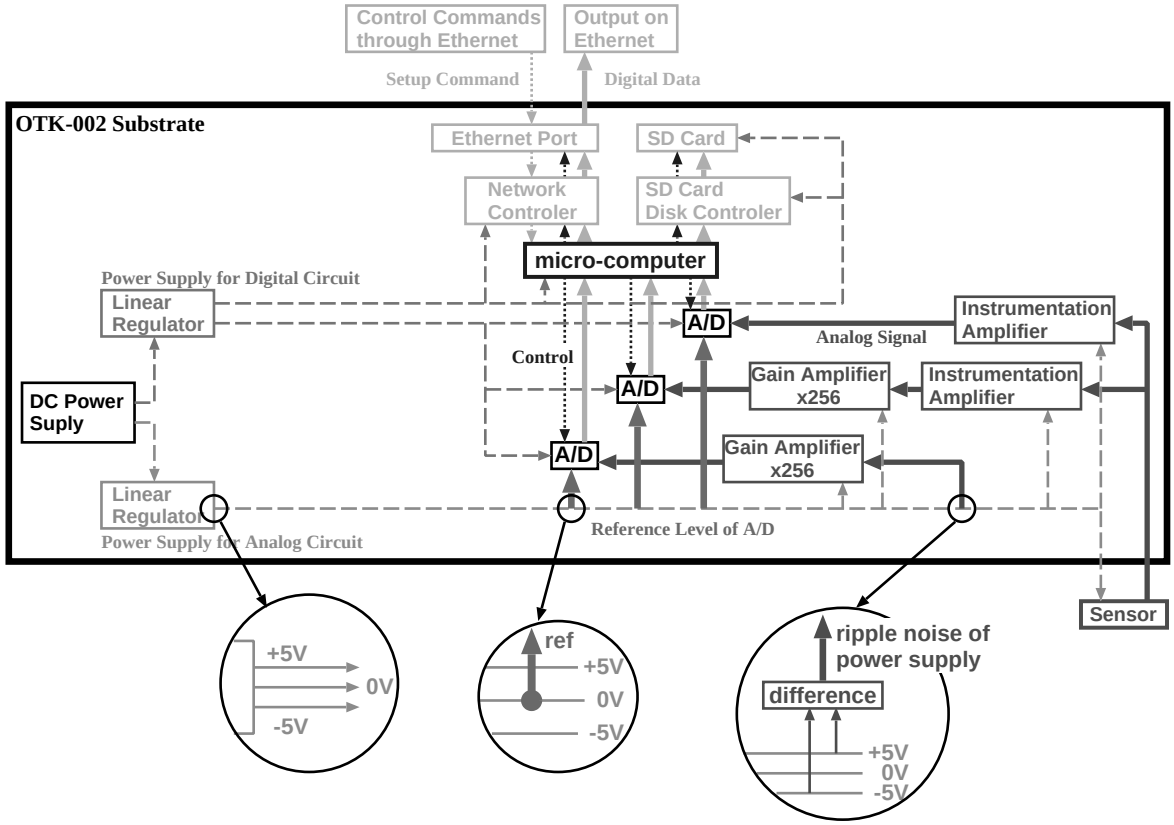

Figure 1 Block diagram of a new data logger. Colors denote different properties of lines such as signals, power supplys, and so on.

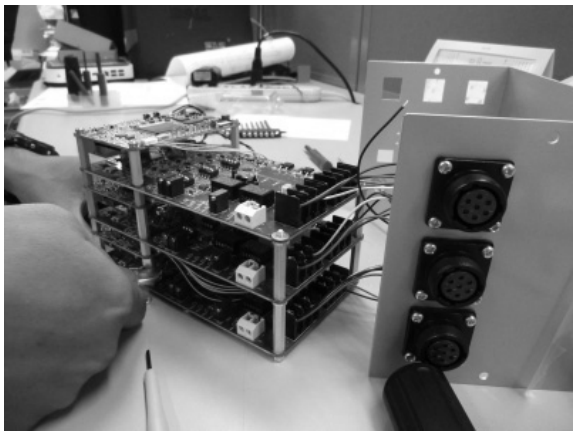
V/kine at 5 seconds. Power of microtremors depends on ground structure, though, sometimes we may have to observe the microtremors whose maximum value is only 0.5 mkine ($= 0.5 \times 10^{-3}$ cm/s) on slightly hard soil ground, for example. In this case, we have to log the signal of only 0.5 mV. This value must be obtained in the most sensitive range for sensors: in the above example, it should be around 0.5-second microtremors. Thus, we have to record precisely a signal with at most 100 μV at 5-second microtremors. This means that enough S/N is required to 10-μV signal for 5-second microtremors.

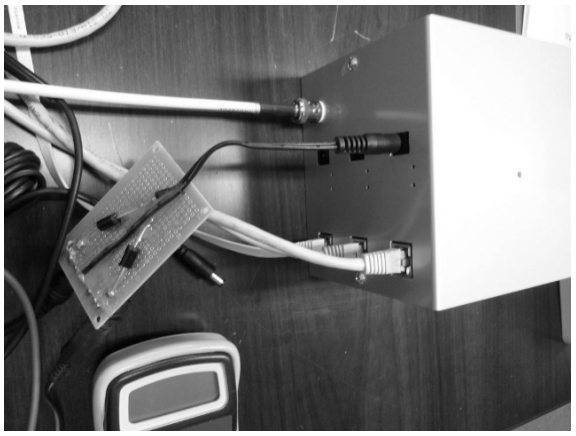
On the other hand, in a case where the input gate voltage to ADC is $\pm$10 V and word length is 24 bit, the minimum value to represent the signal is about 1 μV. Thus, if we use 24bit ADC to manage $\pm$10V, the signal of microtremors in long period range, such as 5 seconds, may be contaminated by quantized noise. Furthermore, since the effective resolution of 24-bit ADC is less than 22 bit, we cannot record precisely 10-μV signal.

To consider the above many problems, we decided our concepts for the design of a new data logger as follows:



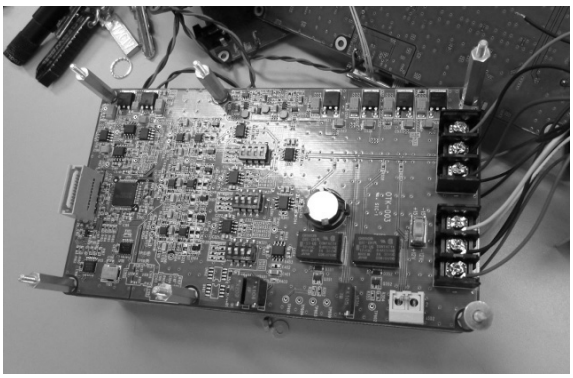
- hybrid system by means of three 24-bit ADCs,
  - direct signal (hereafter, 'x1 signal') to first ADC of three,
  - 256 times gained signal ('x256 signal') to second ADC, and
  - ripple noise of power supply ('x256 power') with 256 times gain to thrid ADC,
- using distinct series-type regulators for analogue and digital circuits to reduce noise from power supply.
- considering the operability and general versatility, power supply circuits for feedback-type sensors and a special circuits to calibrate a MC-type sensor are mounted.

The block diagram of trial production is shown in Figure 1. This figure shows a substrate for one signal component.



The originality of this logger is located at the three ADCs as shown in the figure. Especially, recording the ripple noise of power supply is the new idea to improve the S/N of system. The record of ripple noise of power supply will play an important role as the reference of signals.

ADC requires a reference level of 0V and the ground line (GND) for analogue power supply is used as reference. This reference level fluctuates randomely and degradation of S/N is caused by this fluctuations mainly. This fluctuations are inputted to third ADC as differences of positive and negative power supply lines.



The thrid ADC to record ripple noise of power supply can contribute to simplify the system. Since the data logger records ripple noise always, we can monitor the condition of system. We do not need to mount any temperature compensation circuits and some other specially designed power supply circuits: as a result, quality of the recorded signal is independent of power supply unit and we do not care types of power supply. To obtain the good

Figure 2 Details of the new data logger

S/N records, we just remove the recorded ripples from the records of signal.

The parallel recoding of signal with different gain is conventional idea to keep large dynamic range. This type of data logger could be found in many of classical analogue data recorders, though, recently, we can find very few for digital loggers. However, this type of logging system is reasonable recently, because the cost of ADC is drastically reduced and ADC can be synchronized readily using clock signal from GPS (global positioning system). Considering these situations, we decided use three ADCs for one signal.

In a case where the level of x256 signal is enough large and saturate the upper level of ADC, we can use the data of x1 signal. From this, this system has apparently 32 bit resolution, that is, 24 + 8. Of course, we have to consider the loss of efficient resolution of ADC such as about 22 bit resolution when 10ms of sampling interval. However, this is enough large dynamic range to record the microtremors and strong ground motions.

We would like to emphasize again that the points of this logger is recoding of ripple noise of power supply. This idea comes true the amazing S/N, dynamic range, and low cost.

3. TRIAL PRODUCTION OF DATA LOGGER

Following the concepts descrived in the previous section, a trial production is made. To reduce the cost, we used some products developed for IT-Kyoshin Kei (IT-Kyoshin Kei Research Group, 2010): a substrate for microprocessor to control the system, circuit design for anti-aliasing filter, and so on. On the other hand, instrumentation and gain amplifier circuits at input stage and power supply circuits are newly developed.

To record three components of microtremors and/or strong ground motion, nine-channel ADCs are required, though the microprocessor to control system has not enough power to manage all the nine channels. Thus, we apply three substrates for three components of signals, which are developed for IT-Kyoshin Kei and include four-channel ADC and its controller.

Details of a traial production are shown in Figure 2. System for one component of signal consists of two substrates: the one is large and the other is small. For three components of data, totally six substrates are used as shown in Figure 2(a).

Large substrate mounts input stage and ADC (see Figure 2(c)). First, the signal passes an instrumentation amplifier to compensate the input impedance and is inputted into gain amplifier with 256 times. After that, the signal

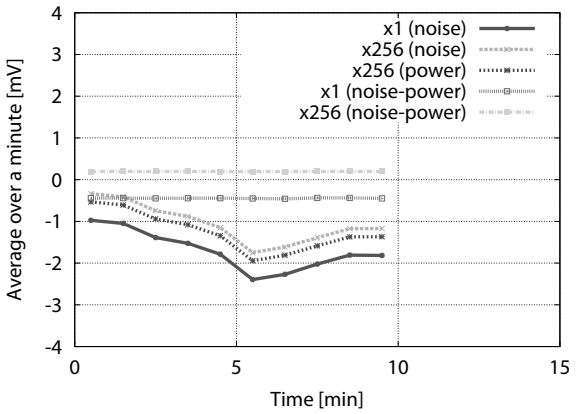

Figure 3 One-minute averages of self-noise. To obtain this data, we short the input connectors and average the data for each one minute. 'x1' and 'x256' stand for different gains, '(noise)' and '(power)' for self-noise and ripple noise of power supply, respectively. Furthermore, '(noise-power)' denotes the data without the ripple noise, which can be caluculated from the self-noise ('noise') minus ripple noise ('power'). '-' in 'noise-power' means minus. Large drift of mean values are observed for 'noise' and 'power', but 'noise-power' is completely corrected and stable.

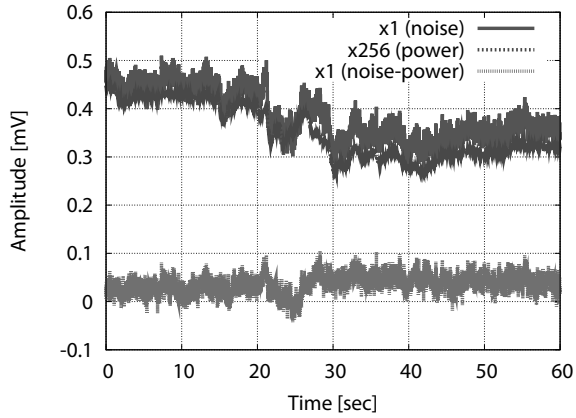
goes through the Bessel filter with second order and 40-Hz cut off frequency for anti-aliasing and moves to ADC. Since the input stage is designed as fully balanced circuit (differential circuit), the signal is received as three lines, that is, positive, negative, and ground lines. This substrate has also own power supply system, whose location on the substrate is decided considering influences to the analogue signals.

Small substrate includes microprocessor to control system: writing data to SD card, receiving command through the ethernet controller, communicating ADC and GPS clock signal generator, and so on (see Figure 2 (d)). The GPS receiver unit is also shown at right-upper side in the photo. Three microprocessors follow this GPS clock signal and are synchronized mutually.

This system works by 12V DC power supply and spends 2100-mA (700 mA x 3) current at most (see Figure 2(b)). In a case of standalone mode, that is, no communications through network and connected to MC-type sensors, it can save much power and spends about 1200 mA (400 mA x 3).

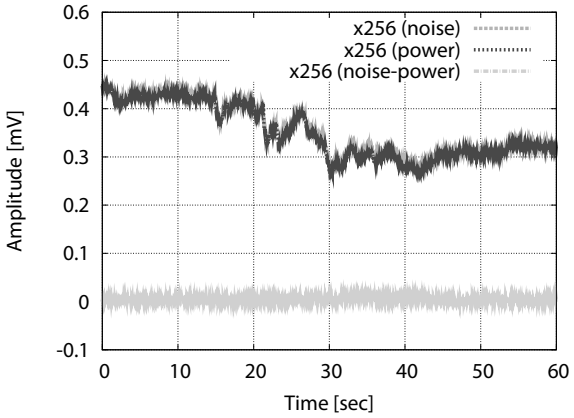
4. PERFORMANCE TEST

To observe the self-noise of system and discuss S/N, the input connectors are shorted and records signals. For observation, we have to adjust the zero-level using trimmers, however, the zero-level is not stable, because of temperature and some other reasons. One-minute averages of self-noise are shown in Figure 3. In this figure, the vertical axis is shown in mV and the upper three lines in legend show x1 signal, x256 signal, and x256 power, respectively. The lower two lines show the data "x1 signal minus (x256 power)/256" and "x256 signal minus x256 power." In this figure, we use a word 'noise' instead of 'signal,' because we deal with the self-noise.



The large drifts are observed for '(noise)' and '(power)': the level of drifts is a few mV in peak-to-peak. This means that we cannot observe any signal of microtremors, whose level must be less than a mV. In this case, self-noise should be same as the ripple noise of power supply and, then, '(noise-power)' should be zero always. As shown in Figure 3, the fluctuation of '(noise-power)' is very small without small offset. We do not care this kind of offset, which depends on the adjustments of the trimmers, because we can remove it easily using numerical analysis.

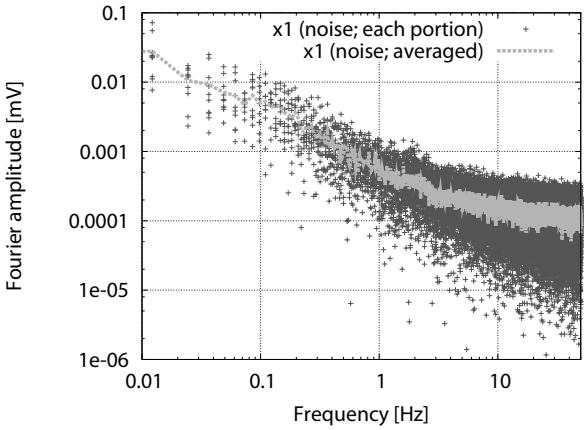
Figure 4 shows time histories of self-noise. In this case, 'x256 noise' should coinside with 'x256 power', however, small diferences are observed as shown in Figure 4(b). 'x256 noise - x256 power' is very stable and the noise with long period is almost removed. 'x1 noise - (x256 power)/256' is also stable but we can find much noise in short period, which may be caused by a kind of quantitave noise.



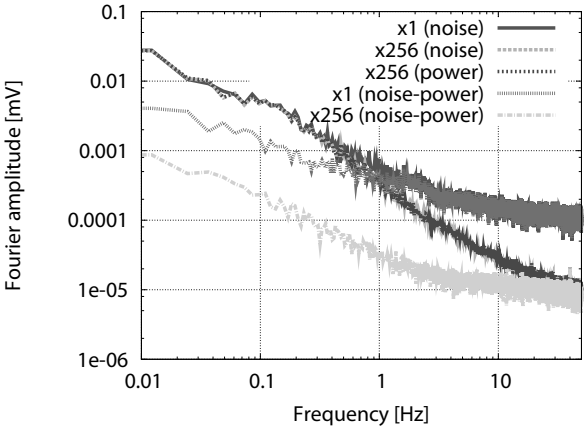
Next, we calculate the Fourier spectrum of self-noise as shown in Figure 5. To calculate the Fourier amplitudes, we use 80-second durations and averaging the 'raw' spectra. The vertical axis is not normalized by the duration and, then, the dimension is same as time histories. In Figure 5(a), red marks show the 'raw' spectra for each duration, and green line is their average. 1/f noise can be observed clearly for 'x1 noise' in lower frequency range than 1 Hz. However, the noise level is flat and horizontal, which is like a white noise, in higher frequency range than a few Hz. This may be caused by quantitative noise of ADC, because the self-noise level is very small and its amplitude cannot reach 8 bit.

The averaged Fourier amplitudes for another data are shown in Figure 5(b). It is observed that 'x256 power' shows the properties of 1/f in lower frequency range than 10 Hz and 'x256 noise - x256 power' shows 1/30 to 1/50 lower level than 'x256 noise': that is, the noise floor of 'x256 noise' is reduced to about 30 to 36 dB (5 to 6 bits in digital). This means that 'x256 power' works very well to reduce the noise in lower frequency range.

Since the amplitude of 'x256 noise - x256 power' is about a few μV, the system covers the dynamic range of 126 dB (21 bits) using only 'x256 signal'. Thus, we use the low gain data, which is 'x1 signal', we can keep huge dynammic range 174 dB (29 bits = 21 + 8 bits), overall. Unfortunately, we cannot converge the high (x256) and low (x1) gain signals because of the small differences of offset and drifts between high and low gain signals. As a result, we have realized 29-bit dynamic range and 24-bit resolution. It should be noted that the above property includes perfomance of analogue circuits, namely, this is not a theoretical specification of ADC.



(a) low gain (x1)



(b) high gain (x256)

Figure 4 Time histories of self-noise of the data logger. The colors in legend corresponds to Figure 3. After removing the ripple noise of power supply, which is '(power)', the fluctuations with long period are disappeared and the data is stable.

(a) Fourier amplitude of direct (x1) input of self-noise.

(b) Fourier amplitudes of self-noise under different conditons.

Figure 5 Fourier amplitude of self-noise of the data logger. The vertical axis is not normalized by the duration of data. Thus, the dimention of vertical axis is same as the time histories. In panel (a), red marks are 'raw' spectra for 80-second duration and green line is averaged spectrum. In panel (b), the meanings of colors and legend are same as Figure 3.

5. CONCLUSIONS

We have developed a new data logger with huge dynamic range and very low noise. In this system, we apply three-channel ADC for one component of signal to record low and high gain signals and ripple noise of power supply. It is observed that the thrid ADC to record the ripple noise of power supply contributes to reduce the 1/f noise, through the performance test of the logger.

Consequently, the noise is reduced to about 30 to 36 dB (5 to 6 bits) and the overall dynamic range is more than 170 dB (29 bits). Furthermore, we apply the consumer-use ADC and reduce the cost.

For further developements, we try to use this new data logger under the various situations and examine its performance.

Abstract: The source rupture area of the 1707 Hoei earthquake which occurred along the Nankai Trough, off southwestern Japan, should be extend further, to the Hyuga-nada, more than 70 km beyond the currently accepted location at the westernmost end of Shikoku in order to explain many recent findings such as those for geodetic data and geological investigations in coastal area and large tsunami in Kyushu, Japan. Numerical simulation of the tsunami using a new source-rupture model for the Hoei earthquake explains the distribution of the very high tsunami observed along the Pacific coast from western Shikoku to Kyushu more consistently with tsunami run-up into Ryujin Lake at Kyushu. It is known that the tsunamis from the 684 Tenmu, 1361 Shokei, and 1707 Hoei earthquakes deposited sand in Ryujin Lake, but lesser tsunamis from other earthquakes were unable to reach the lake. This irregular behavior suggests that, in addition to the regular Nankai Trough earthquake cycle of 100-150 years, there may be a hyper-earthquake cycle of 300-500 years. These greater earthquakes produce the larger tsunamis from western Shikoku to Kyushu than we expect for future Nankai Trough earthquake.

1. INTRODUCTION

Great inter-plate earthquakes have occurred at the Nankai Trough at a recurrence interval of approximately 100 to 150 years due to the subduction of the Philippine Sea plate beneath southwestern Japan (Fig.1).

In the recorded history of the Nankai Trough earthquakes the 1707 Hoei earthquake (hereafter called the Hoei earthquake) was the largest shock in modern Japanese history. It killed more than 20,000 people due to its strong ground motion and the tsunami associated with the earthquake. The fault rupture area of the Hoei earthquake has been thought to spread from Suruga Bay to the westernmost end of Shikoku, which is often referred as a worst-case scenario for the Nankai Trough earthquake.

The source rupture histories of the recent 1944 Tonankai and 1946 Nankai earthquakes were examined extensively based on the analysis of modern instrumental data, such as tide gauge records of tsunami waveforms, seismograms, and geodetic data. However, the source model of the historical Hoei earthquake in 1707, on the other hand, have mostly been deduced from descriptions of earthquake phenomenon in ancient documents such as shaking felt by humans, damage to houses, and visual measurements of tsunami inundation or tsunami run-up height, and pattern of ground elevation an subsidences.

Recently, geological surveys of earthquake-related lacustrine sediment in seashore lakes along the Pacific coast from Shikoku to Kyushu endeavor to clarify the tsunami history of the historical and pre-historical Nankai Trough earthquakes. Ryujin Lake is one such onshore lake that has tsunami-induced oceanic deposits (hereafter called tsunami

lakes), located along the coast of the Hyuga-nada in

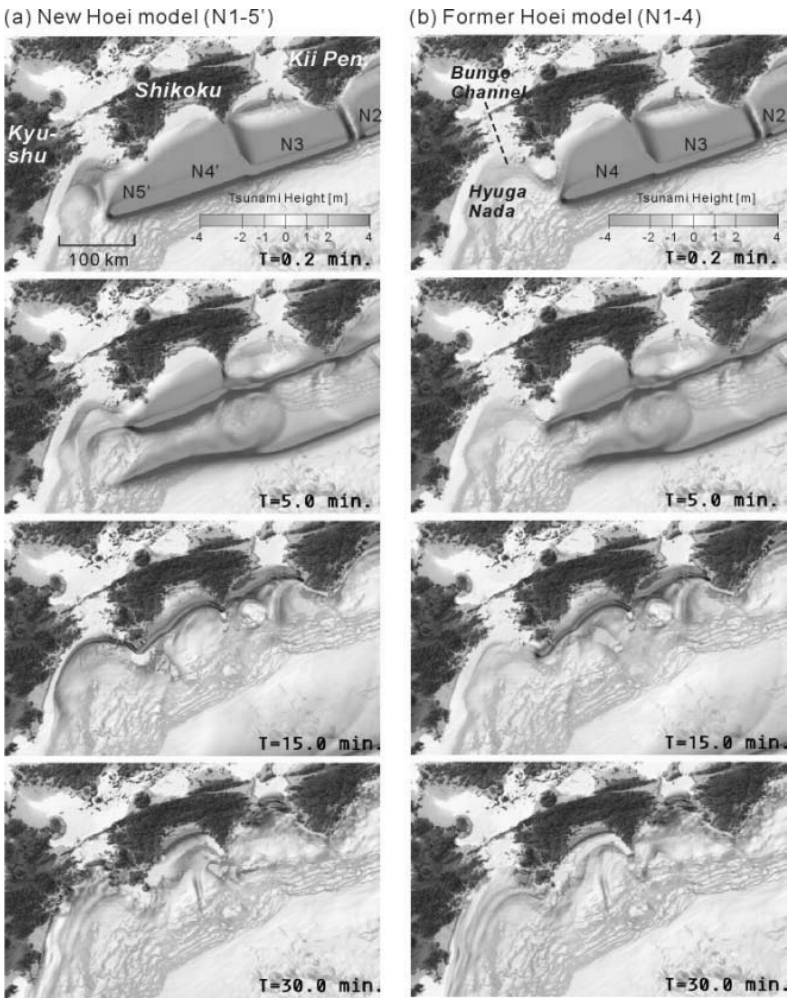

Figure 4 Snapshots of tsunami propagation from the Kii Peninsula to Kyushu (a) New Hoei earthquake model with fault segments N1 to N5 (b) former Hoei model (after An'naka et al., 2003) with fault segments N1 to N4.

Kyushu. Ryujin Lake has a thick cover of marine deposits, including coarse-grained sea sands and marine sediments containing oceanic plankton carried by Nankai Trough earthquake, not every 100 to 150 years, but were only deposited in the 1707 Hoei earthquake, the 1361 Shohei earthquake, and the 684 Tenmu earthquakes, probably associated with larger tsunamis than usual. Also, recent findings in the historical documents claim that the height of the tsunami during the Hoei earthquake at the village of Yonouzu, near Ryujin Lake, was more than 10 m, which is very much larger than regular tsunamis associated with the earthquake.

The data from the Japanese GEONET nation-wide GPS network illustrating the current ground deformation pattern of undergoing recovery process of post- Nankai Trough earthquake and studies on inter-plate coupling along the Nankai Trough using this data reveal strong interplate coupling along the Nankai Trough extends to Hyuga-nada

Following these new findings and supporting instrumental data, we will reexamine the source model for the Hoei earthquake and extended the source-rupture area 70 km eastward to the Hyuga-nada from the westernmost end of Shikoku.

We will demonstrated by tsunami simulation that our new source Hoei earthquake source model can explains large tsunami observed in Kyushu and tsunami inundation into Ryujin Lake more consistently than previous models.

2. TSUNAMI SIMULATION FOR THE 1707 HOEI EARTHQUAKE

We first conducted tsunami simulation for the Hoei earthquake using a source model of An'naka et al. [2003] which consists of four fault segments (N1 to N4) extending from Suruga Bay to the westernmost end of Shikoku, a total length of 605 km.

Vertical ground deformation due to fault rupture of the N1 through N4 fault segments are calculated using the program following Mansinha and Smylie [1975]. The result show large ground upheavals of up to 2 m above the shallowest end of the source fault segment on the trench side

and some of upheaval can be found on land, including at Cape Muroto, Cape Shiono, and along the coast of Suruga Bay. On the other hand, large surface subsidence of as much as 2 m is found widely on land in a narrow belt zone extending from Shizuoka to the westernmost end of Shikoku. These are consistent with the observed ground deformation pattern of the Hoei earthquake.

Using the results of the coseismic ground deformation pattern, we conducted a tsunami simulation. The area of the simulation is 540 km by 860 km which has been discritized by a nested mesh model that connects gradually 30 m, 90 m, and 270 m mesh model to allow efficient simulation of the tsunami in heterogeneous bathymetry. The bathymetric model was provided by the Central Disaster Mitigation Council, Cabinet Office, Government of Japan. Then propagation of the tsunami and tsunami run-up are calculated based on a finite-difference method (FDM) of a nonlinear, long-wave tsunami model [Goto and Ogawa, 1997].

Snapshots of tsunami propagation obtained from the simulation are illustrated in fig. 2 at time T = 1, 5, 10, 20, 40, and 80 min from the time the earthquake started. The snapshots shows that the radiation of tsunamis from rectangular fault sources is very strong in the direction perpendicular to the trough axis, while it is very weak in the direction parallel to the trough. As the tsunami approaches the shore, its speed decreases suddenly and its height increases very drastically. The onshore height of the tsunami, more than 8 m, is several times larger than the height of the initial tsunami above the source area along the Pacific coast from the westernmost end of Shikoku to Hyuga-nada. The tsunami lasts for several tens of minutes after the earthquake and a number of tsunami trains are captured within Tosa Bay.

Distribution of maximum simulated tsunami height is illustrated in fig. 3. From historical records, tsunami heights of 9 m at Tosa Shimizu and Ashizuri Cape and more than 4 m along the coast from Ashizuri Cape to Hyuga-nada are known to have occurred. The simulated maximum tsunami height along the Pacific coast from Tosa Bay to Suruga Bay generally agrees well with observed tsunami run-up during the Hoei earthquake [e.g., Hatori, 1974, 1985; Murakami et al., 1996]. However, the height of the simulated tsunami from western Shikoku to Hyuga-nada in Kyushu is less than half of the actual height observed. For example, historical archives document that at Yonouzu village, at the northern end of Hyuga-nada, the tsunami was more than 10 m and killed 18 people [Chida et al, 2003. Yet the simulated tsunami height at Yonouzu is less than 4 m, much shorter than the tsunami experienced with the Hoei earthquake.

3. REVISION OF THE SOURCE MODEL FOR THE 1707 HOEI EARTHQUAKE

In order to better explain the height of the Hoei earthquake tsunami from Cape Ashizuri to Hyuga-nada, we revised the present source model of the Hoei earthquake developed by An'naka et al. [2003] based on the findings of a number of recent geodetic and geological investigations of the Nankai Trough.

Ten years of data from the nationwide GEONET GPS network illustrates pattern of vertical ground deformation of 2 mm/year has occurred on land from Enshu-nada to Hyuga-nada. This pattern of vertical ground movement is considered to illustrate the process of recovery of ground surface deformation due to the Nankai Trough earthquakes. We also consulted recent studies on the spatial distribution of inter-plate coupling rates along the Nankai Trough [e.g., Hashimoto, 2009] based on the inversion of the GEONET data. It shows that an area of strong inter-plate coupling with high coupling ratios is found from Suruga Bay to Hyuga-nada, more than 100 km beyond the westernmost end of Shikoku which we have considered the evidence that seismic energy is now accumulating to cause a large earthquake in the future.

Following these new findings, we revised the source-rupture model for the Hoei earthquake and extended the border of the Hoei earthquake source segments from the westernmost end of Shikoku to Hyuga-nada, where strong inter-plate coupling has been found.

We set a 70 km by 120 km subfault segment, N5, on the west of the N4 subfault segment and extended the source rupture area of the Hoei earthquake to Hyuga-nada. The ground surface deformation pattern derived using subfaults N1 to N5 agrees well with our expectation of gentle (40 cm) ground subsidence in the area around Yonozu and Ryujin Lake, where large tsunami attacked, and some subsidence of the ground surface at Cape Ashizuri as noted by Kawasumi (1950). It also corresponds well to the present ground elevation field derived from the GEONET.

We then conducted a tsunami simulation using the revised source model of the Hoei earthquake to see the contribution of the N5 subfault segment in increasing simulated tsunami height along the coast from Shikoku to Kyushu. Snapshots of tsunami propagation are compared in fig. 4 with that for the former source model. Maximum simulated tsunami heights for the new model are compared with those of the former model in fig.3. The comparison clearly demonstrates the development of a larger tsunami with heights of 5 m to over 10 m over a wide area along the Pacific coast from the westernmost end of Shikoku to Hyuga-nada due to the N5 subfault. The height of the tsunami due to the N5 fault is very strong to spread large tsunami wavefront from Cape Ashizuri to Hyuga-nada.

The maximum tsunami height along the coast near Ryujin Lake as calculated by the present simulation is 6 m, while it is a maximum of 2 m for the former Hoei earthquake source model. Thus, larger tsunami at Yonozu and tsunami run-up into Ryujin Lake might occur when the Nankai Trough fault rupture extends to Hyuga-nada, but not during events like the 1854 Ansei Nankai and 1946 Showa Nankai earthquakes, in which the fault rupture did not extend past the westernmost end of Shikoku. Our newly simulated tsunami height of approximately 6 m but not as high as 10 m at Ryujin Lake also confirms the interpretation

of Okamura et al. [2004] that larger tsunami inundation occurred in the Ryujin lake though narrow channel connecting lake and sea but tsunami did not overtopping of beach hills that are 10 m high.

4. CONCLUSION

Of the series of repeating megathrust earthquakes in the Nankai Trough, the Hoei earthquake is considered to be the most damaging, with its linkage of Tokai, Tonankai and the Nankai earthquakes, and fault ruptures extending from Suruga Bay to the westernmost end of Shikoku, about 600 km in length [An'naka et al., 2003].

However, the recent discovery of the thick cover of tsunami-induced deposits caused by the Hoei earthquake has overturned our understanding. The existence of the tsunami deposits in the onshore lakes in Kyushu was not well explained by the expected ground deformation pattern produced by the former Hoei earthquake source model where the fault rupture stopped at the westernmost end of Shikoku. The source model also failed to explain the larger tsunami experienced during the Hoei earthquake from Cape Ashizuri to Hyuga-nada.

An inferred property of the present crustal deformation pattern illustrated by the GEONET GPS measurements and a number of studies on inter-plate coupling along the Nankai Trough subduction zone based on the GPS data indicate that Hyuga-nada may also be in the area of the Nankai Trough earthquake nucleation zone. Following these new geological and geodetic findings, we revised the source model of the Hoei earthquake by introducing a new subfault segment at Hyuga-nada on the western side of Nankai earthquake segment.

We succeeded in explaining development of the large tsunami from Cape Ashizuri to Hyuga-nada with maximum tsunami heights of 5 to 10 m that attack along the Pacific coast from the westernmost end of Shikoku to Hyuga-nada. This agrees with the heights of tsunamis observed along the Pacific coast from Cape Ashizuri to Hyuga-nada during the Hoei earthquake [Hatori, 1974, 1985; Murakami, 1996] very consistently.

The extension of the source rupture area to Hyuga-nada would produce increased shaking in Kyushu. Exactly what the intensity was in Kyushu in 1707 is unclear; we are unaware of any historical documents that permit a meaningful comparison of intensities of the 1707 and 1856 earthquakes.

The linkage process between different subfaults in Nankai Trough earthquakes of more than 700 km and described by at least five fault segments may contribute significantly to the severity of the disaster, especially the tsunamis. Researchers have claimed that delayed rupture between subfaults amplifies tsunami height over a wide area due to overlap of individual tsunamis from different fault segments [Kawata et al., 2003; Imai et al., 2010]. We should be prepared for a diversity of rupture processes during future earthquakes along the Nankai Trough.

Finally, this study suggests that earthquake rupture extent along the Nankai Trough may not be as limited as previously described: as combinations of subfaults to produce Nankai, Tonankai, or Tokai earthquakes. The Hoei earthquake was a much larger event in which rupture spread as far as Hyuga-nada. Such larger events do not occur during the regular Nankai Trouh earthquake cycle of 100-150 years, but may occur in a hyper-earthquake cycle of 300 to 500 years. The larger tsunami and tsunami deposits at Ryujin Lake in Kyushu left by large tsunamis from the 684 Tenmu, 1361 Shohei, and 1707 Hoei earthquakes, attest to such a hyper-earthquake cycle.

Abstract: A magnitude M_s=8.0 earthquake occurred on May 12, 2008 in Sichuan, China. Surface rupture and severe damage were observed during the great event. Liquefaction also reported in the Chengdu plain. The nonlinear soil response should be occurred during the strong shaking of this event. During the Wenchuan earthquake, National Strong Motion Observation Network System of China obtained a large number of acceleration records from the main shock (~ 460 free-field strong motion stations). In this study, the strong motion records are used to identify the nonlinear site effects during the 2008 Wenchuan, China earthquake. The horizontal-to-vertical spectral ratio has become popular in study of the site effect and the determination of the predominant period of a site. Wen et al. (2006a) extended this method to identify the nonlinear soil response during strong motion events. Due to only the main shock records are available now, we can identify the soil response is linear or nonlinear based on variation of the predominant frequency with time using the moving window spectral ratio method.

1. INTRODUCTION

Nonlinear site effects, such as an increase in damping and reduction in shear wave velocity as input strength increases, are commonly recognized in the dynamic loading of soils from geotechnical models. During the findings of recent years indicate that nonlinear site effects are more common than previously recognized in strong-motion seismology (Beresnev and Wen, 1996). Direct seismological evidences of nonlinear site effects were reported by using the spectral ratio techniques of soil-to-rock or surface-to-borehole station pair (Wen *et al.* 1994, 1995; Beresnev *et al.* 1995a, 1995b).

A magnitude M_s=8.0 Wenchuan, China earthquake occurred at 14:28 of May 12, 2008 (Local time). It caused 69,197 people killed and 215,000 buildings totally damaged. The surface rupture along the Yingshow-Beichuan fault and Kuanshian-Chiangyio fault (Longmenshan fault system) are about 240 and 70 km length, respectively. During the Wenchuan earthquake, National Strong Motion Observation Network System of China obtained a large number of acceleration records from the main shock (~ 400 free-field strong motion stations). Therefore, a lot of high quality data had been recorded that triggered by this disaster event (Figure 1). The Wenchuan earthquake not only directly caused heavy damages on the structure and huge human life loss near the epicenter area, but also induced the secondary damages to the buildings in that region (Zhang et al. 2008). From the field surveys, many places, such as Chendo, Deryang, and Menyang area (Figure 2, Yuan et al. 2009; Du and Xing 2010), show the soil liquefaction were related to local geology and intensity. It implies that the nonlinear soil response should occur pervasively in those areas. The normal spectral ratio method of a two-station pair can not apply to this large alluvium area. In this study, the horizontal-to-vertical (H/V) method was used to study the nonlinear site response during the 2008 Wenchuan, China earthquake.

2. METHOD USED TO IDENTIFY NONLINEAR SITE RESPONSE

Nonlinear site effects, such as an increase in damping and reduction in shear wave velocity as input strength increases, are commonly recognized in the dynamic loading of soils from geotechnical models. During the findings of recent years indicate that nonlinear site effects are more common than previously recognized in strong-motion seismology. Direct seismological evidences of nonlinear site effects were reported by using spectral ratio techniques (Wen 1994). Nakamura (1989) proposed a hypothesis that microtremor site effects can be determined by simply evaluating spectral ratio of horizontal versus vertical components of motion observed at the same site. Lermo and Chávez-García (1993) shows that this method can use to

earthquake record for studying the site effect. Wen *et al.* (2006a) using the horizontal-to-vertical spectral ratio method to identify nonlinear site response. The results show the applicability of H/V technique for nonlinear site response identification. In this study, we calculated the H/V ratios of the Wenchuan mainshock record at each station and compared the variation of the predominant frequency with time using the moving window spectral ratio method to identify the site response at each station during the 2008 Wenchuan, China earthquake.

3. RESULTS OF THE NONLINEAR SITE RESPONSE ANALYSIS

3.1 H/V Ratios in the Liquefaction Area

Many places had observed soil liquefaction after the 2008 Wenchuan earthquake (Yuan et al. 2009; Du and Xing 2010). Figure 3a shows the time-frequency H/V spectra of the near-fault station 51SFB. The ratio shows clearly de-amplification and dominant frequency shift effect in the strong motion portion. The ratio of Window C (Figure 3b), with PGA = 23.31 gals, seems move back to linear response.

Station 51WCW (汶川臥龍) recorded very high peak ground acceleration (953.79 gals on Window B). Figure 4a shows the time-frequency H/V spectra of 51WCW. The dominant frequency shift to lower frequency is clearly shown in the results of the 2048 points window for the two strong motion portions (Windows B and D). For the latter portion of weak motion part, the dominant frequency shift back to higher frequency (Figure 4b).

After analyzed the data of the stations in Figure 1b during the Wenchuan, China earthquake, the results were shown in Figure 5. Red symbols show the station has strong nonlinearity, purple symbols show the station has weak nonlinearity, blue symbols show the station did not have nonlinear effect. The results show that the nonlinear site effects existed in most near fault area. The liquefaction areas are within the nonlinear soil response area (Figure 6).

3.2 Quantitative analysis of nonlinearity

In previous study, the strong and weak motion's H/V spectral ratios are compared to show the nonlinearity qualitatively. Some stations are not easy to clarify it had nonlinear response or not. So, Wen et al. (2006b) identify the nonlinearity, quantitatively, by the deviation between the H/V spectral ratios of strong and weak motions. Which was calculated as follow:

$$d(f) = \frac{s(f) - w(f)}{\sigma(f)} * 100\% \qquad (1)$$

where *s(f)* is the H/V ratio of the strong motion event, *w(f)* and $\sigma(f)$ are H/V ratio of the weak motion event and its standard deviation. Noguchi and Sasatani (2008) proposed to use the quantitative index of nonlinear site response DNL (degree of nonlinear site response) defined as follow:

$$\mathrm{DNL} = \sum \left| \log\left(\frac{R_{strong}(f)}{R_{weak}(f)} \right) \right| \bullet \Delta f \qquad (2)$$

where R_{strong} and R_{weak} are H/V spectral ratio of the strong and weak motions, and sum it from 0.5 to 20 Hz frequency band.

Due to only the main shock data are available now, so as that shown in Figures 3b and 4b, the different windows from the main shock records are used to quantitatively analyze the H/V ratios of strong and weak motion. The DNL values are calculated from the strong motion window (e.g. window B in Figures 3 and 4) and the weak motion window (final later portion as window C in Figure 3). Figure 7 compare the DNL values and the PGAs on window B for that station. It clearly show that when PGA greater than about 100 gal, the strong motion records will show nonlinear effect.

4. CONCLUSIONS AND DISCUSSIONS

Liquefaction hazard occurred in the epicenter area during the May 12, 2008 Wenchuan, China earthquake. In this study, the horizontal-to-vertical spectral ratio method is used to identify the nonlinear site effects during the earthquake. The results show that the nonlinear site effects existed in most near fault area. The liquefaction areas are within the nonlinear soil response area. The DNL between the H/V ratios of strong motion and weak motion are calculated in the frequency band of 0.5~20 Hz. The DNL value has positive relationship with PGA value. The stations, with nonlinear site response, seems on the range of DNL > 3.0 and PGA > 100 gal. The DNL analysis use the strong and weak motion portion on the same record, after receiving the weak motion record from the small magnitude after shocks, we can check the results again.

Due to the site condition of each strong motion station is not clear at the moment, only simply separated as soil and rock site. If it can have more detail information, for example the Vs30, then we can compare the DNL value with Vs30. This information will be useful for engineering application.

yamanaka@depe.titech.ac.jp

Abstract: We proposed a waveform inversion to deduce a 2D S-wave velocity profile for shallow soil layers from SH-wave data obtained in a refraction survey. The waveform inversion method is based on the approach by Takekoshi and Yamanaka (2009). Preprocessing of SH wave data is included in our methods to eliminate the effects of source time function for a wave generator in the refraction seismics. The wave data at each site are deconvolved using the observed data at a reference station. The misfit function is defined as differences between the calculated and observed waveforms after the deconvolution process and it is minimized with a hybrid heuristic search method. Theoretical SH-wave is generated from a finite difference computation of SH-wave propagating in a 2D inhomogeneous media. We conducted numerical experiments using synthetic SH-wave data in two shallow soil models. The inversions of the synthetic data could reconstruct the true models very well indicating a validity of the method. We, then, applied the waveform inversion to actual SH-wave data obtained at 8 stations in a shallow refraction exploration. The obtained 2D profile is similar to that from a conventional travel time analysis.

1. INTRODUCTION

S-wave velocity distribution in ground is one of the important factors to estimate local site amplification at a site covered with soft soils, such as basin and reclaimed area. Several kinds of S-wave velocity measurements are available for the purpose of estimation of site amplification. One of the major methods is PS-logging using bore measurements. Although we can determine an accurate S-wave velocity distribution from the logging, surveying cost would be more expensive than surface explorations techniques. The microtremor exploration is one of the important techniques to deduce S-wave velocity profile of soils with low cost, and has been applied in various kinds of S-wave exploration in earthquake engineering (e.g., Arai and Tokimatsu et al., 2005,). The microtremor technique is used to determine a 1D profile of S-wave velocity. This can not be used for a site with irregular interfaces or strong lateral heterogeneity of S-wave velocity.

Tomographic inversions of travel times of S-wave generated with artificial sources can be used to map inhomogeneous S-wave velocity. Surface wave However, it is required to prepare many travel time data from many sensors along a surveying line. This is one of the disadvantages in the methods based on tomographic inversions. Recently, surface waves in the refraction data are used in shallow S-wave profiling from dispersion analysis (e.g., Hayashi and Suzuki, 2004). Since travel times of initial S-wave are not used in the surface wave method, it is easily applied in noisy urban area. Although a two-dimensional image of S-wave velocity can be derived from the surface wave method, it is required to prepare many observed stations for detailed imaging. Furthermore separation of surface wave modes must be done before the dispersion analysis, when higher mode surface waves have larger or similar amplitudes to the fundamental modes. Takekoshi and Yamanaka (2009) have proposed a waveform inversion technique using shallow seismic refraction data to a 2D inhomogeneous S-wave profile. The effectiveness of the method was examined using numerical experiments.

In this study we applied the waveform inversion technique by Takekoshi and Yamanaka (2009) to actual data obtained in shallow seismic refraction exploration for mapping a 2D S-wave velocity model. First, we show a flow for data pre-processing of observed data before the inversion. We then conduct numerical test of the data processing and inversion using numerical data. Finally we applied the technique to the actual data.

2. METHOD

2.1 Pre-processing of Data

Characteristics of SH-waves observed in refraction survey are controlled with physical parameters of ground and source effects of wave-generator. We usually use plank-hammering to generate SH-waves. It is not easy to

estimate source time function and radiation patterns of such sources from observed data. Therefore, these source effects must be moved from observed data to retrieve effects of subsurface structure. A deconvolution technique is applied to the SH-waves. The spectrum, of SH-wave observed at site *j*, $O_j(\omega)$ is divided with that at a reference site,*r*, $O_r(\omega)$ as

$$\frac{O_j(\omega)}{O_r(\omega)} = \frac{S(\omega)G_j(\omega)}{S(\omega)G_r(\omega)} = \frac{G_j(\omega)}{G_r(\omega)}. \quad (1)$$

This processing provides a ratio of Green's function between the two sites in the time domain, $D_j^o(t)$. In actual processing the following equation is used to avoid numerical instability.

$$D_j^o(t) = \mathrm{F}^{-1}\left[\frac{O_j(\omega)O_r^*(\omega)}{O_r(\omega)^2 + \varepsilon}\right], \quad (2)$$

where F^{-1} and * mean the inverse Fourier transform and complex conjugate. ε is a small value and to be 0.1% of averaged amplitude of observed data. We also apply band-pass filtering during this processing in the frequency domain.

2.2 Parameterization of Soil Model

S-wave velocity structure of shallow soils is modeled using the parameterization by Takekoshi and Yamanaka (2009) as shown in Figure 1.

A soil model consists of surface layers over a basement having a constant S-wave velocity that is one of the unknown parameters in the waveform inversion. The surface layers are divided into layers separated by the interfaces. For example, the model in Figure 1c has three surface layers. The depth shape of each interface is described with basis functions by Aoi et al. (1995). Using linear combination of a basis function ck(x) and a coefficient pk, the interface depth d(x) at location x is written as

$$d(x) = \sum_k^L p_k c_k(x) \quad (3)$$

where *L* is number of basis function. The basis function is defined as

$$c_k(x) = \begin{cases} 1/2 + 1/2\cos(\pi/\Delta(x - x_k)) & x_{k-1} \le x \le x_{k+1} \\ 0 & otherwise \end{cases} \quad (4)$$

where Δ and x_k are constant given in advance. The interface depth parameters are defined for each interface of a multi-layered model. The unknown parameters to be determined on the waveform inversion are the coefficients p_k in the equation (3) with respect to the interface shape. In order to model lateral variation of S-wave velocity in surface layers, it is divided into blocks as can be seen in Figure 1c. S-wave velocity for each block is also one of the parameters in the inversion. In order to stabilize the inversion we used smoothing of the S-wave velocity of the blocks in each layer with a weighted 3-points smoothing operation.

The unknown parameters to be determined in the inversion are P_k, S-wave velocities of all the blocks in surface layers and S-wave velocity of the basement. For example, if we use 15 basis functions for each interface, total number of the unknown parameters for the model in Figure 1 are 76 (15*3P_k, 10*3+1 S-wave velocities).

The above-mentions parameterization of the subsurface structure can allow to model soils layers separated by geologically discontinuous interfaces with S-wave variations. We therefore assume small variations of S-wave velocities in the blocks that belong to the same layer in the inversion. This can be implemented with making narrow search limits of the S-waves for the blocks.

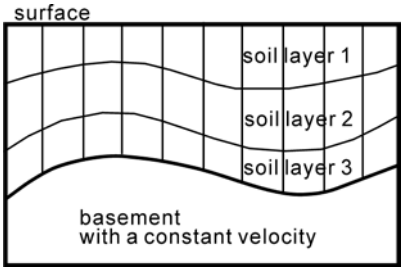

Figure 1. Schematic illustration for parameterization of subsurface structural model in the waveform inversion.

2.3 Definition of Misfit

The misfit function to be minimized in the inversion is defined using observed and theoretical traces to determine the model parameters. The misfit, *E*, is calculated from

$$E = \frac{1}{M}\sum_{j=2}^{M}\frac{\sum_{i=1}^{N}\left[\overline{D_j^o(t_i)} - \overline{D_j^c(t_i)}\right]^2}{\sum_{i=1}^{N}\left[\overline{D_j^o(t_i)}\right]^2} \quad (5)$$

where $Dj^o(t)$ and $Dj^c(t)$ are the observed and calculated SH-waves after the devonvolution processing. *N* is the number of stations along the surveying line.

In the calculation of the misfit, synthetic SH-waves are generated using finite difference approximation of a 2.5D equation of motion of SH-waves. The 2.5D equation of motion due to SH-waves is numerical solved with 4th-order and 2nd-order central finite difference approximation in space and time. The staggered finite difference grid is used in the approximation. The absorbing and sponge buffer conditions are subjected in the non-physical boundaries in the bottom, left and right sides of a finite difference grid model. The free surface condition is applied in the upper boundary of the model.

2.4 Inversion Algorithm

It is expected that the misfit function has a complex multi-model shape. An appropriate initial model is required

in the least-squared inversions, because of the local search characteristics. However, we often have no a priori knowledge on subsurface structure, especially for shallow near-surface soils. We therefore applied global search algorithms to minimize the misfit function in this study.

Heuristic approaches are one of the global search algorithms used in various kinds of geophysical inversions, such as GA and SA (e.g., Yamanaka, 2005). Since the heuristic inversion methods require many numbers of forward calculations, the heuristic approaches are not so often applied in inversions with relatively heavy forward computations. We however used the hybrid heuristic method proposed by Yamanaka (2007), because the method is capable to find the optimal model with less computational efforts than those for the conventional heuristic algorithms. Details can be shown in Takekoshi and Yamanaka (2009).

3. NUMERICAL TEST OF INVERSION

3.1 Two-Layer Model with Inclined Interface

Figure 2a shows a two-dimensional S-wave velocity model used in numerical experiment of the waveform inversion including data pre-processing. The model consists of a surface layer and basement with S-wave velocities of 200 and 500m/s, respectively. The model is digitized with grid points having a cell size of 0.2m. We calculated synthetic SH-waves at 8 sites on the surface at interval of 5meters in this model using the FD code. A point source having time function of Ricker wavelet with frequency of 30 Hz is set on the surface at distance of 10 meters from the left end of the model. Figure 3 shows the calculated SH-waves after the deconvolution processing. We used the data at 0 meters as the reference motion in the preprocessing. These waves were used as synthetic data in the numerical experiments. Reflected phases and surface waves can be identified in the waveforms.

In the waveform inversion, two-layer model is assumed with 20 blocks in the surface layer. The interface is model using 20 coefficients of Pk in the above equation. Total number of the unknown parameters is 41 in this numerical test. 10 inversions using different initial values of random number generator were conducted, and acceptable models were estimated from the all models examined in the 10 inversions. Average of the minimum misfits in the 10 inversions is shown in Figure 4 with its standard deviations at each generation. The minimum misfit decreases gradually with in the 130 generations, then it does significantly over the 150 generations. It suggests that the models around the global minimum model are sampled by the inversion. Figure 2b shows a model averaged of the minimum models from the 10 inversions. Their standard deviation is also shown in Figure 2c, by which we can understand stability of the inversions. The inverted model is almost the same as the true model with differences of basement depth in the left side from the source. This part is not constrained in the inversion because of no existence of observed data. The small standard deviation in Figure 2c indicates that model with the global minimum misfit is found in the inversion. Figure 3 also compares observed SH-waves with those for the inverted model. The two SH-waves are in agreement with each other.

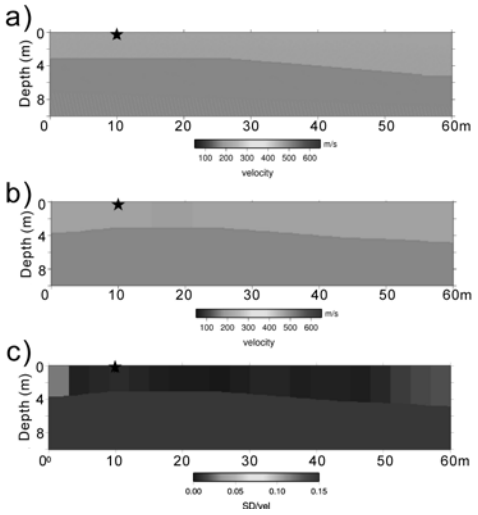

Fig.2. 2D S-wave velocity models in numerical experiments. The top model is assumed to generate synthetic observed data in Fig.3, and middle model is derived from inversion of the synthetic waveforms. The bottom shows the standard deviation of the S-wave velocity at each block in the inverted models from 10 inversions using different initial values of a random number generator. A star in each figure shows the source location.

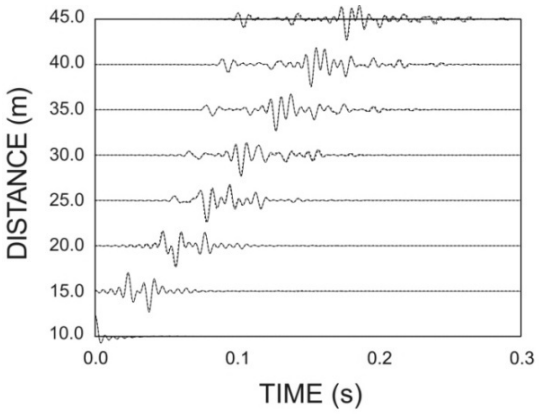

Fig.3. Comparison of synthetic observed waveforms (solid line) with theoretical waveforms for inverted model (broken line) in numerical experiment using a model in Fig.2. Each trace indicates SH-wave after deconvolution processing and is normalized with its maximum value.

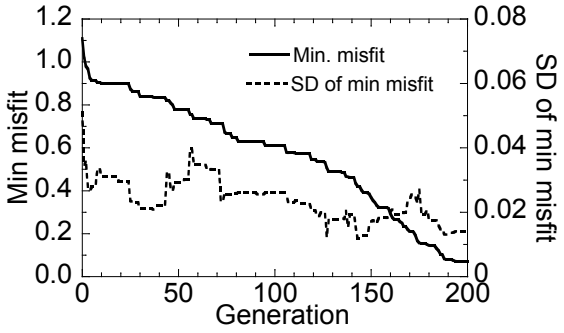

Fig.4. Variation of average of the minimum misfits at each generation from 10 inversions with different initial values of a random number generator (solid line) with its standard deviation (broken line) in numerical experiment using a model in Fig.2.

3.2 Three-Layer Model with blind layer

The second numerical experiment was conducted using a three-layer model with a blind layer. It is noted that a blind layer can not be identified in conventional travel time analysis of seismic refraction data. Figure 5 shows the model assumed in the second numerical experiment consisting of two layers over the basement. The top layer has a higher velocity then that of the second layer. Therefore the thickness of the top layer can not be known in the conventional travel time analysis. In the inversion, each interface is modeled by 20 Pks, and the surface layers are model with 20 blocks.

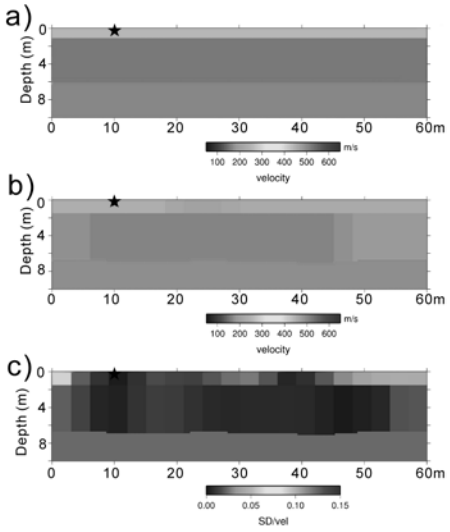

Fig.5. 2D S-wave velocity models in numerical experiments. The top model is assumed to generate synthetic observed data in Fig.6, and the middle model is derived from inversion of the synthetic waveforms. The bottom shows the standard deviation of the S-wave velocity at each block in the inverted models from 10 inversions using different initial values of a random number generator. A star in each figure shows the source location.

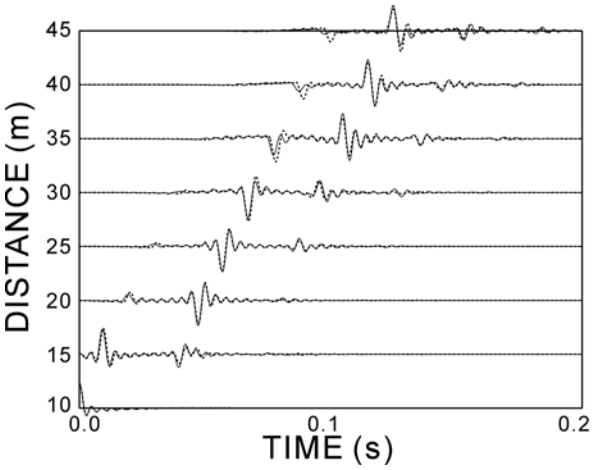

Fig.6 Comparison of synthetic observed waveforms (solid line) with theoretical waveforms for inverted model (broken line) in numerical experiment using a model in Fig.5. Each trace indicates SH-wave after deconvolution processing and is normalized with its maximum value.

The inverted model and standard deviations are shown in Figures 5b and 5c. Although the basement depth in the inverted model is slightly deeper than that of the true model, the blind top layer is well reconstructed with the inverted model. The comparisons of SH-waves for the true and inverted models are displayed in Figure 6. The agreement between the two SH-waves is well except for the amplitudes for the reflected phase at 0.1 second at sites of 35 to 45 meters. This might be caused by the slight different of the basement depth.

4. APPLICATION TO ACTUAL DATA

4.1 Measurements

The measurement was conducted at a sports ground of our university in Yokohama as shown in Figure 7. The surveying line is 35 meters long. 8 horizontal sensors with natural frequency of 10 Hz were installed at interval of 5 meters along the line. Four sources were served long the line; two were placed at the two ends of the surveying line, and the others are located at offset distance of 20 meters from the two ends. SH-waves were generated with plank hammering of the wooden plate at the sources, and recorded at every 0.5 msec with a digital recorder. Each data were stacked 20 times to increase S/N ratio.

The observed SH-waves from the sources at 0 and 35 meters are displays in Figure 8. Two traces shown at each site are the SH-waves from hitting of the wooden plate in the right and left directions to identify SH-waves with different polarity. From the arrival times of the initial onsets of the SH-waves we conducted conventional travel time analysis as shown in Figures 9a and 9b. The basement with an

S-wave velocity of 460 m/s is overlain by the surface layer with an S-wave velocity of 260m/s and thickness of about 10 meters. The 2D model is relatively simple without any strong lateral variation and steep interfaces.

4.2 Waveform Inversion

We conducted waveform inversion for the SH-waves generated from the source at 0 meters. We used the SH-waves observed at the site of 0 meters as the reference data in the deconvolution processing. In the forward calculation, we again used the Ricker wavelet with a frequency of 20 Hz. A three-layer model is modeled with 10 interface coefficients and 10 blocks in the surface layers. Totally 41 unknown parameters were to be determined in the inversion.

Figure 10a and 10b shows the inverted model and its standard deviations. The inverted model is very simple as expected in the model by conventional analysis. The surface layers have small lateral velocity variations. The average S-wave velocities of the surface layers are 230 and 360 m/s, respectively. The depth to the basement with an S-wave velocity of 477 m/s is about 12 meters in entire of the surveying line. The small standard deviation in Figure 10b clearly indicated the inversion found models near the global minimum misfit. The S-wave velocities for the top layer and the basement are similar to those from the conventional travel time analysis as shown in Figure 9. The existence of the second layer can not be found in the travel time analysis. The depth to the basement is 2 meter deeper than the inverted model.

Figure 11 compares observed and calculated SH-waves. Synthetic SH-waves for the model from the conventional travel time analysis is also shown in the figure. The large phases in the observed SH-waves are well reconstructed with the synthetic SH-waves for the inverted model. However, the SH-waves calculated for the travel time analysis can not well explain the large later phases.

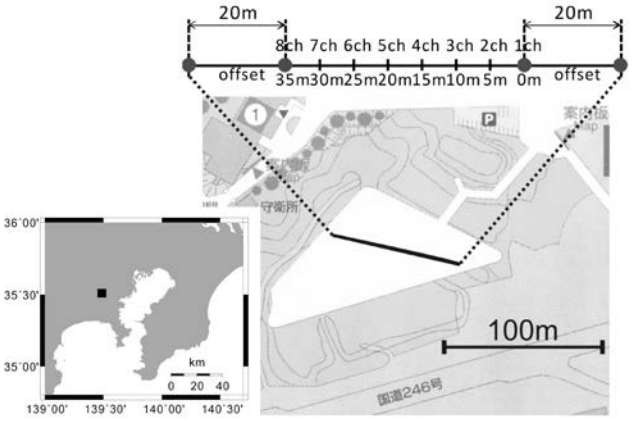

Figure 7. Location of observation sites of shallow refraction exploration. Four circles along the surveying line show shot points to generate SH-waves.

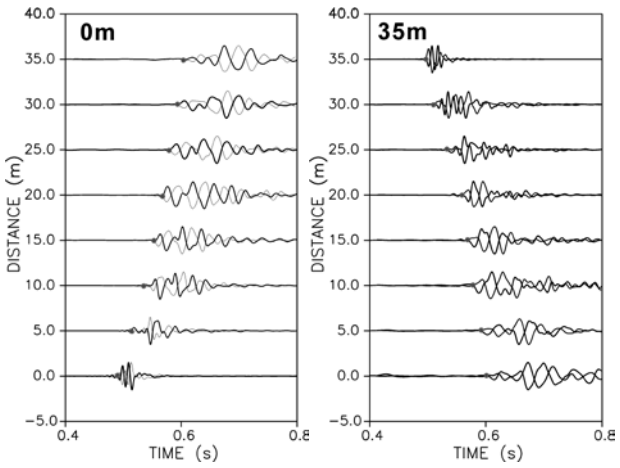

Figure 8 Observed SH-waves and their spectra. The top figures show SH-waves observed along the surveying line due to shots at distances of 0m and 35m. The attached circles in the traces indicate arrivals of initial motions. The lower figure shows spectra of SH-waves due to a shot at 0 m.

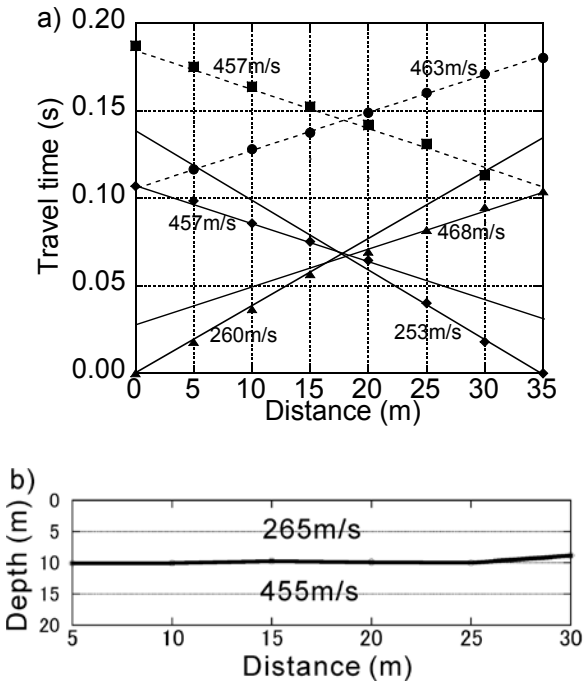

Figure 9 Results of conventional analysis of travel time of initial motions. Top is the travel time diagram and bottom is S-wave velocity model along surveying line.

Comparison of observed waveforms (thin-solid line) with theoretical waveforms for inverted model in Fig.12a (thick-solid line) and model from conventional travel time analysis in Fig.10 (broken line). Each trace indicates SH-wave after deconvolution processing and is normalized with each maximum value.

5. CONCLUSIONS

We proposed an inversion technique of SH-waves observed in shallow seismic refraction explorations to deduce 2D inhomogeneous models of shallow soils. In the method we added pre-processing of the observed data by introducing deconvolution using reference station to eliminate the effects of sources. The other part of the inversion is almost the same as Takekoshi and Yamanaka (2009). We conducted numerical experiments of the waveform inversion using synthetic data. The effectiveness of the method is clearly shown from the numerical experiment for the model having a blind layer. We also applied the technique to actual refraction data, and could determine a model that fits more the observed SH-waves than the model from the conventional travel time analysis. These results clearly indicate effectiveness of the waveform inversion technique. We will try to apply our technique various kinds of shallow soils explorations to examine its applicability.

Abstract: The deep basin-edge structure beneath Kobe City is a plausible cause of ground motion amplification in the damage belt during the 1995 Kobe earthquake. Strong motions were recorded at two neighboring sites, Takatori and Shin-Nagata, located in the western part of the damage belt. The latter site, which was the basement of a high-rise building, recorded motion less than half the amplitude observed at the former site. This difference has gone unresolved in terms of the relationship between the level of ground motions and actual damage. This paper investigated input earthquake motion to the high-rise building at Shin-Nagata during the 1995 Kobe earthquake. Spatial variation of ground motions in the western part of Kobe City was examined using a 3-D finite difference method that considered both the seismic fault and the 3-D subsurface structure, which played an important role in the difference in ground motion level at the two sites. A 2-D underground model estimated the loss of input motion due to the constraint of an embedded rigid base, which contributed to the reduction of the observed motion associated with the site-specific nonlinearity of the surrounding surface soil.

1. INTRODUCTION

The 1995 Hyogo-ken Nanbu, Japan earthquake (hereafter, referred to as the 1995 Kobe earthquake) killed more than 6,000 people. Strong ground shaking during the earthquake devastated numerous structures, including old wooden houses. Most of the structural damage was spatially concentrated in the "heavily damaged belt zone," which corresponds to a Japanese seismic intensity scale of 7 (Japan Meteorological Agency (JMA) scale). Figure 1 illustrates this zone, which is a 1-2-km-wide area between Rokko Mountain and Osaka Bay. Ground velocity waveforms obtained from records of the event contain large-amplitude pulses with a predominant period of about 1, which is caused in the rupture process by a seismic fault beneath Kobe City.

One plausible explanations for the peculiar damage pattern observed is the existence of a basin-edge structure in the deep subsurface soil beneath Kobe City (e.g., Motosaka & Nagano 1997). Kobe City is located just within the border of the Osaka Plain, and the level of the seismic bedrock abruptly drops off at the foot of Rokko Mountain.

Although more than 16 years have passed, damage caused by the 1995 Kobe earthquake has been the icon for natural disaster prevention with regard to seismology, earthquake engineering, and civil/structural engineering. Nevertheless, some issues remain unresolved from the standpoint of the relationship between observed ground motion and actual damage.

Strong ground motion were recorded in and around the heavily damaged belt zone in Kobe City during the main shock. In the western part of the worst-hit area, two strong ground motion records were obtained for Takatori (TKT) and Shin-Nagata (SNT). The former is a record of ground surface motion (Nakamura et al., 1996). The latter is from the first basement level of the 25-story steel reinforced concrete (SRC) building shown in Figure 2 (Yasui et al. 1998). The SNT record includes the effects of the soil-structure interaction (SSI). The amplitudes of the ground motions at two sites are quite different, even though both sites, which are separated by about 1 km, are within the damage belt.

Figure 3 shows the velocity waveforms and pseudo-velocity spectra at the two sites rotated to the fault-normal (FN) direction as a principal axis N150E and N140E, for TKT and SNT, respectively.

The ground motion record from the TKT site is one of the most important records of the Kobe earthquake because the peak ground velocity (PGV) exceeded 1.5 m/s, the largest ground velocity reported in Japan at that time. Its waveform is pulse-like with a predominant period of about 1 s. In contrast, the PGV at SNT is approximately 0.6 m/s, which is less than half of that at TKT. This difference applies to both the PGV and the response spectra. Accelerometer data at SNT were slightly saturated during the main shock, however, this introduced only a minor error in the velocity

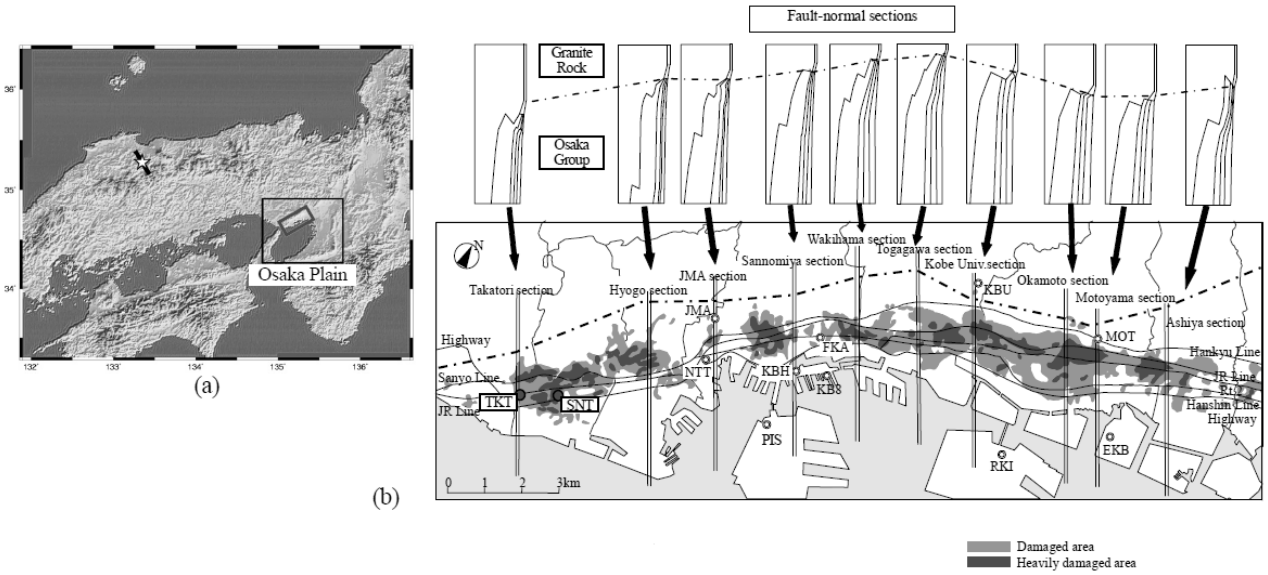

Figure 1. Location of Kobe City, Japan, and the damage belt during the 1995 Kobe earthquake. (a) Kobe City is located in the western part of Honshu Island, Japan. The thick inclined rectangle in (a) corresponds to area (b) the heavily damaged belt zone. A dash-dotted line indicates the structural boundary between rock and sediments along Rokko Mountain. Fault-normal sections of a deep underground structure for 2-D analyses are illustrated. Takatori (TKT) and Shin-Nagata (SNT) are about 1 km apart and are both located in the western part of the damage belt. (Nagano & Yamada, 2002)

waveforms because the duration of the saturation was limited. The peak ground acceleration (PGA) loss is estimated to be about 10% of the restored accelerometer data (Yasui et al. 1998).

These observations suggest the need to address several different questions. Why is there such a large discrepancy between the two records in very short distance? Is there any variance in the characteristics of the ground motion amplification due to deep or shallow geological conditions? Is there any significant loss of foundation input motion due to the embedded basement of the building?

This paper focuses on earthquake input motion to the high-rise building at SNT during the 1995 Kobe earthquake using three approaches: (1) a 3-D finite difference method (FDM) to elucidate the spatial variations considering both the seismic fault and the 3-D basin-edge structure; (2) amplification characteristics using recorded motions after the 1995 Kobe earthquake at SNT, and (3) the foundation input motion analysis, considering the strong nonlinearity of the surrounding surface soil.

2. SPATIAL VARIATION OF GROUND MOTIONS IN THE WESTERN PART OF KOBE CITY

2.1 Methodology and Modeling

Strong ground motions in the western part of Kobe City are evaluated using a 3-D FDM that considers both the seismic fault and the 3-D basin-edge structure in the western part of the Osaka Plain.

Figure 4(a) shows the finite difference (FD) modeling region. The lengths of planar regions are 32 and 42 km in the NS and EW directions, respectively. The velocity structure is referred from geological data from the Osaka Prefecture

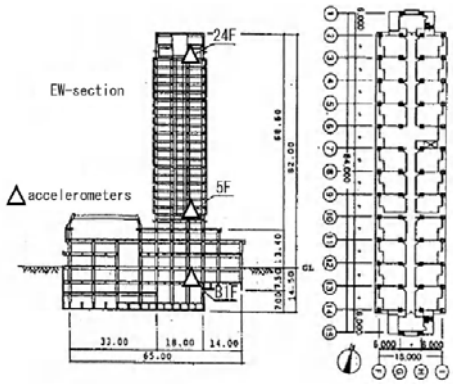

Figure 2. High-rise SRC building constructed at SNT, and the location of accelerometers. The seismograms in Figure 3 were obtained at the first basement floor level. The section plan is illustrated in the EW direction. (after Yasui et al. 1998)

(2006), where the thrust-type basin-edge structure is properly modeled along the Rokko Mountain. Sediments on seismic bedrock are modeled in nine layers from 0.4 to 1.2 km/s for V_S, as shown in Table 1. Figure 4 (b) shows a cross section of the underground structure through SNT in N135E direction. Seismic bedrock abruptly drops off at the boundary between rock and sediments.

5	53	90	4.94	1.46×10^{18}	4	10

rake angle: 180° , rupture velocity: 2.8 km/s

A numerically efficient FD technique that combines non-uniform and discontinuous grids is applied for 3-D wave propagation analysis (Nagano, 2004). The entire soil region is divided into two regions at a specific depth modeled by different non-uniform grids. Grids in the bottom region, for bedrock, are coarser than those in the top region, which included sediment. This significantly reduces the number of grids. The boundary between the two regions is set at a depth of 4.1 km. The minimum grid spacing is 50 m; therefore, synthetic motions with a frequency component up to 1.6 Hz can be properly evaluated.

The source model is characterized by the five asperities (Matsushima & Kawase, 2009), as shown in Figure 4(a) and Table 2. Asperity No. 5 exists in a shallow region, just beneath the western part of Kobe City, including TKT and SNT, significantly contributes to amplification of the strong ground motions at two sites. All calculated velocity waveforms and recorded ground motions are low-pass filtered at 1.6Hz.

2.2 Simulation of Ground Motions at TKT and SNT and Their Spatial Variations

Synthesized ground motions at TKT and SNT were compared with records in Figures 5 and 6 and rotated in fault-normal direction, N140E. The 3-D FDM reproduces the ground motion at TKT in terms of both peak velocity

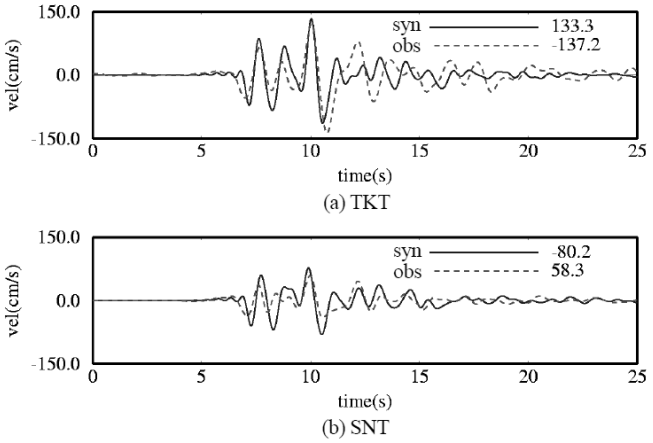

Figure 5. Comparison of synthesized and observed velocity waveforms in the FN direction at TKT and SNT.

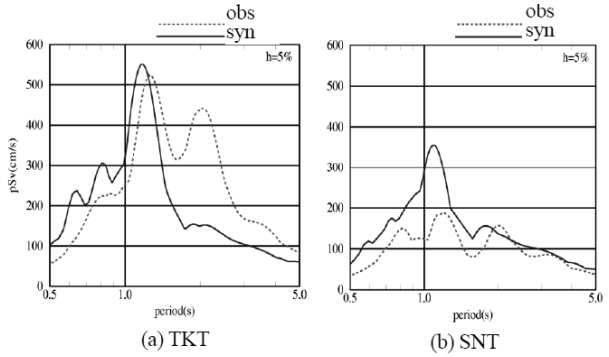

Figure 6. Comparison of pseudo-velocity spectra(h = 5 %) in the FN direction at TKT and SNT.

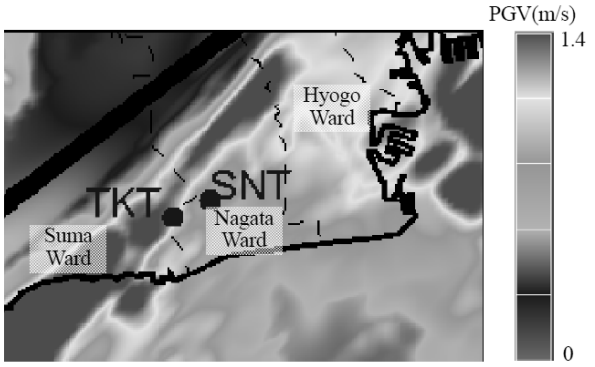
and the spectral peak with a 1.2 s period. The amplitude of the synthetic motion at SNT is 0.6 times that of TKT, which is still overestimated, but consistent with the observed relationship.

Figure 7 shows the peak velocity contour in the FN direction for the western part of Kobe City. A high-amplitude region spreads in Nagata and Suma Ward. In the western part of Hyogo Ward, the peak ground velocity (PGV) is small. This is consistent with the distribution shown in Figure 1. Figure 8(a) plots the peak velocity distributions in the FN section through TKT and SNT. The horizontal axis x is the distance from the boundary between rock and sediments to the coast. PGV amplitude peaks can be seen in where x = 1-2 km, corresponding to the damaged belt zone. TKT is located at edge of the peak region, while SNT is outside the peak region. This amplification appears to be due to constructive interference of multi-passing waves in the basin-edge structure, as shown in Figure 4 (b).

The PGV distribution is slightly different from the incidence of a plane shear wave (S wave), in that the location of the peak moves to the edge and the peak area is narrow. These are consequences of the rupture directivity effects of the asperity beneath TKT and SNT. Figure 8(b) compares the calculated PGV distribution with the actual damage ratio of the wooden structure in the same region,



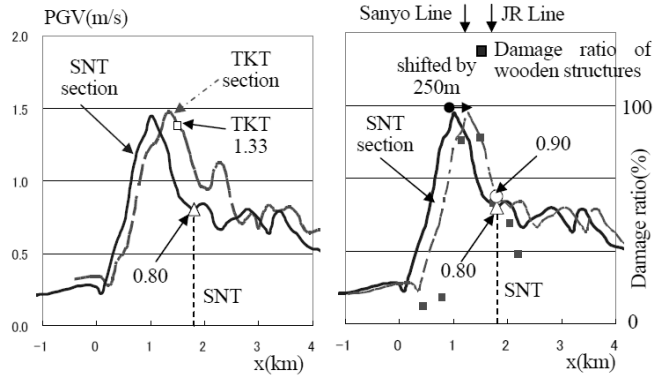


Figure 7. Contour distribution of PGV in the FN direction in western Kobe City.

(a) PGV Distribution (b) Comparison with damage ratio of wooden structures in SNT section

Figure 8. PGV distributions in the FN sections through TKT and SNT and comparison with the damage ratio of wooden structures along the SNT section.

according to a detailed survey (Inoue et al, 1996). Heavily damaged area can be seen between the Sanyo and JR Lines. The damage ratio around SNT is smaller than that in the most devastated area. 3-D FDM results indicate a peak location nearer to the mountain side than to the actual damage peak. Shifting the calculated PGV distribution by 250 m to the bay side provides better consistency with the actual damage ratio, as shown in Figure 8(b).

One reason for this inconsistency is the modeling of the deep subsurface structure. In the geological model of the Osaka Prefecture (2006), only one bedrock step exists at the structural boundary. According to the detailed survey based on reflection exploration (Huzita & Sano, 1996, Sano, 1998), another latent fault exists in the sediment side, adjacent to the rock-sediment border, resulting in two bedrock steps. This difference in basin-edge modeling could be one reason for the peak location shift of the PGV distribution. Even when PGV distribution in the 3-D FDM is shifted to the coast, the PGV at SNT is estimated at 90 cm/s, which is smaller than that at TKT.

Results by 3-D FDM suggest that large-amplitude discrepancies in the records for TKT and SNT are partly due to the spatial variations of the ground motion in very short distance in the FN direction, due to the coupling effects of a rupture of the asperity beneath, and a step-like bedrock boundary. Other reasons for the significant reduction of ground motion at SNT need to be explored because the calculated amplitude at SNT is still overestimated compared with the observed motion, as shown in Figures 5 and 6.

3. AMPLIFICATION CHARACTERISTICS BASED ON OBSERVED GROUND MOTION

3.1 Observation Sites at and around SNT

After the 1995 Kobe earthquake, strong motion seismometers were installed at several sites around SNT, as shown in Figure 9. Ground motions were recorded during numerous events, even though amplitude levels were much smaller than those during the 1995 Kobe earthquake. Seismograms at SNT were recorded in the SRC building and their structural response characteristics were also

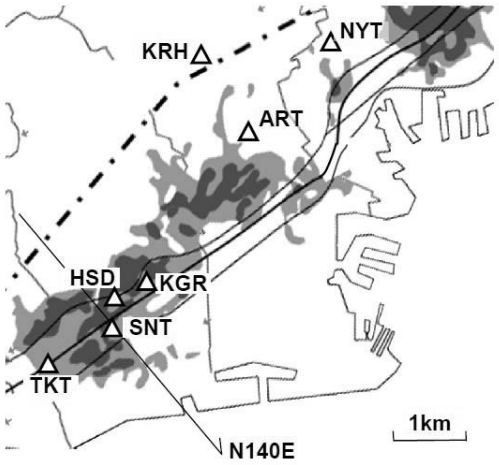

Figure 9. Observation sites for strong ground motions in the western part of the Kobe urban area.

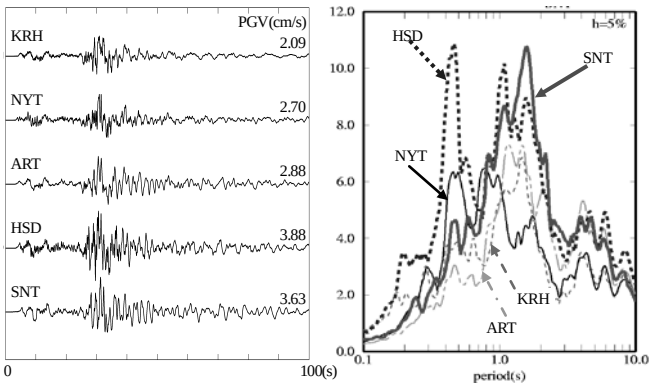
investigated in detail (Nakamura, 2003).

Using these records, site characteristics at SNT can be roughly estimated by calculating the transfer functions between the other sites. Here, we selected 12 events in Table 3, for which seismic records at SNT and surrounding sites were obtained simultaneously.



All motions are rotated to the building axis, i.e., longitudinal direction, N335E, corresponding to the FN direction, and the transverse direction, N65E, corresponding to the fault-parallel (FP) direction.

3.2 Ground Motions during the 2000 Tottori-Ken Seibu Earthquake

During the 2000 Tottori-ken Seibu earthquake (No.4 in Table 3), the JMA seismic intensity scale in Nagata was 4—the largest recorded since the 1995 Kobe earthquake. Figure 10 shows velocity seismograms and pseudo-velocity spectra (h = 5%) in the FN direction for five sites, including SNT. The PGV distribution along the FN section, including SNT, is plotted in Figure 11. The plots also include PGVs of the ground motions recorded in the Higashi-Nada area, the eastern part of the Kobe urban area, for comparison. The horizontal axis is taken as the distance from the structural edge between rock and sediment.

(a) Velocity waveforms (b) Pseuso Velocity Spectra(h=5%)

Figure 10. Velocity waveforms and response spectra in the FN direction of seismograms at five sites in the western part of Kobe city during the 2000 Tottori-Ken Seibu earthquake.

The PGV gradually increases from KRH and NYT near the structural border, to the sites in the sediment and coastal area. A long-period component, around 5 s, was predominant in ground motions in Kobe during the 2000 Tottori-ken Seibu earthquake (Nagano, 2004), leading to a gradual increase of the PGV distribution to the coastal area from mountain side, as indicated by the trend in Higashi-Nada area (Nagano et al., 2003). On the other hand, the recorded motion at SNT was smaller than at HSD, 300 m toward the mountain, in terms of the PGV and a short-period component of less than 1 s. These could be the results of the constraint on the ground motion by the embedded basement.

3.3 Site Characteristics at SNT and Neighboring Sites

The nearest observation sites to SNT are Hosoda-Cho (HSD) and Kagura-Cho (KGR) under the JMA. The seismometer at HSD was in operation until 2001, and then moved to KGR, 500 m to the east from HSD, after 2002. Both sites were located in the damage belt during the 1995

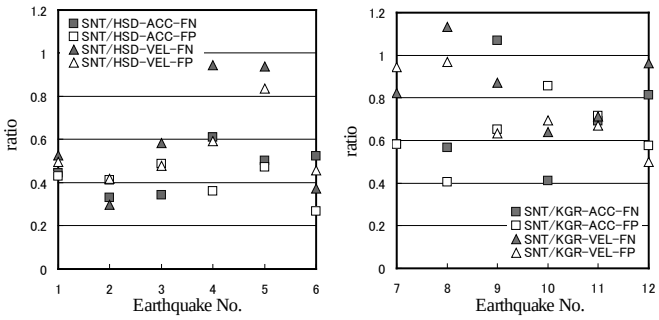

Figure 12. PGV and PGA ratios of SNT to neighboring sites after the 1995 Kobe earthquake

(a) SNT/HSD (b) SNT/KGR

Figure 13. Fourier amplitude ratios at SNT to neighboring sites in the FN direction after the 1995 Kobe earthquake

Kobe earthquake. Using seismograms simultaneously recorded at SNT, HSD, and KGR, shown in Table 3, PGA and PGV ratios are plotted in Figure 12. Ground motions at SNT are in general smaller than either of the other two sites. The ratios of PGA are smaller than the PGV ratios, corresponding to a large reduction of the high-frequency component, as shown in Figure 10.

Figure 13 traces the Fourier amplitude ratios, SNT/HSD and SNT/KGR for each of six earthquakes, as well as averaged data. The amplitude ratio is less than one in the frequency range above 2 Hz, due to the input loss effect of the embedded foundation. On the other hand, the reduction of ground motion is not as noticeable at frequencies below 2 Hz, which was predominant during the 1995 Kobe earthquake, as shown in Figure 3. Therefore, it is rather difficult to account for the reduction in ground motion at SNT during the 1995 Kobe earthquake only using the recorded motion observed during small amplitude events that occurred after the Kobe earthquake. The constraint effect of the embedded basement around 1 s is small when the ground motion level is small, and the surrounding soft soil is linear.

4. FOUNDATION INPUT MOTION CONSIDERING SITE NONLINEARITY OF SURROUNDING SOIL DURING MAIN-SHOCK

4.1 Underground Structure Model Including Embedded Basement

Reduction of the seismic motion at SNT was analyzed in terms of the loss of input motion due to a rigid foundation embedded in soft surface soil. The 2-D model in Figure 14 serves used as the subsurface structure passing through SNT in the FN direction. This underground model has two soft surface layers on the engineering bedrock (V_S=500 m/s) and another latent fault, the Kariyaoki Fault, adjacent to the basin edge. This geometry and layers are slightly different from the 3-D model previously used, but were calibrated in aftershock simulations by Nagano et al. (1998).

The basement of the building was 84 m long in the FN direction and 14.5 m deep. Rigid, massless solid elements are embedded in the upper layer of soft surface soil in the 2-D underground model.

The transfer function of SNT/HSD is calculated for a vertically incident SV-wave and compared in Figure 15 with the recorded motions from Figure 13(a). The 2-D finite element method (FEM) results explain to some extent, the recorded motions up to 1.2 Hz. In the higher frequency range, the fluctuation of the curve is large in the 2-D FEM, compared with the observed fluctuation.

Foundation input motion is also evaluated by 2-D FEM as a transfer function of the basement divided by the free field motion at SNT obtained from a 2-D model without a basement. The input motion decreases in the frequency range above 1.2 Hz. This amplitude reduction is not seen in the lower frequency range; thus, it is difficult to explain the reduction in ground motion at SNT during the 1995 Kobe earthquake using linear soil properties.

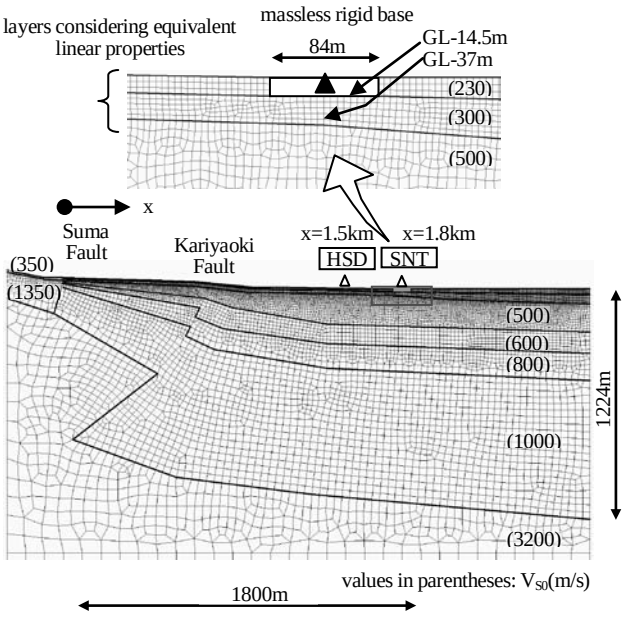

Figure 14. Underground structure used in the 2-D FE model to evaluate foundation input motion at SNT.

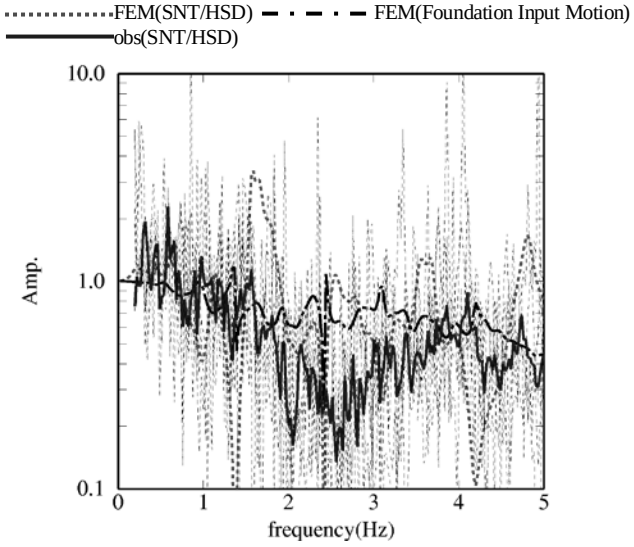

Figure 15. Transfer functions of the foundation at SNT and comparison with observation.

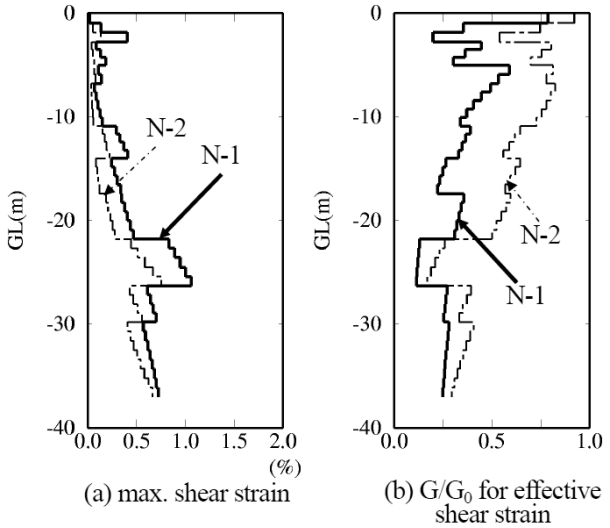
4.2 Equivalent Soil Properties During the 1995 Kobe Earthquake

Yasui et al. (1998) carried out a detailed analysis of the dynamic soil-structure interaction (SSI) problem at the SNT site. They simulated nonlinear structural response using records for three floors (B1F, 5F, 24F) in the building, along with ground motions on the free-field surface, based on an iterative scheme that included nonlinearity of the surrounding soil. The peak structural response at the first floor was estimated to be 23% less than the free-field motion for peak acceleration, and 10% less for peak velocity. The estimated PGV for the free field at SNT is 0.65 m/s, which is still less than half the PGV at TKT.



In Yasui et al. (1998), equivalent soil properties were determined using an iterative scheme based on data records at SNT. This approach helps ensure that the site nonlinearity associated with the surrounding soil is taken into account in the SSI analysis. The average ratio of the equivalent S-wave velocity, V_{Se}, to the initial S-wave velocity, V_{S0}, is 0.84 in the soft surface layers on engineering bedrock.

Table 3 provides the detailed S-wave structure beneath SNT, and the equivalent soil properties of surface layers were evaluated by time-domain nonlinear analysis. Outcropped motion on the Osaka Group layers at TKT (peak acceleration is 6.17m/s^2, and peak velocity is 1.37m/s) serves as input motion to the one-dimensional soil column at GL-37m. Considering the relationship between SNT and TKT from the 3-D FDM, its amplitude is reduced to 60% of the original motion.

(a) sand (b) clay

Figure 16 Nonlinear characteristics of surface soil

(a) max. shear strain (b) G/G_0 for effective shear strain

Figure 17. Distribution of maximum shearing strain and reduction of shearing stiffness in depth

Two cases of standard soil nonlinearities, e.g., the N-1 (Osaki et al., 1978) and N-2 (Koyamada et al., 2005) models, are referred in the time-domain nonlinear analysis and evaluation of equivalent soil properties. In both models, averaged parameters for sand and clay were given for the Ramberg-Osgood model and the Hardin-Drnevich model, respectively. Curves of G/G_0-γ, h-γ are illustrated in Figure 16 for two models, compared with Yasui et al.(1998).

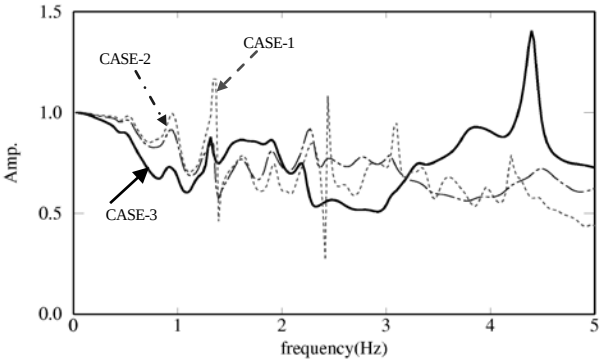
Figure 17 shows the distribution of maximum shearing strain and reduction of shearing stiffness in the depth direction, as results of the nonlinear analyses of the 1-D soil column. Averaging G/G_0 in the soft soil part estimated the coefficients for the reduction of V_S as 0.56 and 0.72 for N-1 and N-2, respectively. These values are smaller than the 0.83 used in Yasui et al.(1998). In the N-1 model, stiffness degrades more rapidly with an increase of shearing strain, resulting in a larger shearing strain in the nonlinear analysis than for the N-2 model.

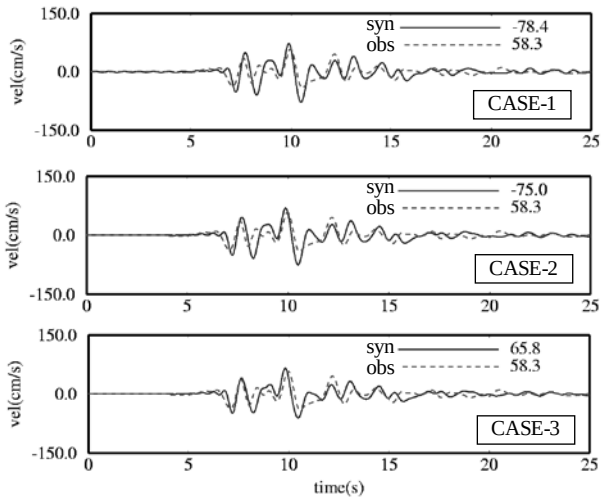
4.3 Foundation Input Motion Embedded in Soft Surface Soil

Next, input motion analysis studied three cases of equivalent soil properties. CASE-1 used the original linear properties and CASE-2 employed the average coefficient for the reduction of V_S from Yasui et al. (1998), i.e., 0.83. A smaller V_S, 0.56, evaluated using the N-1 model was used in CASE-3. The same coefficients and damping ratio were applied for each layer in both CASE-1 and CASE-2.

Transfer functions of the foundation input motion for a vertically incident SV-wave are plotted in Figure 18. In CASE-1 and CASE-2, the decrease in amplitude is small for frequencies below 1 Hz. It is hard to account for a reduction of ground motion amplitude at SNT based on these first two cases. In CASE-3, a small trough appeared at around 0.8 Hz in the foundation input motions. The foundation response seems reduced as a result of the constraint of a rigid base on the waves in the soft surface layers, especially due to the constraint effect at the sides of the rigid base.

To assess the effect of foundation input loss on the





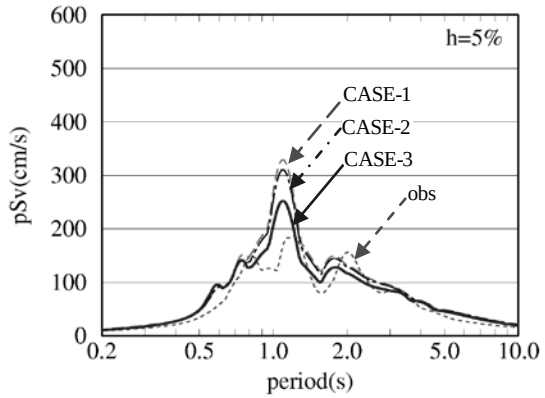


Figure 18. Transfer functions of foundation input motions to free surface motions for three cases

(a) Velocity Seismograms

(b) Pseudo velocity spectra (h=5%)

Figure 19. Comparison of calculated foundation input motion and observed motion at SNT. (a) velocity seismogram, and (b) the pseudo velocity spectra (h=5%).

seismograms, the responses of a rigid foundation at SNT were evaluated. Although SNT, calculated by 3-D FDM, is ground motion on an outcrop of engineering bedrock, we refer it as free field motion for convenience, then multiply it by the transfer function given in Figure 18. Figure 19 shows the calculated velocity seismograms and the response spectra.

For CASE-1, the peak velocities remained almost the same as for the original ground motion, implying that the kinematic effect of a rigid foundation alone cannot account for the large reduction at SNT. In CASE-2, which uses the site nonlinearity in Yasui et al. (1998), both the velocity waveform and response spectrum were almost the same level as in CASE-1. The peak velocity in CASE-3 was reduced to 0.66 m/s, almost the same as the observed ground motion.

CASE-3 still overestimates the actual motion at SNT, however, the loss of foundation input motion due to the strong site nonlinearity of the surrounding soil partially accounts for a significant reduction of the recorded motion at SNT in comparison with TKT.

5. CONCLUSIONS

This paper investigated input earthquake motion to the high-rise building at Shin Nagata (SNT) during the 1995 Kobe earthquake to determine the cause of the large discrepancy in motion between SNT and Takatori (TKT). Three approaches were used: a 3-D finite difference method evaluated the spatial variations, considering both the seismic fault and the 3-D basin-edge structure; studying the amplification characteristics using recorded motions after the 1995 Kobe earthquake at SNT; and foundation input motion analysis took into account the strong nonlinearity of surrounding surface soil.

Conclusions are summarized below.

(1) 3-D FDM showed that the large discrepancy in amplitudes from the records of TKT and SNT is partly due to the spatial variation of the ground motions in a very short distance in the FN direction, resulting from the coupling effects of a rupture in the asperity and step-like bedrock structure. The peak ground velocity at SNT is 0.6 times of that at TKT.

(2) It is difficult to account for the reduction in ground motion at SNT during the 1995 Kobe earthquake using only the recorded motions observed in the small amplitude events after the Kobe earthquake. The constraint effect of the embedded basement around 1s is small when the ground motion level is small and the surrounding soft soil is linear.

(3) The loss of foundation input motion due to the strong site nonlinearity of the surrounding soil partially accounts for a significant reduction in the recorded motion at SNT in comparison with TKT.

Acknowledgements:

The authors would like to thank the West Japan Branch Office of the Urban Renaissance Agency for providing strong motion data at SNT. Comments from Dr. Mitsuru Nakamura, Ohbayashi Corporation, on the observation system at SNT were useful. We also used the data of K-NET, JMA, and the Railway Technical Research Institute.

SENSITIVITY OF GROUND RESPONSE ANALYSIS TO SHEAR WAVE VELOCITY PROFILE

Pulpong Pongvithayapanu

Lecturer, International Maritime College, Kasetsart University, Si Racha campus, Thailand
pulpong@src.ku.ac.th

Abstract: The sensitivity of ground response analysis to shear wave velocity profiles was calibrated for Bangkok subsoil. The shear wave velocity was obtained from down-hole seismic tests conducted at several locations in Bangkok. Conventional shear wave profiles were obtained that expressed variation of the shear wave as step functions against depth. A new interpretation method was proposed, which exhibited the influence of effective in-situ overburden stress on the profile. Furthermore, a simple linear correlation between shear wave velocity and depth was obtained. Both profiles produced no significant difference in ground response analysis. The proposed correlation was simple, portable and therefore suitable for many practitioners.

1. INTRODUCTION

One of the most important input parameters used in ground response analysis using either the equivalent linear method or the nonlinear method is the shear wave velocity (V_s) at low strain. Determination of V_s is becoming a normal part of dynamic site evaluation studies. V_s, measured either by in-situ or laboratory techniques, is a soil property used to determine the maximum shear modulus, G_{max}, or the stiffness of deposit soils. The field measurement of V_s at low strain can be carried out by several methods, such as seismic reflection and refraction, seismic cross-hole, seismic down-hole (up-hole) and seismic cone tests. V_s can be determined by laboratory measurement, for instance, using the bender element test, which can be performed in a conventional triaxial apparatus or with an odometer device. To attain a reliable V_s profile from such direct V_s measurements requires experience and engineering judgment, as well as complicated experimental instrumentation. In addition, the determination of the in-situ V_s is uncertain, due to the unpredictability of local variations in soil deposits and anisotropic stress conditions. Furthermore, the use of in-situ determination of V_s in several areas is scarce. Thus, in addition to direct measurement of V_s, many researchers have put much effort both in the field and the laboratory to approximate V_s using empirical relationships between V_s and various soil properties.

As mentioned previously, V_s can be estimated by other means. Hardin (1963) correlated V_s with the effective confining pressure and void ratio. Fumal (1978) related V_s with depth and Dickenson (1994) proposed a nonlinear relationship between V_s and undrained shear strength for soils in the San Francisco Bay area. The correlation based on the SPT *N-value* and V_s has been well formulated by many scholars, such as Ohsaki (1973) and Imai (1982). Though the precision of the V_s value attained by these correlations may vary greatly, it would still be useful in areas where the measurement of V_s has not been broadly explored.

In Thailand, the Bangkok Metropolitan Area (BMA), which includes the capital city with a population of approximately 10 million people, is known as an area of low seismic activity. The closest potentially active faults are in the west of Thailand, about 200 to 300 km away. More active seismic sources in Burma are between 600 km and 1,000 km from the BMA. However, the BMA is situated on a soft clay layer. This uppermost layer of soft marine clay (usually referred to as "soft Bangkok clay") is about 15 to 18 m thick. Underneath this soft clay layer are layers of stiff clay and sand, respectively. It is widely recognized that "soft clay", if encountered by medium to high seismic forces, can amplify the earthquake ground motion 3-6 times, in terms of peak ground acceleration (*PGA*).

To perform a complete seismic site response analysis, the V_s profile is one of the crucial input parameters that has to be determined. Though the low strain amplitude shear modulus of soft Bangkok clay has been determined already in the laboratory by Shibuya (1999), Teachavorasinskun and Amornwithayalax (2002) and Teachavorasinskun et al. (2002), the in-situ value has not been broadly determined. Therefore, an available in-situ V_s profile is suitable and should be adopted in the ground response analysis of the BMA. Since 1995, many scholars have measured the V_s profile around the BMA by various conventional methods. Shibuya (1997) obtained V_s profiles using the seismic cone test. Ashford (1997 and 2000) conducted a series of down-hole seismic tests along the north–centre–southeast of the BMA (Figure 1) and also estimated V_s from specific field and laboratory soil data using a number of published

empirical correlations, which were then developed into a generalized V_s profile. Moreover, the V_s profile obtained from the conventional methods appeared to have some variations, resulting in over- or under- estimation, because of a lack of suitably accurate values for some parameters in the V_s calculation. Teachavorasinskun (2004) interpreted the down-hole seismic tests of Ashford (1997 and 2000) by adding a correction to the V_s calculation, which acknowledged the surface distance of the point of wave generation in the down-hole tests. The linear increase of V_s with depth can be observed from this study. This proposed simple linear correlation between V_s and depth around the BMA is an essential, practical and portable component for further research. This useful correlation may at least contribute to the relative uniformity of subsoil conditions around the BMA.

The current study aimed to compute the site response in terms of Peak Ground Acceleration (*PGA*) and the soil amplification factor of the generalized subsoil around the BMA, by employing a linear V_s profile depicted by practical simple correlation (Teachavorasinskun, 2004) and comparing it with the step function V_s profile developed by estimation and in-situ measurements from earlier studies, such as Ashford (1997) and Warnitchai (2001). The one-dimensional site response analysis program, DEEPSOIL V3.7, developed at the University of Illinois at Urbana-Champaign by Professor Youssef M.A. Hashash and his students was adopted for the current study.

2. GROUND RESPONSE ANALYSIS

It is generally recognized that ground response analysis can determine, to some extent, the performance of the local soil conditions of a specific area that been shaken by a medium to strong earthquake. Some soils, especially those containing soft clay, might amplify (though some might de-amplify) the earthquake ground motions to about 3-6 times the *PGA*. Therefore, in an area located on layers of thick soft clay, such as Mexico City, the San Francisco Bay area and the BMA, particular attention should be paid to prevent damage, as well as loss of human life. A complete idealized ground response analysis can be categorized into three major steps: 1) the analysis of the rupture mechanisms, that is the fault characteristics and the direction of rupture propagation relative to the site at the source of an earthquake; 2) the analysis of the propagation of shear waves triggered by the fault through the bedrock below the site of interest; and 3) the analysis of the surface ground motion influenced by the local soil conditions above the bedrock. While the source mechanisms, as well as source-to-site behavior are somewhat crucial in ground response analysis, the local soil conditions always play an important role in the determination of surface ground motion as influenced by any seismic force. Another reason to simplify the ground response analysis is that in some countries, such as Thailand, information on the fault characteristics within or near the country is very limited. Therefore, the problem of ground response analysis can be simplified to the determination of the soil response to the motions of the bedrock directly beneath it.

In order to undertake ground response analysis, many soil parameters need to be entered into the program. Those parameters include the unit weight of soil, geometry (soil thickness), soil damping characteristics and shear modulus or V_s profiles. The appropriate input bedrock motion is vital in the analysis. The frequency content parameter and the duration of earthquake motion appear to have a substantial effect on the response of local soil conditions.

2.1 Generalized Soil Profile and Basic Soil Properties of the BMA

The generalized soil profiles and the basic soil properties of the BMA used in this research were based on data obtained from the literature (Ashford, 1997 and 2000; Shibuya, 2003; Teachavorasinskun, 2004) with some adjustments (Figure 2). It is recently known that the BMA is composed of layers of soft-to-stiff clay and medium-to-dense sand in the topmost 80 m. It is also recognized that BMA subsoil is relatively uniform throughout the entire area. The generalized soil profile of the BMA consists of five layers of different thicknesses and properties of subsoil underlain by elastic bedrock. The first layer of soft clay is 15 m thick. The second layer contains the first stiff clay and is 10 m thick and is over the first dense sand which is 15 m thick. The fourth layer is a second layer of stiff clay with a thickness of 5 m. The last layer of the generalized soil profile is the second dense sand layer with a thickness of 35 m. It should be noted that the properties of the bedrock profile under the BMA area vary in the range of 550 to 2,000 m in depth and are not exactly identified. The aquifer system above this bedrock is known to be very complex (Brand, 1976) and no rock outcrop is located in the area. A variety of bedrock types, such as gneiss and quartzite have been identified (Shibuya, 2003). Therefore, in this analysis, the bedrock was simplified to be just under the generalized soil profile of the BMA with a unit weight of 23.60 kN/m^3, with V_s being about 1,000 m/s.

2.2 Shear Wave Velocity Profile of the BMA

In this study, the sensitivity of the V_s profile on the estimation of ground response analysis of BMA was evaluated by exploiting the generalized (best-estimated) V_s profile developed by Ashford (1997 and 2000), called a step V_s profile, and the linear V_s profiles developed by Teachavorasinskun (2004) as comparative V_s profiles in the analysis (Figure 2). The step V_s profile was derived from the specific field and laboratory soil data from nine sites around the BMA, using several published empirical correlations, and then the estimates were confirmed by referring to actual in-situ V_s measurements at another six sites, namely, AIT and SIIT (north of the BMA), Chula 1 and 2 (in the centre of the BMA) and Nong Gu Hao and Lad Krabang (south of the BMA) using a down-hole method. The step V_s profile is a conventional step-function profile extensively employed in the representation of in-situ measurement of V_s from various measurement methods, including down-hole seismic and

seismic cone tests. However, it has been recently recognized that an erroneous profile can occur if some of the parameters are ignored in the surface distance of wave generation in the V_s calculation. In addition, the measurement method itself gives a variation in V_s. The V_s value obtained from the seismic cone test was greater than that measured by the cross-hole seismic method. Therefore, in uniform layers of subsoil, as occur in the BMA, the new simple correlation between V_s and depth interpreted and corrected from the existing data of down-hole seismic tests can be used to represent the V_s profile more simply and practically. Figure 2 represents the step V_s and the simple V_s profiles. It can be discerned from Figure 2 that the simple V_s profiles seem to be at the boundary values of the step V_s profile. It is also noticeable that the boreholes of Chula 1 and 2 and of AIT and SIIT are in the north and centre of the BMA, while the Nong Gu Hao and Lad Krabang boreholes are in the southeast of the BMA. The linear V_s profiles of Chula 1 and 2, as well as for the AIT and SIIT sites, are almost similar. In addition, an almost-parallel line between Nong Gu Hao and Lad Krabang sites could be observed. As a result, only two of these profiles, (Chula 1 and 2 and Nong Gu Hao sites), were selected as the linear V_s profiles in the analysis.

2.3 Soil Models for Ground Response Analysis

The cyclic properties of clay, the shear modulus reduction curve and the damping ratio, employed in this equivalent linear analysis were taken from Teachavorasinskun et al. (2002). They proposed a hyperbolic equation of the equivalent shear modulus degradation curve as well as a damping ratio versus the single amplitude shear strain curve for soft-to-medium Bangkok clay (Figure 3). The shear modulus curves show that the proposed curve of soft Bangkok clay by Teachavorasinskun et al. (2002) agrees well with the curves by Vucetic (1991) with a plastic index (*PI*) range of 15-50. It should be noted that the typical range of *PI* for soft Bangkok clay is between 30 and 60. The curve of Hardin (1972) over-estimates somewhat the shear modulus reduction curve of soft Bangkok clay. For soft Bangkok clay, the damping ratio curve, PI = 30, from Vucetic (1991) was adopted, because in a previous investigation by Teachavorasinskun et al. (2002), no unique relationship resulted from the damping ratio test results, due to the dependency of the damping ratio on some cyclic load characteristics, specifically the rate of loading and the initial confining pressure. The soil modulus and damping factor curves produced by Seed (1970) were used in the response analyses for sand.

2.4 Input Motions

The strong ground motion time histories were selected based on the frequency content as well as the epicentral distance from the available strong motion databases, namely the COSMOS virtual data center and the USGS National Strong-Motion Project (NSMP). The BMA study area is quite far from any current, known, potentially active faults in the western part of Thailand (approximately 200-300 km). Though those active faults can produce an earthquake of about M_w = 7.8 (Teachavorasinskun and Pongvithayapanu, 2006), owing to the path and distance effects, the high frequency content of the earthquake wave will be filtered and attenuated as it travels through the soil layers and bedrock underneath the BMA. For this reason, the relatively low frequency but long shaking duration of the 1999 Hector Mine earthquake (on October 16, 1999 at 2:46:44 am near California, USA) was picked as an input source for this analysis. However, an earthquake motion of relatively high frequency content, such as the 1988 Burma-India border earthquake, was also employed to observe the effect of the frequency content parameter in this ground response analysis. The characteristics, the motion time histories and the Fourier amplitude spectrum of these two earthquake scenarios are shown in Table 1 and Figure 4. The high frequency content of the 1988 Burma-India border earthquake can be observed from the relationship of the Fourier amplitude spectrum against frequency. In contrast, the 1999 Hector Mine earthquake had a relatively low frequency content.

2.5 Peak Acceleration Profiles and Amplification Ratio

It can be seen from the results of site response analysis that there were no significant trends in the peak acceleration, amplification ratio and pseudospectral acceleration (*PSA*) between the step V_s profile and linear V_s profiles employed in this study. For the peak acceleration throughout the entire depth of the generalized BMA subsoil profile, the difference was very small at depths below 40 m, especially with the input motion of low frequency content. However the high frequency content of earthquake input motion gave slightly more divergent results between those of the three V_s profiles, particularly near the ground surface. The complete results of peak acceleration profiles are plotted in Figure 5. The results for the amplification ratio show that the BMA subsoil of various V_s profiles could be amplified by high frequency input motion about 4-6 times in terms of *PGA* and by low frequency input motion about 4-7 times in terms of *PGA*. The step V_s profile and linear V_s profiles of the AIT & SIIT sites resulted in almost the same amplification ratio (Figure 6). The peak amplification ratio occurred in the frequency range between 0.5 and 1 Hz. Figure 7 shows the elastic response spectra in terms of *PSA* with 5% damping, which indicates clearly that for all the V_s profiles there was not much difference in the shape of the *PSA* response spectra.

3. CONCLUSIONS

From the one-dimensional ground response analysis of the BMA using the equivalent linear method and various V_s profiles, it can be inferred from the computed results that the simple linear V_s profile against depth could be used with a certain degree of satisfaction to predict some of the ground response parameters, such as peak ground acceleration, amplification ratio and the response spectrum. It should be acknowledged that the ground response analysis can be strongly influenced by the V_s profile. However in some areas, such as where there is low seismic activity from earthquakes,

experimental and in-situ test data of basic dynamic properties of the subsoil are somewhat scarce, a simple linear correlation of the V_s profile against depth could be employed to estimate the ground response analysis around such areas. Because of the fairly uniform layers of subsoil conditions underneath the BMA, the linear and practical correlations can capably represent the V_s profile through a finite depth of subsoil layers. In addition, it could be observed that the frequency content and the peak acceleration of input earthquake motion significantly affected the ground response analysis results, especially with regard to values of the amplification ratio and response spectra.

Abstract: Bangkok and its vicinity have substantial risks from distant earthquakes arises due to the ability of the underlying thick soft clay to amplify ground motions. The seismic regulation and design standards for buildings have been issued and updated occasionally according to the recent assessment of seismic hazards whilst site characterization for evaluation of seismic wave amplification has been primitively investigated. This research aims to quantitatively investigate site characteristics of subsoils by economical and practical technique of microtremor observations. The technique of single point observation with Horizontal-to-Vertical spectral ratio (H/V) method to estimate the predominant period and the technique of array observation with Spatial Autocorrelation (SPAC) technique for exploration of shear wave velocity profile are conducted for 36 sites in approximately 80 km by 80 km area. The results of shear wave velocity profiles are firstly compared with the available results from previous researches and they are found to be in good agreement. Site classifications based on the predominant period and the average shear wave velocity are presented and discussed with distribution of thickness of soft clay and geotechnical properties. Relations among average shear wave velocity from surface to different depth and predominant periods are investigated for their consistencies.

1. INTRODUCTION

Local site conditions can substantially influence the characteristics of ground shaking, such as amplitude, frequency content, duration, and earthquake damages. Several examples from catastrophic earthquakes have revealed that ground motion intensity can be amplified, frequency contents become narrow band, and duration of shaking can be lengthened due to a seismic interaction of soft shallow soil layers with deep basin structure below at the site. The local site effects are taken into account for seismic design by classifying site into categories based upon the geotechnical properties of the site and different levels of design ground motion are provided. The famous site characterization scheme has been established by the National Earthquake Hazard Reduction program (NEHRP 2004) and widely accepted in many countries. The average of shear wave velocity from the surface to 30-m depth (V_{S30}) is adopted as the key index for site classification. Recent studies have discussed on limitation on using V_{S30} to predict site amplification (Gallipoli and Mucciarelli 2009) and attempted to include site predominant period obtained by Horizontal-to-Vertical spectral ratio (H/V) study (Lang and Schwartz 2006)

Bangkok and the vicinity area, with more than ten million populations, is located about 120 to 300 km from low to moderate seismicity faults and 400 to 1000 km from highly active Sumatra subduction zone. The area is situated on a large plain underlain by the thick alluvial and deltaic sediments of the Chaophraya Basin. This plain consists of thick soft clay, about 15 to 20 m in the metropolitan area. The problem of soil amplification of ground motions of Bangkok is, therefore, appears to be susceptible to the teleseismic earthquakes. In fact, occasional events of tremors generated from remote earthquake were felt and caused chaos to Bangkok residents. The seismic regulation and design standards for building was firstly issued in 1997 and recently updated according to improvement of researches (DPT 2009). Among these pertinent tasks, site characterization for evaluation of seismic wave amplification has been primitively investigated. Owing to the limited information, this research aims to quantitatively investigate site characteristics of subsoils by economical and practical technique of microtremor observations. The technique of single point observation with Horizontal-to-Vertical spectral ratio (H/V) method to estimate the predominant period and the technique of array observation with Spatial Autocorrelation (SPAC) technique for exploration of shear wave velocity profile down to about 100 m are conducted for 36 sites in approximately 80 km by 80 km area.

2. MICROTREMOR OBSERVATION TECHNIQUES

The conventional approach for shear wave survey such as PS logging tests with boreholes has crucial disadvantages

as it is costly and time consuming. On the other way, microtremor observations have been raised up as a tool for evaluating site effects. This technique has several advantages; economical, environment friendly for urban area and effective for low or moderate seismicity area. In this study, the microtremor measurements, which can be readily conducted on the ground surface without drilling any borehole, are conducted for extensive surveys in the Greater Bangkok area to provide site characteristics useful for ground motion evaluation. The technique of single point microtremor observation with Horizontal-to-Vertical spectral ratio (H/V) method is applied to estimate the predominant period and the technique of array microtremor observation with Spatial Autocorrelation (SPAC) technique is applied for exploration of shear wave velocity profile.

2.1 Horizontal to Vertical Spectral Ratio Method (H/V spectral ratio)

This technique was proposed by Nakamura (1989) to interpret records of microtremors for the dominant period of subsoil sediments and also the estimated amplification level. In this method, the ratios of horizontal to vertical Fourier Spectra of microtremors are used to eliminate the source effect. This technique requires the horizontal and vertical component of microtremors measured at a single station only. The H/V spectrum plots are obtained by taking the ratio of the Fourier Spectra of the horizontal to the Fourier Spectra of the vertical component, as shown in equation 1.

$$\text{H/V spectrum} = \frac{\sqrt{F_{NS} \times F_{EW}}}{F_{UD}} \tag{1}$$

where F_{NS}, F_{EW} and F_{UD} are the Fourier amplitude spectra in the north-south, east-west and up-down directions, respectively. The peak of the H/V spectrum plot is interpreted as predominant period and amplification ratio. In spite of the wide popularity of the H/V spectral ratio method, there exists inconsistency of the assumption used in this method with theory. Nakamura's method assumes that microtremors are composed of body waves and thus is theoretically inconsistent with the results that show that microtremors are composed of surface waves. However, a number of researches have experienced that the H/V spectral ratio can be utilized to estimate the predominant period of a site, and it has broadly been applied to evaluate site effect and seismic microzonation.

2.2 Spatial Autocorrelation Method (SPAC method)

This technique was proposed by Aki (1957) based on the relationship between the temporal and spatial spectra of waves to obtain phase velocity dispersion curve. The basis of SPAC method is to simultaneously record the vertical component of microtremors for several positions to obtain Rayleigh wave samples propagating from a wide range of azimuthal angles. The coherency spectrum can then be computed for any pair of sensor in the array to evaluate the correlation among them to determine phase velocity characteristic which is dispersive. The coherencies for all measurement pairs having the same spatial distance are then azimuthally averaged to provide the spatial autocorrelation coefficients of inter-station distance r, $\rho(\omega, r)$. By assuming that, the wave energy propagates with only one velocity at each frequency, ω, it can be shown that the spatial autocorrelation coefficient for a circular array is given by (Aki, 1957, Okada, 2003):

$$\rho(\omega, r) = J_0\left(\frac{\omega r}{c(\omega)}\right) \tag{2}$$

where J_0 is the Bessel function of the first kind with the zero-th order and $c(\omega)$ is the (dispersive) phase velocity at frequency ω for the Rayleigh waves with the fundamental mode. From the dispersion relation of phase velocity and frequency, the results from field observations are then compared with those derived theoretically from a horizontally layered earth model by iteration procedure. The results of best-fit shear wave velocity–depth profile can be determined from the inversion analysis, in which this study applies the technique developed by Yokoi (2005) which employs the combination of Down Hill Simplex Method with Very Fast Simulated Annealing.

3. FIELD OBSERVATIONS AND ANALYSIS OF DATA

3.1 Area of Study

The investigated area is located within latitudes 13° 30' N to 14° 5' N and longitudes 100° 5' E to 100° 50' E, covering Bangkok and the vicinity provinces named Nakhon Pathom in the west, Nonthaburi and Pathumthani in the north, Samut Sakhon and Samut Prakan in the south. The area lies on a large alluvial plain of delta area where two main rivers, Chaopraya and Tha Chin, empty into the Gulf of Thailand in the south. Figure 1 shows the investigated area where 36 observation sites are distributed almost evenly inside.

Figure 1 Area of Study

3.2 Microtremor Observation

The measurement system consists of a portable data acquisition with 24 bit A/D converter and four units of the three components, moving coil type, velocity sensor with 2-second natural period. The sensors are connected to the data acquisition unit through cables. Before conducting measurement in each site, huddle test was performed for coherency and phase differences among the sensors. The applicable range of frequency was identified as from 0.8 to 17 Hz. At each record, data was recorded for 20 minutes with sampling frequency of 200 Hz. The data was divided into segment of 4096 data points and used for the analysis.

The arrangement of sensors for SPAC observation was selected as equilateral triangular array where one unit is placed at the center of circular and the other three are on the perimeter as shown in Figure 2. Four array arrangements were set for each site, with radius (r) of 9, 25, 35 and 50 m. In addition, pairs of peripheral stations with inter-station distance $\left(\sqrt{3}r\right)$ of 15.9, 43.3, 60.6 and 86.6 m are also included for calculating of SPAC coefficients. The maximum depth for inversion analysis was set to 90 m. The data of single station measurement were used to determine H/V spectrum ratio.

4. Results and Discussions

4.1 Comparison of V_{S30} with different techniques

First, the average of shear wave velocities from the surface to 30-m depth (V_{S30}) obtained by this study were compared with results from several techniques done by previous researchers. The number of pervious tests is limited which include seismic downhole tests by Palasri and Ruangrassamee (2009) named as D1 and Ashford (2000) named as D2, microtremor with frequency-wave number (F-k) spectral analyses by Arai and Yamazaki (2002) named as FK and multichannel analysis of surface waves method named as MASW. This research conducted the measurement at approximately the same location of total 7 sites. The results of V_{S30} are compared and shown in Figure 3. Despite the fact that results are not exactly identical for all tests, they are found to be in good agreement among different techniques employed.

The study remarks on a simple way to estimate V_{S30} from dispersion curve, without inversion analysis. Konno et. al. (2007) proposed that the phase velocity of Rayleigh wave with wave length of 40 m (C_{40}) can be used to approximate V_{S30}. The results from this study are presented in Figure 4 in which the applicability of the approximation technique can be clearly observed in spite of some degree of under estimation existed.

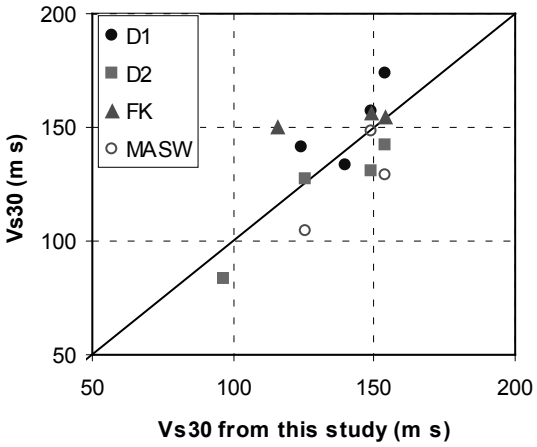

Figure 3 Comparison of V_{S30} obtained from this study and other techniques

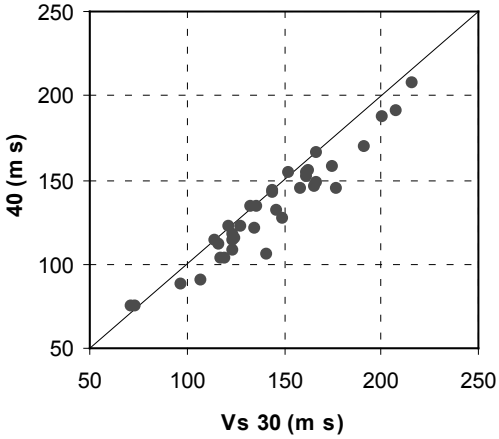

Figure 4 Comparison of V_{S30} obtained from this study and its estimation by phase velocity with wave length of 40 m

4.2 Results from Microtremors and Soil Data

The shear wave velocity and predominant period obtained from microtremor of 36 sites are discussed with soil profile classification in this area. Tuladhar (2003) used the boring log data to classify soil profile into several classes, which is re-drawn in Figure 5 and 6 for the profile and location of area, respectively.

Soil class A (A1, A2 and A3) has larger depths of soft soil layers (16 to 20 m). For class B (B1, B2 and B3), the thickness of soft clay is about 10 to 14 m. Soft clay is followed by first stiff clay and first sand for these soil classes. In soil class C (C1 and C2), which represents area nearby the boundary of the plain, the first layer is medium stiff clay about 8 to 10 m, and follow by first stiff clay or first sand layer.

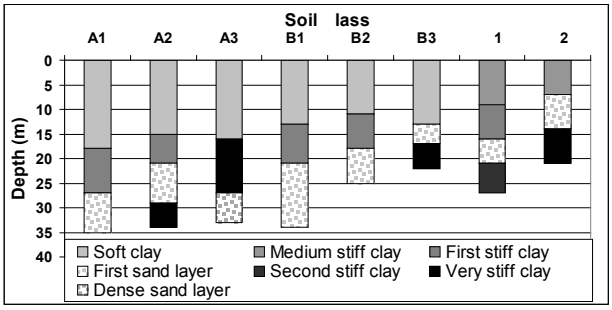

Figure 5 Generalized Soil Profiles in the Study Area

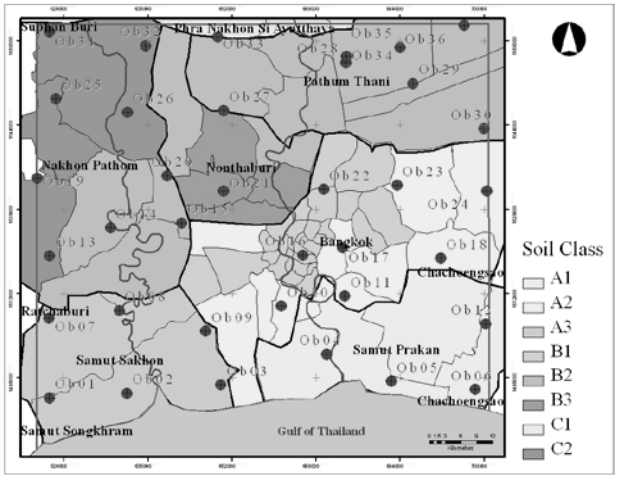

Figure 6 Location of Soil Classification Area

The results of average of shear wave velocity from the surface to 30-m depth (V_{S30}) and predominant period (T_P) are depicted in Figure 7 and 8, respectively.

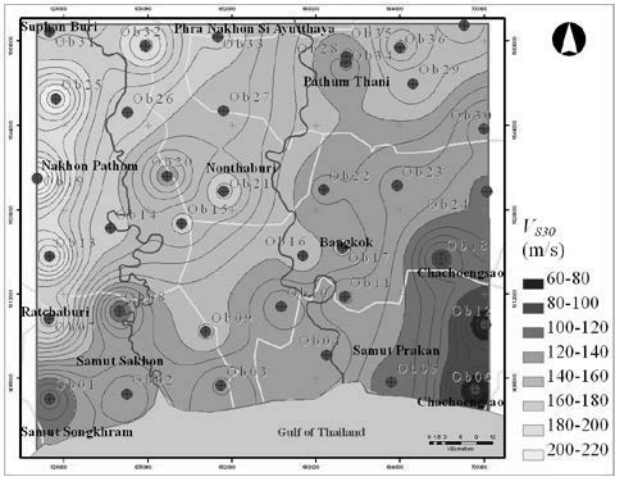

Figure 7 Map of V_{S30} for the Greater Bangkok

The variation of the values can be clearly distinguished where V_{S30} varies from 70 to 220 m/s and T_P varies from 0.4 to 1.1 second. The area with lowest V_{S30} and longest T_P is located in the south-east part where soil class is A1, which contains the deepest layer of soft soil. Area along the Gulf of Thailand exhibits low V_{S30} and long T_P, which is also consistent with properties of soil class A1, A2 and A3. For soil class B1, B2 and B3, V_{S30} is increased and T_P is shortened as soil becomes stiffer. The hardest soil type in this study located in the north-west part, class C2, yields highest V_{S30} and shortest T_P.

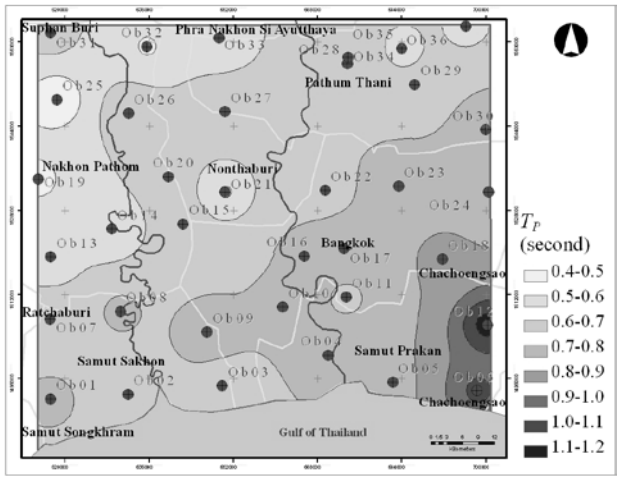

Figure 8 Map of Predominant Period for the Greater Bangkok

4.3 Discussion on Average Shear Wave Velocity and H/V Spectral Ratio

The microtremor technique provides both information on velocity structure of and predominant period of subsoil. There have been discussions on the latter result obtained by ambient H/V spectral technique since this technique is theoretical inconsistent by the assumption on type of wave mainly composed in the signal. In addition, shallow shear wave profiles, V_{S10}, was proposed for an economical site classification scheme (Gallipoli and Mucciarelli 2009). The following discussion provides relations among the average shear wave velocity at different depth, 10 m to 90 m, and the predominant periods obtained in this study. Figure 9 shows V_{S30} plotted in the abscissa and V_{S10}, V_{S50}, V_{S70}, and V_{S90} in the ordinate. From these relations, results from regression analysis in a form of $y=ax^b$ and the coefficient of determination (R^2) are provided in Table 1. It can be clearly noticed that, except V_{S10}, deeper shear wave velocities correlated well with V_{S30} by nearly linear relationship. The map of V_{S10} is shown in Figure 10 which could be misleading because V_{S10} is highly influenced by the uppermost layer of soft clay. This finding is contradicted to the investigation in Gallipoli and Mucciarelli 2009 which is resulted from different geological conditions.

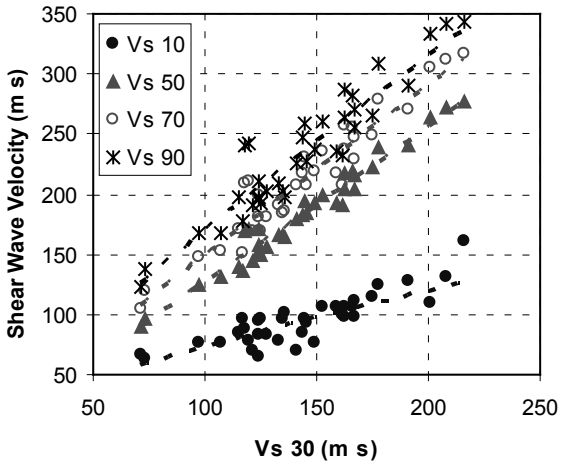

Figure 9 Relations among V_{S30} and V_{S10}, V_{S50}, V_{S70}, V_{S90}

Table 1 Results of Regression Analysis for V_{S30} and V_{S10}, V_{S50}, V_{S70}, V_{S90}

Type	a	b	R^2
V_{S10}	2.86	0.705	0.682
V_{S50}	1.19	1.01	0.963
V_{S70}	1.76	0.964	0.916
V_{S90}	2.78	0.892	0.893

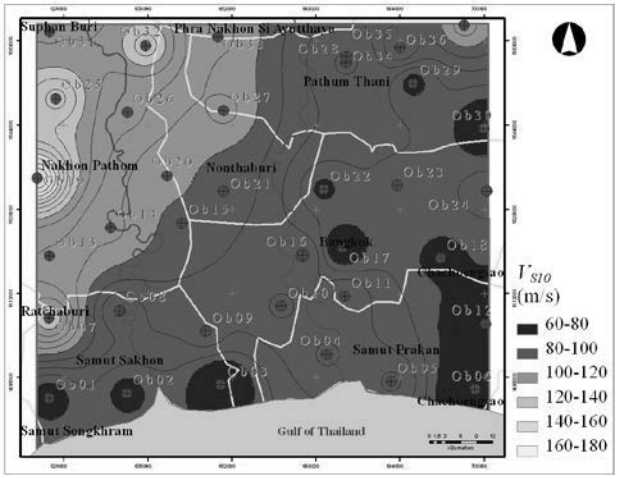

Figure 10 Map of V_{S10} for the Greater Bangkok

Figure 11 shows predominant frequencies $(1/T_P)$ plotted in the abscissa and V_{S10}, V_{S30}, V_{S50}, V_{S70}, and V_{S90} in the ordinate. Table 2 provides results from regression analysis in a form of $y=ax^b$ and the coefficient of determination (R^2). It can be noticed again that, except V_{S10}, deeper shear wave velocities correlated well with the predominant frequencies by nearly linear function. This could support the applicability of H/V spectral ratio technique that the information of deep ground structure can be achieved where the uppermost layers do not absolutely dominate the results.

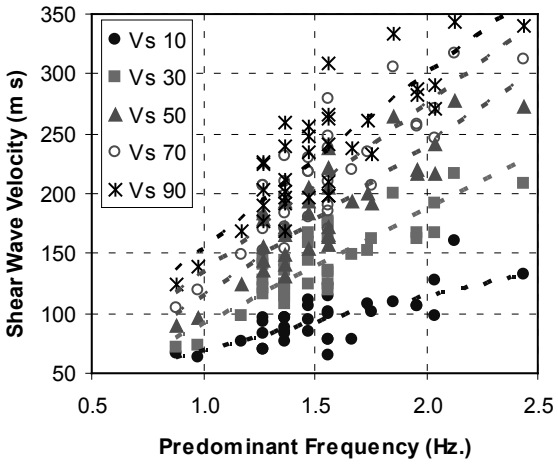

Figure 11 Relations among Predominant Period and V_{S10}, V_{S30}, V_{S50}, V_{S70}, V_{S90}

Table 2 Results of Regression Analysis for Predominant Period and V_{S10}, V_{S30}, V_{S50}, V_{S70}, V_{S90}

Type	a	b	R^2
V_{S10}	69.0	0.730	0.521
V_{S30}	91.7	1.03	0.747
V_{S50}	115	1.07	0.759
V_{S70}	135	1.03	0.742
V_{S90}	154	0.958	0.734

4. CONCLUDING REMARKS

Site characterizations in the Greater Bangkok by microtremor observation are presented in this paper. From 36 observation sites in 80 by 80 km^2 area, shear wave velocity profiles, by SPAC method, and predominant periods, by H/V spectral ratio method, are presented and discussed with soil classification based on boring log data. The area along the Gulf of Thailand and the south-east part of the study area exhibit very low V_{S30} of 70 m/s and long predominant period of 1.1 second while high V_{S30} of 220 m/s and short predominant period of 0.4 second are found the north-west part. This characterization is in accordance with generalized information from boring log data of soil layers.

The relations among the average shear wave velocity at different depth, 10 m to 90 m, and the predominant periods are discussed. It was shown that shallow shear wave velocities to 10 m depth, influenced by thick soft clay in this study, were not reasonably correlated with deep shear wave velocities. The predominant periods were shown to be able to represent shear wave velocity profiles down to 90 m.

Abstract: The **E**ngineering **G**eological **D**atabase for **T**SMIP (EGDT) was constructed by the National Center for Research on Earthquake Engineering (NCREE) and the Central Weather Bureau (CWB) in Taiwan from 2000 to 2010. SPT-N (Standard Penetration Test) values were obtained by in-situ experiment; otherwise, the critical physical characteristics of soils, such as void ratio, specific gravity, effective size, liquid limit, etc., were being measured from the samples, as well as the soils were classified according to the USCS. P and S wave velocity profiles were also measured by a suspension PS-logging system. The drilled depths in this project must exceed 35 m to ensure that Vs30 is able to be measured; moreover, several boreholes were drilled over 50 m or 100 m according to the annual contract stipulations. Nevertheless, some boreholes drilled in the first or second year do not reach the required 30 m. The database contains 469 surveyed stations, which are about 69% (469/682) of the free-field TSMIP network. We therefore used the database to evaluate the empirical Vs equations for different areas, as well as the station sites were classified according to the Vs30 criterion of NEHRP. Everyone can search or apply for the data from the website: http://geo.ncree.org.tw/.

1. INTRODUCTION

Site effect is a very important issue in both seismology and earthquake engineering. Different characteristics of near surface layers cause various effects at sites. The so-called Vs30, the average shear wave velocity of the top 30 meters, is a well-known parameter used on defining the hardness of sites. Anderson et al. (1996) indicated that layers of the depth in top 30 meters have a considerable influence on the characteristic of the ground motion generated. Vs30 was further recommended as a significant parameter for recent building code (BSSC 2001; Dobry et al. 2000); moreover, it was used by the Next Generation Attenuation of ground motions project (NGA) in strong ground motion prediction studies (Power et al. 2008; Chiou et al. 2008). It should be noted that the strong motion recordings in Taiwan were also included in the NGA database by the executive - Pacific Earthquake Engineering Research Center (PEER).

For collecting high-quality instrumental recordings of strong ground motion caused by earthquakes, the Taiwan Strong Motion Instrumentation Program (TSMIP) was carried out by the CWB from 1991. Most of the stations were installed in the metropolitan districts of Taiwan for earthquake hazard reduction. These data were really useful for understanding earthquake source mechanism and improving seismic design of buildings, as well as studying seismic wave propagation, including local site effect.

In order to use the collected strong motion recordings more effectively and precisely on earthquake engineering, the NCREE and the CWB had established a free-field strong motion drilling project to construct the EGDT since 2000. 469 free-field strong motion stations had been surveyed in the past decade.

439 of the 469 surveyed stations included wave velocity profiles and most of the profiles reached a depth of 30 m, so that the site classification was done according to the Vs30 criterion of NEHRP Provision. In the process, Vs30 values were estimated by a reliable extrapolation for the profiles did not reach 30 m. Otherwise, we also analyzed the relations between shear-wave velocity (Vs), N value, and depth to evaluated empirical Vs equations in different regions of Taiwan.

2. ENGINEERING GEOLOGICAL DATABASE FOR TSMIP

2.1 Summary of the EGDT

Taiwan Island results from the collision of the Philippine Sea Plate and the Eurasian Plate. The rate of the subduction system is still about 80 mm/yr today, which made a four-kilometer-high mountain belt and high uplift rate of 5-7 mm/yr in marine terrace (Liew et al. 1993), as well as high seismicity in and around the island. Otherwise, Taiwan was considered suffering the highest erosion rate in the world (Koppes and Montgomery 2009). That is why the geology, topography, and seismicity are various and

complex in Taiwan.

After the destructive Chi-Chi earthquake, the variable geological conditions at strong motion stations were considered must to be known, and then the site effect might be assessed. The work will be an important reference material to reduce the hazard from another possible earthquake in the future.

In the first year, 2000, the surveyed focused on the co-stations of TSMIP and Taiwan Rapid Earthquake Information Release System (RTD). Then the stations located on the Western Plain were surveyed in 2001. Surveyed stations achieved a number of 469 until 2010, about 69% (469/682) of the free-field TSMIP network (Figure 1).

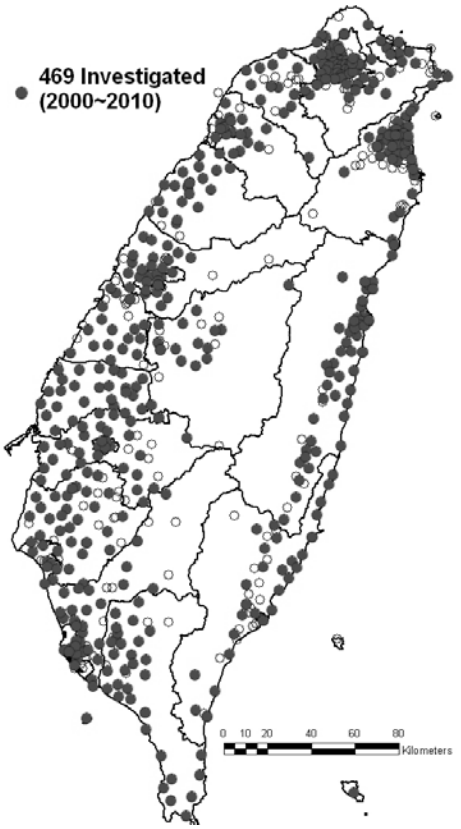

Figure 1 Distribution of the free-field TSMIP stations. The red circles are surveyed station whereas the open ones are still not.

The investigations of TSMIP included drawing surface chart nearby, in-situ standard penetration test, experiments of critical physical characteristics for soils in laboratory, such as void ratio, specific gravity, effective size, liquid limit, grain size distribution size, Atterberg index, etc., as well as the soils were classified according to the Unified Soil Classification System (USCS). Otherwise, P and S wave velocities were also measured using a suspension PS-logging system. Sampling rate of the suspension PS-logging system can up to 2.5 μs and frequency of the velocity measurement is 0.5 or 1 m per point. Some boreholes drilled in the first and second year did not reach the required 30 m, thus the drilled depth in the project was stipulated 35 m at least to ensure that Vs30 is able to be measured after 2001. Furthermore several boreholes were drilled over 50 m or 100 m according to the annual contract stipulations. However, there were still a few velocity profiles did not reach 30 m due to borehole collapse after 2001. 22 boreholes were drilled larger than 50 m in the database and the deepest one is 150 m at TCU138.

All of the in-situ procedures and sampling are under the criteria of American Society for Testing and Materials (ASTM) in this project. The core sampling was made for colluvium, gravel formation, and rock formation, but not for soil layers. During drilling process, SPT was carried out every 1.5 meters (every 3 to 5 meters in gravel layer) or when encountered the interface of different materials; moreover, disturbed samples were also sampled at the same time. The following physical characteristics and soil classification were executed under the ASTM criteria in a laboratory certificated by the Taiwan Accreditation Foundation (TAF).

After drilling, the borehole was casing a PVC pipe and then the gap between PVC pipe and borehole was grouted. Suspension PS-logging system has two receivers at a fixed distance of 1 m, as well as a source was integrated in a tube. That is why the continuous measurement and velocities at depth were capable by this system. P and S wave velocities were calculated by the differences of arrival times (Figure 2).

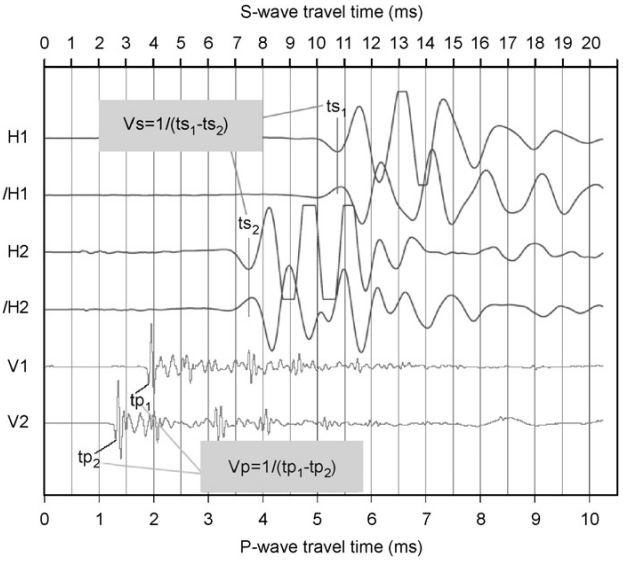

Figure 2 Illustration of the suspension PS-logging method. Vs and Vp were calculated from the formulas on the sketch. (After Kuo et al. 2009, Fig. 9)

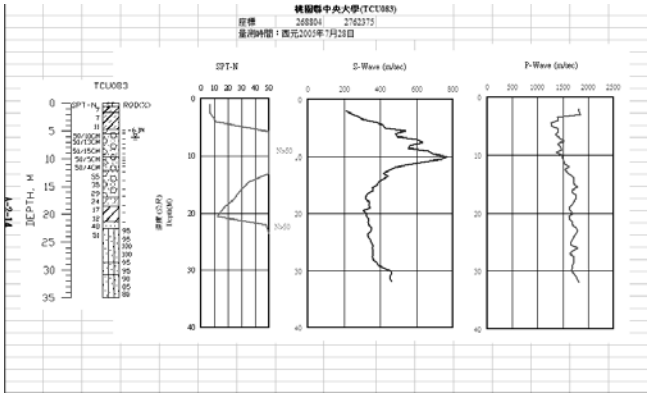
2.2 Requested Data Format

The data we provided now included six parts, they are strata description, result of soil physical property tests, P and S wave velocities, SPT-N values, strata profiles and coordinates, and plan view and photos, respectively. They are free for request and provided in Excel format. Figure 3 showed an example at TCU083. Some supplements, such as raw data (ORG format) of PS-logging system, photo of core



samples, and aerial photographs (Figure 4) were also free, but a further application procedure is needed.

3. CHARACTERISTICS OF NEAR-SURFACE STRATA

This section exhibited the studies about the characteristics of the near-surface strata. They might be significant reference materials for site effect and strong motion prediction researches. However, the data used by the following empirical Vs equations and Vs30 extrapolations were until 2009. The last drilled results of 2010 were only adopted on the site classification now.

3.1 Empirical Vs Equations

Many researchers had evaluated empirical equations of shear wave velocity because of the efficiency and economy. Fourteen representative results (Ohsaki and Iwasaki 1973; Hamilton 1976; Imai 1977; Ohta and Goto 1978; Seed and Idriss 1981; Sykora and Stoke 1983; Lee 1992; Pitilakis et al. 1999; Japan Road Association 2002; Chen et al. 2003; Holzer et al. 2005, Chapman et al. 2006; Hasabcebi and Ulusay 2007; Lee and Tsai 2008) were shown in Table 1. Those researches established relations among soil indexes. We are following the method proposed in the previous article (Kuo et al. 2011) to evaluate empirical Vs equations

in other regions of Taiwan. The codes of TSMIP stations were given according to the abbreviations of seven regions of Taiwan, which are TAP, TCU, CHY, KAU, TTN, HWA, and ILA. Kuo et al. (2011) evaluated the equations for TAP (Taipei Basin) and ILA. The present study evaluated the equations in other five regions using the data of EGDT, and the results were shown in Table 2 as well as the published results in TAP and ILA (Kuo et al. 2011). It should be noted that the empirical equations in Table 2 using the data until 2009, however, they might be some different after the data of 2010 is joined. However, the equations can only be applied to the strata shallower than or equal to 50 m as well as N smaller than 50 because of our data collection.

Because empirical equations in HWA and TCU passed the rule of thumb test, but failed in stepwise selection, we could not implement multivariable analysis for the data of the two regions due to multicollinearity. There are only a few data sets in HWA and TTN (fewer than 200 data sets), so that we did not consider the soil types or it might be unreasonable in statistics. The empirical equations were plotted together in Figure 5. The empirical Vs equations in Figure 5 were displayed as a function of N that we let the parameter of depth as 20 meters. The S wave velocity in TTN and HWA are obviously larger than in other regions. This phenomenon reflects the real geological background of Taiwan.

Table 1 Fourteen representative empirical equations of shear wave velocity quoted by this study.

Author	Regression equation	Soil type	Samples
Ohsaki and Iwasaki (1973)	$Vs=82N^{0.39}$	All	220

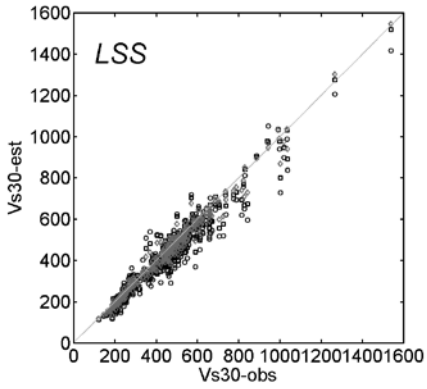
3.2 Extrapolations of Vs30

53 of the 439 drilled boreholes did not reach 30 m in the EGDT. It will be a problem when calculating Vs30 for not only the stations in Taiwan, but also those in other countries. The earlier article (Kuo et al. 2011) discussed this problem and then compared three frequently used techniques, which are least square of single station (LSS), statistical extrapolation (STS), and bottom constant velocity (BCV). They indicated BCV is the most accurate method for stations in TAP and ILA regions.

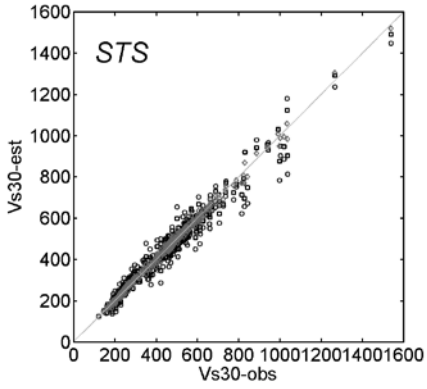
Based on the procedure of Kuo et al. (2011), we further compared the accuracy of the techniques using the boreholes (until 2009) attain to 30 m. 367 boreholes were used in the examination by using an error percentage (Err%):

$$Err\%=\frac{\sum|V_{rel}-V_{est}|/V_{rel}}{n}\times 100\% \qquad (1)$$



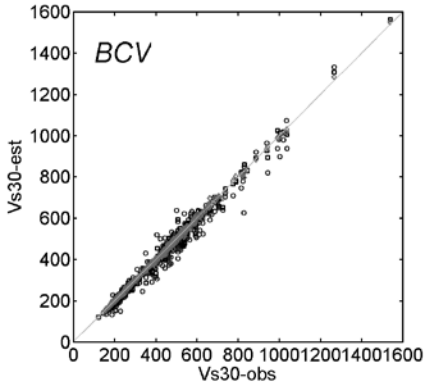
Where V_{rel} is the measured S wave velocity, V_{est} is estimated S wave velocity by extrapolations, and n is the number of data. The error percentages were showed in Table 3 and indicated the same result as Kuo et al. (2011), that is, obviously BCV is the most accurate and stable extrapolation in the regions.

In addition, Figure 6 illustrated the estimated Vs30 (y-axis) by the three extrapolations (Figure 6(a) ~ (c)) as well as the estimated results by Lee and Tsai (2008) (Figure

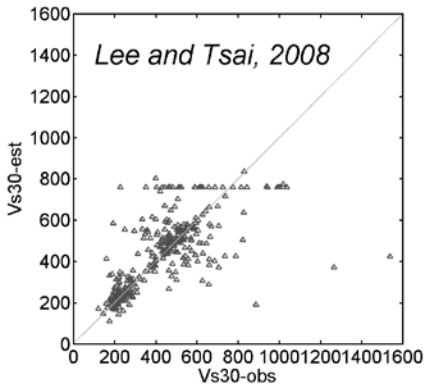


6(d)) versus the real Vs30 (x-axis) obtained by PS-logging for the 367 boreholes. The assumed depths of 15, 20, and 25 m were represented as open blue circles, open black squares, and open magenta diamonds, respectively. The discrepancies between the estimated and real Vs30 decrease as assumed depths increase in Figure 6(a) ~ (c). Otherwise, the divergences of BCV are the least. The phenomena indicated again the error is becoming smaller as depth increasing, and BCV can get the best Vs30. Figure 6(d) denoted the results of Lee and Tsai (2008) still have large disagreements even if the largest estimated Vs30 had been restricted by a value of about 800 m/s. It should be noted that Lee and Tsai (2008) also used the data of EGDT but only until 2005 as well as other 4885 engineering boreholes in their geo-statistical method.

Table 3 The Err% obtained from extrapolations at three assumed depths. The percentages after "±" are the standard deviations.



Assumed depth	Mean Err% of 367 boreholes		
	LSS	STS	BCV
15 m	11.26% ±8.03%	7.37% ±6.61%	6.66% ±5.69%
20 m	8.06% ±6.15%	4.68% ±4.05%	3.12% ±2.85%
25 m	5.69% ±4.41%	2.17% ±1.95%	1.17% ±1.27%



(a) Estimated Vs30 by LSS versus real Vs30.

(b) Estimated Vs30 by STS versus real Vs30.

(c) Estimated Vs30 by BCV versus real Vs30.

(d) Estimated Vs30 by Lee and Tsai (2008) versus real Vs30.

Figure 6 Estimated Vs30 by different methods (y-axis) versus real Vs30 obtained by PS-logging measurements (x-axis).

3.3 Site Classification of Drilled TSMIP Stations

Site classifications were achieved for the 439 drilled TSMIP stations according to the Vs30 criteria of NEHRP (Table4). Vs30 were estimated by BCV for these stations did not be drilled to 30 m. The results were illustrated in Figure 7. There are one of class A, 29 of class B, 200 of class C, 193 of class D, and 16 of class E. In Taiwan, most stations belong to class C and D (89.5%); the others are only 10.5%. Stations of class D and E mainly distributed on plains and basins with unconsolidated sediments; stations of class C are located on northwestern Taiwan and around the Central Mountain and the Coast Range; stations of class B are mostly located on the north of Taiwan and several on mountain areas; the unique class A in the database only appears in the Coast Range.

Table 4 Site class Definition of NEHRP in terms of Vs30 and brief geological descriptions.

NEHRP site class	Description	Range of *Vs*30 (m/s)
A	Hard rock	$Vs30 > 1500$
B	Firm to hard rock	$1500 \geq Vs30 > 760$
C	Dense soil and soft rock	$760 \geq Vs30 > 360$
D	Stiff soil	$360 \geq Vs30 \geq 180$
E	Soft soil	$180 > Vs30$

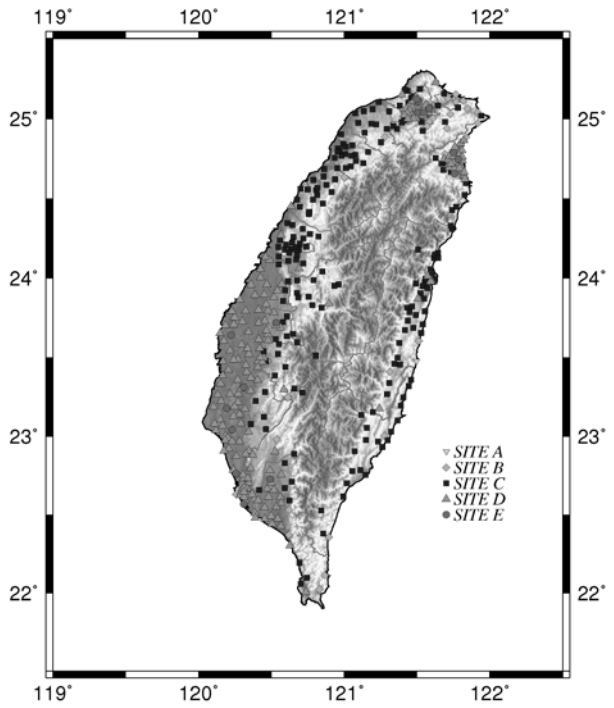


Figure 7 Distributions and site classifications of 439 drilled free-field TSMIP stations in Taiwan.

4. CONCLUSIONS

The goal of this article is to introduce the Engineering Geological Database for TSMIP in Taiwan, as well as the main results investigated recently by ourselves. The empirical Vs equations could offer important information about near-surface velocity profiles for calculation of seismic wave propagation, like SHAKE; otherwise, the Vs30 provided the significant parameter of site effect in earthquake engineering, and also for strong ground motion prediction.

Many organizations applied for the data of EGDT, such as the United States Geological Survey, the University of Southern, PEER, the State University of New York, the Tokyo Institute of Technology, the Karlsruhe University, the Carleton University, the University of Sheffield, the China Earthquake Administration, and local institutes in Taiwan. Dozens of researches which used the data has been published; include SCI articles, EI articles, proceedings of conferences, master and Ph.D. thesis, and technical reports. For example, the amount of published SCI journal articles is 11 (Huang et al. 2005, 2007, 2009; Wang et al. 2006; Sokolov et al 2007; Wen et al, 2008; Lee and Tsai 2008; Pavlenko and Wen 2008; Kuo et al. 2009, 2011; Lin et al. 2009). Those articles might make you more understand about the database and give you some ideas of using the data.

Acknowledgements:

It is gratefully acknowledged that the EGDT was constructed by many participants in the past decade. Additionally, the authors thank Dr. Cheng-Chao Lee for providing many helpful reference materials.

Abstract: In our previous work (Qian et al, 2010), we presented the theory of a hybrid boundary element method which can be applied to study the effects of liquid layer on seismogram synthesis in multi-layered solid/liquid media. In this paper, we show the numerical implementation of the method and state a step-by-step procedure of applying the algorithm to a general multilayered fluid-solid media. First, two models containing irregular fluid-solid interfaces are used to test the validity of the method. Then, a preliminary application is conducted in the Kanto basin area by a realistic model for the Kanto basin including sea water. The difference appearing in the synthetic seismograms due to the presence of the water layer can be clearly observed. This kind of synthesis could help us understand the influence of water layer on the seismic ground motion at land, in which seismologists may be mostly interested.

1. INTRODUCTION

This work is the second part of a series study about water effects on seismogram synthesis in multilayered media with irregular interfaces. In the first part of the series study (Qian et al, 2010; hereafter referred to as article I), we have developed and presented the theoretical formulation of an extended synthesis method for simulating seismoacoustic scattering by an irregular fluid-solid interface within a multilayered medium. As the second part of the series study, the present article will be devoted to assessing the validity of the formulation obtained earlier and showing its applicability. For the sake of continuity of the presentation, we shall first briefly summarize the theory and fundamental formulas needed in the present article. We shall then test its validity by comparing the results calculated using our formulation with the existing results by the reflection/transmission matrix method (Okamoto and Takenaka, 1999), two fluid-solid models are used for this testing: one is an elastic half space containing a basin-like water layer, and the other one is an elastic half space containing a flat water layer with a basin. Finally, as a preliminary application of our formulation, we shall simulate the wave propagation in a realistic Kanto basin model including sea water layer to see how much is changed in the synthetic seismograms due to the appearance of the water layer.

2. SUMMARY OF THE ALGORITHM

2.1 Solution procedure

In this subsection, we shall briefly summarize the theory developed in article I and describe the procedures of its implementation. The problem to be considered is illustrated in Fig. 1. In this model, there are L homogeneous layers $\Omega^{(i)}$ (i=1, 2, …, L) over a half-space, among which the ith layer is bounded by two irregular interfaces $\Gamma_{(i-1)}$ and $\Gamma_{(i)}$ (Throughout the paper, the superscript with round brackets is used for layer index and the subscript with round brackets for interface index). The uppermost layer is water which is assumed to be linear, incompressible liquid without viscosity. An arbitrary seismic source is embedded in the sth layer. The properties of an arbitrary solid layer $\Omega^{(i)}$ are described by the elastic constants $\lambda^{(i)}$, $\mu^{(i)}$ and mass density $\rho^{(i)}$. As shown in article I, this problem has been theoretically solved by using a hybrid boundary element method. This method can be regarded as an extension of the approach (Ge and Chen, 2007 and 2008), combining the traditional boundary element method with the global reflection/transmission matrix propagators (Chen, 1990 and 1995), which was originally developed for efficient seismogram synthesis in multilayered solid media with irregular interfaces. The procedure of applying the introduced algorithm to calculate a seismic ground motion in a general irregular multilayered water-solid medium can be summarized as follows.

Step 1 By using the free surface condition calculate the global matrix propagators in the uppermost layer, i.e. the water layer, by the following equation

$$\begin{pmatrix}\mathbf{D}_{qq}^{(1)}\\ \mathbf{D}_{pq}^{(1)}\end{pmatrix}=\left(-\mathbf{G}_{(1)}^{(1)}\quad \mathbf{H}_{(2)}^{(1)}\right)^{-1}\mathbf{G}_{(2)}^{(1)}, \tag{1}$$

where **H** and **G** are the coefficient matrices obtained by integrating the fundamental solutions of the potential problem (Balas et al, 1989) over elements at both interfaces $\Gamma_{(i)}$ and $\Gamma_{(i+1)}$. The detailed definitions of the global matrix propagators **D** can refer to our previous work (Qian et al, 2010). Suppose each interface is discretized into *N* elements, the global matrix propagators obtained in Eq. (1) obviously have the dimension *N*×*N*. (Here, one important point is that the form of Eq. (1) is different from those used to obtain global matrix propagators in solid layers since the wave propagation problem in the water layer is taken as a potential problem and no shear waves exist.)

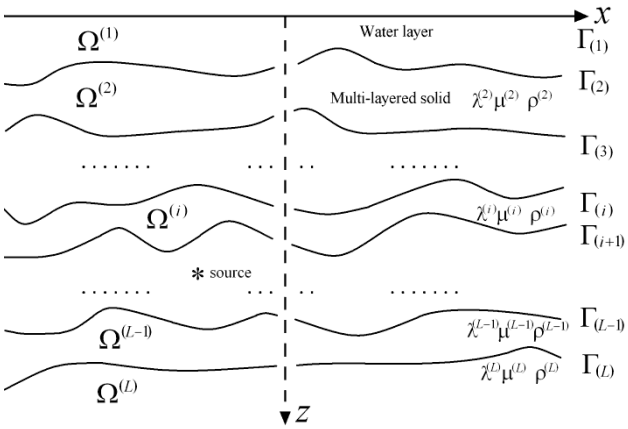

Fig. 1 A multi-layered water/solid model with irregular interfaces

Step 2 By using the continuity conditions at the liquid-solid interface (Medina and Dominguez, 1989), extend the global matrix propagators obtained in Step 1 into the same dimension as those defined in solid layers, i.e. 2*N*×2*N*,

$$\mathbf{D}_{tu}^{(1)}=\rho_{\mathrm{f}}\omega^2\begin{bmatrix}\mathbf{D}_{pq}^{(1)}\cdot\mathbf{N}_1^{\mathrm{e}}\cdot(\mathbf{N}_1^{\mathrm{e}})^{\mathrm{T}} & \mathbf{D}_{pq}^{(1)}\cdot\mathbf{N}_2^{\mathrm{e}}\cdot(\mathbf{N}_1^{\mathrm{e}})^{\mathrm{T}}\\ \mathbf{D}_{pq}^{(1)}\cdot\mathbf{N}_1^{\mathrm{e}}\cdot(\mathbf{N}_2^{\mathrm{e}})^{\mathrm{T}} & \mathbf{D}_{pq}^{(1)}\cdot\mathbf{N}_2^{\mathrm{e}}\cdot(\mathbf{N}_2^{\mathrm{e}})^{\mathrm{T}}\end{bmatrix}, \tag{2}$$

where ρ_{f} is the mass density in the water layer and ω is the angular frequency. The matrices $\mathbf{N}_1^{\mathrm{e}}$ and $\mathbf{N}_2^{\mathrm{e}}$ are defined as follows:

$$\mathbf{N}_1^{\mathrm{e}}=\begin{bmatrix}n_1^{\mathrm{e}1} & n_1^{\mathrm{e}2} & \cdots & n_1^{\mathrm{e}N}\\ n_1^{\mathrm{e}1} & n_1^{\mathrm{e}2} & \cdots & n_1^{\mathrm{e}N}\\ \vdots & \vdots & \ddots & \vdots\\ n_1^{\mathrm{e}1} & n_1^{\mathrm{e}2} & \cdots & n_1^{\mathrm{e}N}\end{bmatrix}, \tag{3a}$$

$$\mathbf{N}_2^{\mathrm{e}}=\begin{bmatrix}n_2^{\mathrm{e}1} & n_2^{\mathrm{e}2} & \cdots & n_2^{\mathrm{e}N}\\ n_2^{\mathrm{e}1} & n_2^{\mathrm{e}2} & \cdots & n_2^{\mathrm{e}N}\\ \vdots & \vdots & \ddots & \vdots\\ n_2^{\mathrm{e}1} & n_2^{\mathrm{e}2} & \cdots & n_2^{\mathrm{e}N}\end{bmatrix}, \tag{3b}$$

in which n_1^{e} and n_2^{e} are the components of the unit normal vector of the neighboring solid layer at element 'e'.

Step 3 Use the extended global matrix propagator obtained in Step 2 to calculate the global matrix propagators in the neighboring solid layer, i.e. $\Omega^{(2)}$, by

$$\begin{pmatrix}\mathbf{D}_{uu}^{(2)}\\ \mathbf{D}_{tu}^{(2)}\end{pmatrix}=-\left(\mathbf{H}_{(2)}^{(2)}-\mathbf{G}_{(2)}^{(2)}\mathbf{D}_{tu}^{(1)}\quad \mathbf{G}_{(3)}^{(2)}\right)^{-1}\mathbf{H}_{(3)}^{(2)}. \tag{4}$$

Then use the global matrix propagators obtained in Eq. (4) to calculate the global matrix propagators in the other solid layers below $\Omega^{(2)}$ until the layer neighboring the seismic source layer by

$$\begin{pmatrix}\mathbf{D}_{uu}^{(i)}\\ \mathbf{D}_{tu}^{(i)}\end{pmatrix}=-\left(\mathbf{H}_{(i)}^{(i)}-\mathbf{G}_{(i)}^{(i)}\mathbf{D}_{tu}^{(i-1)}\quad \mathbf{G}_{(i+1)}^{(i)}\right)^{-1}\mathbf{H}_{(i+1)}^{(i)}, \tag{5}$$

where i = 3, 4, …, s−1 with s denoting the seismic source layer.

Step 4 In case of a plane wave incidence problem or a seismic source located at the bottom layer, skip this step and jump to Step 5. Otherwise, calculate the global matrix propagators in the bottom layer by using the radiation conditions at infinity, we thus have

$$\begin{cases}\mathbf{D}_{uu}^{(L)}=0\\ \mathbf{D}_{tu}^{(L)}=\left(\mathbf{G}_{(L)}^{(L)}\right)^{-1}\mathbf{H}_{(L)}^{(L)}.\end{cases} \tag{6}$$

Use the global matrix propagators obtained in Eq. (6) to calculate the global matrix propagators in the solid layers which are above the bottom layer but below the seismic source layer by

$$\begin{pmatrix}\mathbf{D}_{uu}^{(i)}\\ \mathbf{D}_{tu}^{(i)}\end{pmatrix}=-\left(\mathbf{H}_{(i+1)}^{(i)}+\mathbf{G}_{(i+1)}^{(i)}\mathbf{D}_{tu}^{(i+1)}\quad -\mathbf{G}_{(i)}^{(i)}\right)^{-1}\mathbf{H}_{(i)}^{(i)}, \tag{7}$$

where $i = L-1, L-2, \ldots, s+1$.

Step 5 Substitute all the global matrix propagators obtained in the above steps into the simultaneous matrix equation in the seismic source layer and solve the problem by

$$\left(\mathbf{H}_{(s)}^{(s)}-\mathbf{G}_{(s)}^{(s)}\mathbf{D}_{tu}^{(s-1)}\right)\mathbf{u}_{(s)}+\left(\mathbf{H}_{(s+1)}^{(s)}+\mathbf{G}_{(s+1)}^{(s)}\mathbf{D}_{tu}^{(s+1)}\right)\mathbf{u}_{(s+1)}=\mathbf{F}, \tag{8}$$

where $\mathbf{u}_{(s)}$ and $\mathbf{u}_{(s+1)}$ are the displacement solutions at the upper and lower interfaces of the source layer, respectively.

Step 6 Obtain the displacement solutions at the fluid-solid interface by the global matrix propagators defined in Step 3 by the recursive relation

$$\mathbf{u}_{(2)}=\mathbf{D}_{uu}^{(2)}\mathbf{D}_{uu}^{(3)}\cdots\mathbf{D}_{uu}^{(s-1)}\mathbf{u}_{(s)}. \tag{9}$$

Step 7 Execute the Fast Fourier Transform (FFT) on the displacement solutions obtained in Eq. (9) to get the seismic

ground motion in time domain finally.

2.2 Technical note on fluid-solid continuity conditions

In this subsection, we shall present one technical note on the application of the continuity conditions at the fluid-solid interface. In general, the unit normal vector at the fluid-solid interface can be defined in two ways: one is defined as the outward unit normal vector of the solid layer and the other is defined as the outward unit normal vector of the fluid layer, as shown in Fig. 2.

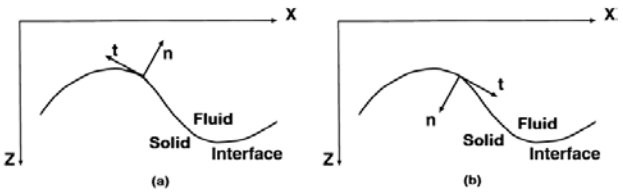

Fig. 2 Geometry of a fluid-solid interface. **n** and **t** are the unit normal and tangential vectors of the interface.

The extension equation of the global matrix propagators in Step 2 will be changed depending on which way is used to define the unit normal and tangential vectors at the fluid-solid interface. Equation (2) stated in Step 2 corresponds to the case shown in Fig. 2(a). In case of the selection of Fig. 2(b), the extension equation will be changed into

$$\mathbf{D}_{tu}^{(1)} = -\rho_{\mathrm{f}}\omega^2 \begin{bmatrix} \mathbf{D}_{pq}^{(1)} \cdot \mathbf{N}_1^{\mathrm{e}} \cdot (\mathbf{N}_1^{\mathrm{e}})^{\mathrm{T}} & \mathbf{D}_{pq}^{(1)} \cdot \mathbf{N}_2^{\mathrm{e}} \cdot (\mathbf{N}_1^{\mathrm{e}})^{\mathrm{T}} \\ \mathbf{D}_{pq}^{(1)} \cdot \mathbf{N}_1^{\mathrm{e}} \cdot (\mathbf{N}_2^{\mathrm{e}})^{\mathrm{T}} & \mathbf{D}_{pq}^{(1)} \cdot \mathbf{N}_2^{\mathrm{e}} \cdot (\mathbf{N}_2^{\mathrm{e}})^{\mathrm{T}} \end{bmatrix}, \quad (10)$$

where all the elements of the matrices $\mathbf{N}_1^{\mathrm{e}}$ and $\mathbf{N}_2^{\mathrm{e}}$ need to be changed consequently. This technical note looks no big deal, but it plays an important role in the numerical implementation.

3. NUMERICAL IMPLEMENTATION

3.1 Validity Tests

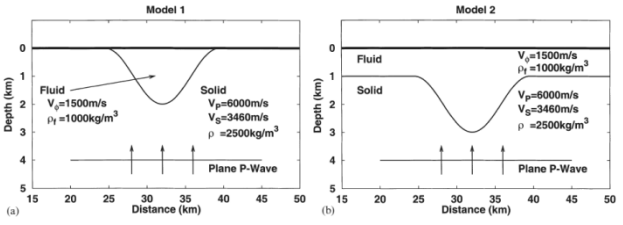

Fig. 3 The two models used to test the introduced algorithm

Before applying the introduced algorithm to practical problems, we should test its validity by comparing our numerical results with the existing solutions. However, we do not have exact (analytic) solutions for problems of irregularly layered structures, so it is important to compare the results of completely different numerical methods to ensure validity. For such purpose, we calculate the case of a plane *P* wave vertically incident onto irregularly layered fluid-solid structures in the two models, as shown in Fig. 3. The detailed values of the structural parameters can refer to the work (Okamoto and Takenaka, 1999). In their work, the existing results for the two models calculated by the reflection/transmission matrix method are available to make the necessary comparison.

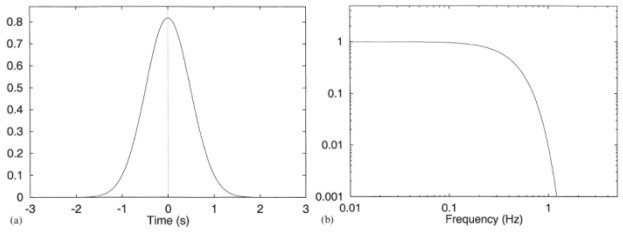

Fig. 4 The time function and its spectral amplitude used in our test calculations (Okamoto and Takenaka, 1999)

The time function of the input plane wave is

$$f(t) = \begin{cases} \sqrt{\alpha/\pi}\exp(-\alpha t^2), -T_s/2 \le t \le T_s/2 \\ 0, \qquad\qquad t \ge T_s/2\,,\ t \le -T_s/2 \end{cases}, \quad (11)$$

where the pulse duration T_S is set to 4.2 s and α is set to 2.1. Its shape and spectrum are shown in Fig. 4.

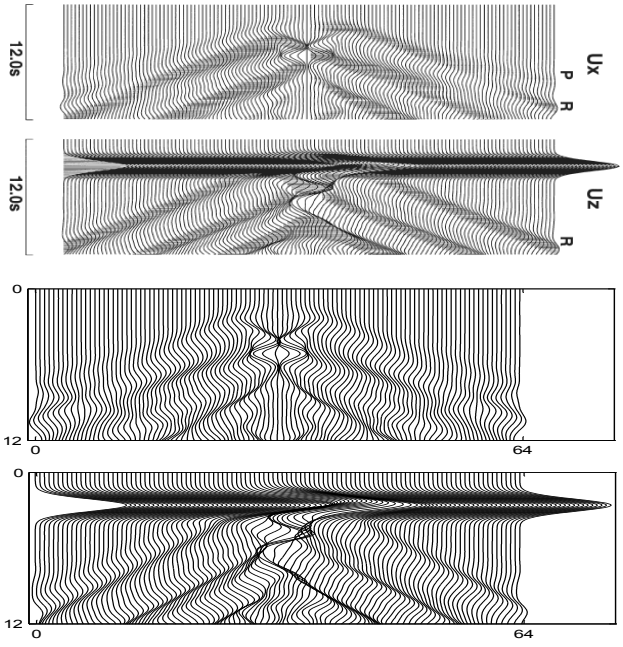

Fig. 5 Time responses along the fluid-solid interface of Model 1: the one on top calculated by the reflection/ transmission matrix method, and the one at bottom calculated by the present method.

Model 1. Figure 5 shows the displacements of both horizontal and vertical components along the fluid-solid interface of Model 1. The one on top is calculated by the reflection/transmission matrix method in the work (Okamoto and Takanaka, 1999). And the one at bottom is calculated by the present hybrid boundary element method. Inside the

irregular part of the model, i.e., the basin structure, the large-amplitude multiple reflections in the water basin are well observed in the waveforms calculated by both the present method and the reflection/transmission matrix method. Both the scattered *P* waves (P) and a *Rayleigh* wave (R), which are indicated in the top plot, can also be well and clearly observed in our calculated seismograms.

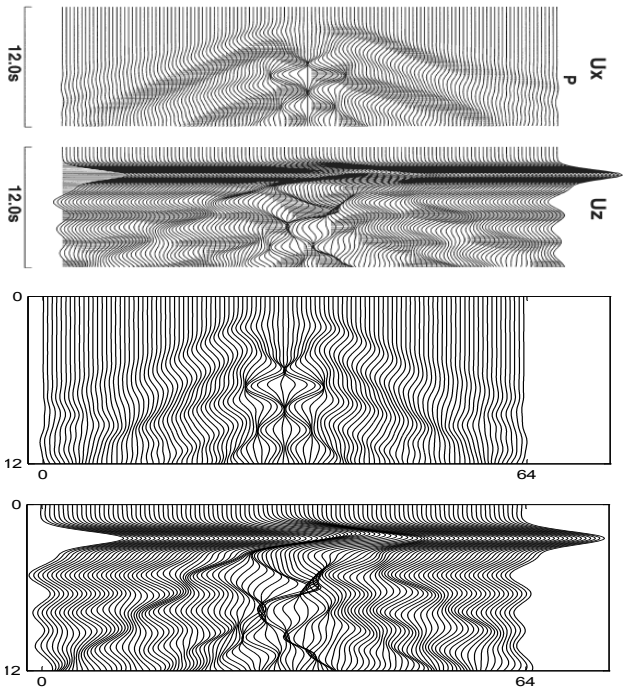

Fig. 6 The same as Fig. 5, but for Model 2.

Model 2. Figure 6 shows the displacements of both horizontal and vertical components at the fluid-solid interface of Model 2. In this case, the 'observation points' are all located at the water layer bottom. The one on top is calculated by the reflection/transmission matrix method in the work (Okamoto and Takenaka, 1999). And the one at bottom is calculated by the present hybrid boundary element method. Again, the synthetic seismograms calculated by both methods agree with each other very well. The periodic multiple reflections at the flat portion of the water layer are clearly observed and interfered by the scattered waves from the inside of the irregular part of the model, which are modeled very well by both methods.

The above two testing calculations show the validity of the present method and the correctness of our computational program, respectively. Next, we shall start a preliminary application to a realistic model in Kanto basin area.

3.2 Preliminary Application to a Realistic Model

In this subsection, we consider a relatively complex model, as shown in Figure 7. The model consists of a water layer on the top and three solid layers bonded by irregular interfaces. Table 1 shows the detailed parameters of each layer in the model. A vertically incident *SV* wave is taken into account for this synthesis. The time function of the incident plane wave is a Ricker wavelet defined as (Ricker, 1977)

$$u(t) = (2\pi^2 f_c^2 t^2 - 1)\exp(-\pi^2 f_c^2 t^2), \qquad (12)$$

where f_c is the characteristic frequency of the wavelet and t is the time. Observation points are placed along the fluid-solid interface.

Table 1 Parameters of each layer in the model

Parameter / Layer	Vp (km/s)	Vs (km/s)	Mass density (g/cm^3)
Water layer	1.5	0	1.0
Solid layer 1	1.84	0.50	1.8
Solid layer 2	2.40	1.00	2.0
Solid layer 3	3.00	1.50	2.3

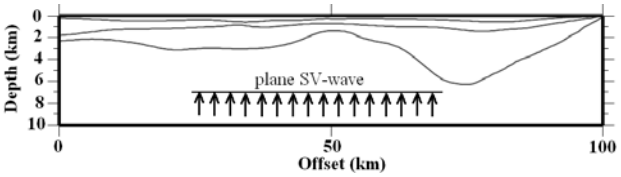

Fig. 7 The 2-D underground profile from Tokyo (139.765827/35.681421) to Simoda (138.89719/34.64911)

Figure 8 presents the horizontal displacements along the fluid-solid interface due to a vertically incident *SV* wave in the multilayered structure shown in Fig. 7. The one on the top of Fig. 8 is for the case when the first layer in Fig. 7 is empty, while the one at the bottom of Fig. 8 is for the case when the first layer in Fig. 7 is filled with water. From the comparison between the two seismograms, we can see that there are only minor differences for the cases with and without the water layer. This is understandable since our incident wave is a vertically shear wave which does not propagate in the water layer. A further comparison between the two cases is conducted for the seismogram at one point close to the leftmost side, which is shown in Fig. 9. It can be readily seen that the major waveform remains very similar and only its amplitude is reduced a little bit in the case of the appearance of the water layer.

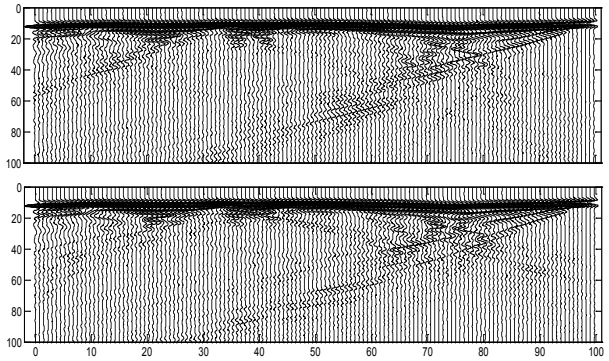

Fig. 8 Horizontal displacement along the fluid-solid interface due to a vertically incident *SV* wave: the case without water layer and the one with water layer.

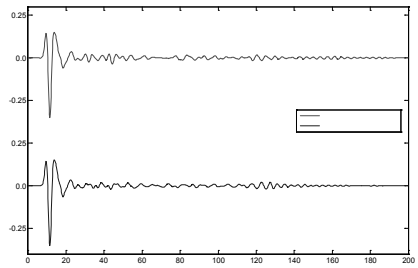

Fig. 9 Horizontal displacement at the point 10 km away from the leftmost side

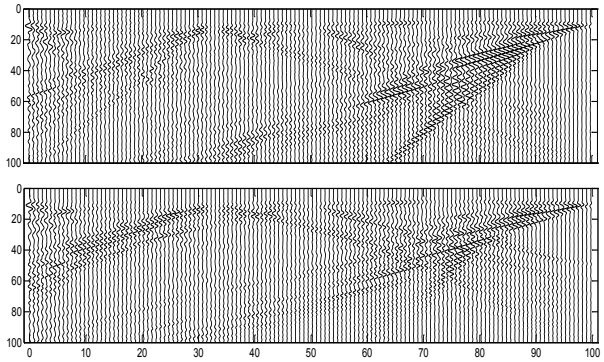

Fig. 10 As Fig. 8, but for vertical displacement

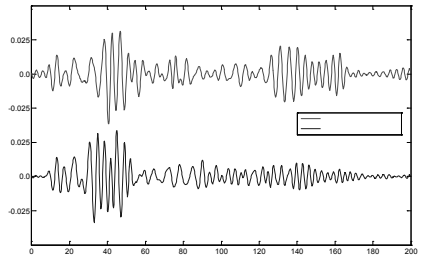

Fig. 11 As Fig. 9, but for vertical displacement

Figure 10 presents the vertical displacements along the fluid-solid interface in the multilayered structure. Different from the case of the horizontal displacement, the comparison between the two seismograms in Fig. 10 shows that large change occurs in the vertical displacement component due to the appearance of the water layer and the main change appears in the later arrival waves. A detailed illustration on the seismograms at the same point as that shown in Fig. 9 is presented in Fig. 11, which confirms the observation in Fig. 10. This is due to the fact that water waves are more easily excited by the vertical component in the case of a vertically incident *SV* wave, which may be contrary to the case of a *P* wave incidence.

Since the structure shown in Fig. 7 is very complex, it is still very difficult to interpret the synthetic seismograms completely. Here, we just show a preliminary attempt to look into the change appearing in the synthetic seismograms due to the presence of the water layer.

4. CONCLUSIONS

In this paper, we show the numerical implementation of the hybrid boundary element method which is an extension of the approach originally developed for seismogram synthesis in multilayered solid media. The extended method can be applied to study the effects of water layer on seismic ground motion in multilayered media. A step-by-step procedure of applying the algorithm to a general multilayered fluid-solid media is stated in detail. Then two models containing an irregular fluid-solid interface are used to test the validity of the formulation and the computation program, resulting in a good agreement with the results calculated by the reflection/transmission matrix method. Finally, a preliminary application is conducted by a realistic model in Kanto basin area including the sea water at Tokyo bay. The difference appearing in the synthetic seismograms due to the presence of the water layer can be clearly observed. This kind of synthesis could help us understand the influence of water layer on the seismic ground motion at land, in which seismologists may be mostly interested.

Abstract: In this study inhomogeneity in seismic propagation paths is focused on as a cause of variability of observed seismic ground motion and preliminary evaluation by numerical simulations has been done. First strength and correlation length of inhomogeneity of seismic velocity in propagation path were inferred based on KiK-net observation records in order to set up realistic models for numerical simulations for inland earthquakes. It was revealed that the estimated inhomogeneity was greater than values in previous studies. It may reflect the strong inhomogeneity in the shallow part of the upper crust. Then numerical simulations were performed in order to study the influence of the strong inhomogeneity on seismic wave. 3D random inhomogeneous models were set up and the finite difference method was applied to obtain velocity time histories in the random media. As a result relatively large fluctuation in peak ground velocity has been observed. The result implies the importance of inhomogeneity in propagation path as a cause of seismic ground motion.

1. INTRODUCTION

Empirical attenuation relations are often utilized for practical prediction of ground motion, but large fluctuation has been observed between the observed values and the attenuation relation. The fluctuation measured as common logarithmic standard deviation of attenuation relation is about 0.2～0.3(Midorikawa and Ohtake 2003). As the value of fluctuation of ground motions has great influence on probabilistic seismic hazard analysis which provides basic data for disaster prevention or seismic risk evaluation, more refined evaluation of the fluctuation is an important problem. Observed seismic ground motion consists of three factors; the source, path and site effect. The contribution of each factor to the total fluctuation has to be evaluated for modeling of the fluctuation more physically. In this study the path effect on variability of seismic motion is focused on.

Though the seismic path is modeled as homogeneous medium in general, PS-logging data in deep boreholes have suggested that random fluctuation of seismic velocity exists in one geological layer (Shiomi et al. 1997). Also coda wave arriving after direct P or S wave can be interpreted as scattered wave generated by inhomogeneity in the propagation path and the calculated envelope of coda wave based on scattering theory can satisfactory explain observed records (Sato and Yamashita 2001).

Inhomogeneity in the path can also affect the variability of seismic ground motion. The effect has been evaluated based on numerical simulations because analytical solution like envelopes has not been obtained yet. For example Shapiro and Kneib(1993) performed the finite difference simulations assuming that the path medium velocity has random fluctuation. As a result they have shown that the amplitude of calculated waves fluctuates and the fluctuation becomes greater with increasing distance. Hoshiba(2000) also simulated plane waves in medium having random velocity distribution and has shown that the fluctuation has peak value at certain distance after which the fluctuation decrease in turn unlike the result of Shapiro and Kneib(1993). Although it is recognized that numerical simulations can evaluate the characteristics of waves in random medium as the above examples, value of fluctuation and dependency on distance are needed to be studied more quantitatively by accumulating simulation cases.

In order to perform realistic simulations one of the most important problems is setting up of parameters of inhomogeneity. Generally random inhomogeneity is expressed by two parameters, the strength (ε) and correlation length (a) of velocity fluctuation. In the past simulation analyses these parameters are thought to be assumed referring to values inferred from observation records. The inferred parameters in past studies seem to range in relatively wide value. For example Wu and Aki (1988) arranged the ε and a values estimated by past studies in various regions in the world. If limited to values in the lithosphere, ε and a respectively changes in the range from one to two orders. Sato et al.(2008) has shown that the fluctuation of calculated waves varies with the change of assumed ε and a by means of 3D finite difference simulations.

As the change of ε or a may result from the difference of regions or scale of regions, it is important to use

inhomogeneous parameters inferred in accordance with the objective of simulations. In this study aiming at simulating seismic waves in relatively short distance by inland shallow earthquakes, ε and a in propagation path are inferred based on seismic observation records. Then numerical simulations are performed assuming the inferred parameters in order to study preliminary the influence of inhomoogeneity on seismic ground motions.

2. ANALYSIS METHOD TO INFRER INHOMGENEOUS PARAMETERS

2.1 Earthquake Observation Data

KiK-net records were used in this study. KiK-net is a seismograph network consisting of about 700 observation sites located nationwide in Japan. At each observation site two seismograph are installed; one at the surface and the other at the bottom of borehole. In order to extract information of inhomogenity in the propagation path observation sites were selected under the condition that the underground seismometers reaches the depth of base rock. The base rock here means so-called "earthquake bedrock" which has S wave velocity more than about 3 km/s. 24 sites were found to meet the above condition and 3 sites of them have been selected for analysis considering the quantity and quality of the observed records. The selected sites are SMNH01(Hakuta, Shimane Prefecture), GIFH09(Hashima, Gifu Prefecture) and MYGH01(Sendai, Miyagi Prefecture). The S wave velocity at the depth of a borehole seismometer of each site is 2.80km/s, 3.04km/s and 3.26km/s respectively.

The analyzed records were selected from records satisfying the conditions; the hypocenteral distance is equal to or less than 80km and the depth is equal to or less than 50km. Also condition that the magnitudes of earthquakes, Mj, are less than or equal to 5 is added so that the shape of wave can be simply pulse-like, which is one of the assumptions of analysis method mentioned later. The specifications of analyzed earthquakes and the distribution of epicenters are shown in Table 1 and Figure 1. The number of used earthquakes at each site is 12, 6 and 4 respectively. The events used at SMNH01 are aftershocks of the Western Tottori Prefecture earthquake in 2000 (M_j7.3), so more short-distance records have been obtained than other two sites.

The records of underground seismometers include down going waves reflected from upper sedimentary layers. The effects have to been removed before analysis. To perform this operation the structure of sedimentary layers is

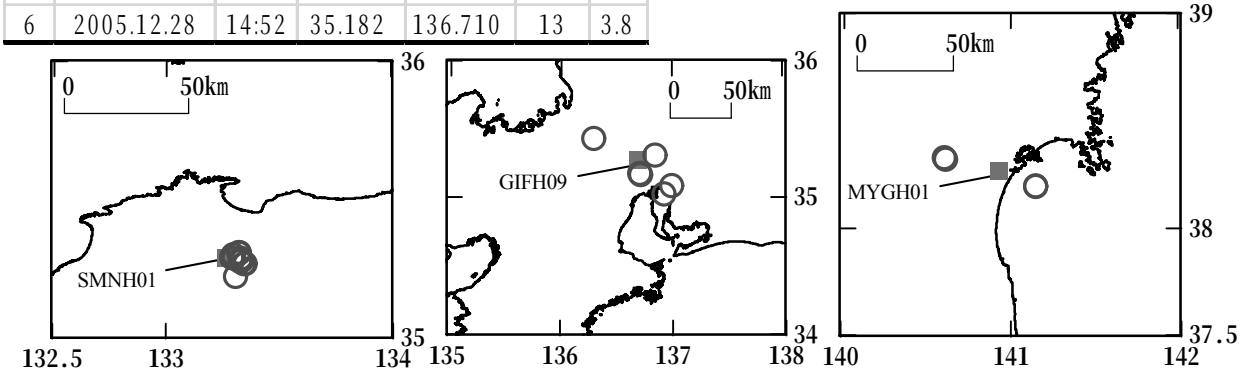

Figure 1 Distribution of Earthquakes Analyzed in This Study

needed. Although the P and S wave velocity (*Vp, Vs*) and thickness of layers beneath KiK-net sites have been made public as PS-logging data, dumping characteristics of the layers (*Q* values) are not included in these models. Also PS-logging data might have some errors from real *Vp, Vs* values. In order to infer *Q* values and improve *Vp, Vs* values we perform inversion analyses of transmission functions calculated from the vertical array records.

As mentioned above the vertical array of KiK-net consists of only two seismometers, so usual method in which one component, for example the transverse component of S wave portion, is inverted may be insufficient to resolve material properties of multiple layers. We used method of Sato et al. (2003) to infer reliable velocity and *Q* values. This method inverts three kind of records simultaneously; transmission function of transverse component of S wave, transmission function of vertical component of P wave and H/V spectral ratio. H/V spectral ratio is defined here as Fourier spectral ratio of radial component to vertical component of P wave of surface records.

The inferred parameters are *Vp, Vs, Qp, Qs* and incident angle at the base rock. The thickness of each layer is same as that of PS-logging data. *Q* value is assumed to depend on both frequency and Vs and is modeled based on Kobayashi et al.(1999) as following.

$$1/Qs = 1/(\alpha \cdot Vs \cdot f^{\beta}) + 1/(\beta \cdot Vs) \qquad (1)$$

In eq. (1) f is frequency (Hz) and α and β are unknown parameters to be inferred by inversion. *Qp* is assigned as *Qs*/2 based on Yoshida et al.(2002).

Based on the inferred underground model the effect of sedimentary layers is removed from the borehole record. One dimensional SH wave theory is used to evaluate transmission function of sedimentary layers and the Fourier spectrum of transverse component is divided by the transmission function to get the time history records at base rock when upper sedimentary layers are removed.

2.2 Estimation of Inhomogenious Parameters

The pulse width of seismic wave radiated from the source is broadened with increasing distance due to scattering in the propagation path. Saito et al.(2002) theoretically obtained mean squared(MS) envelopes of ground motion, *I(r,t)*, in three dimensional inhomogeneous media having the Gaussian type autocorrelation function(ACF) as

$$I(r,t) = 1/(4\pi R^2 t_M) \cdot \pi^2/2 \cdot \sum_{n=1}^{\infty} (-1)^{n+1} n^2 \exp[(-\pi^2/4) n^2 (t-R/V_0)/t_M] \qquad (2)$$

$$t_M = \pi^{1/2} \varepsilon^2 R^2 /(2aV_0) \qquad (3)$$

where R is hypocenral distance, t is lapse time and V_0 is average *S wave* velocity in the random medium.

The inhomogeneous parameters, a and ε can be inferred as ε^2/a by comparing the MS envelopes calculated by using eqs. (2) and (3) with those of observed records. Envelopes of observed records are calculated based on the method of Dziwonski et al.(1969). Basically fitting of calculated and observed MS envelopes is performed in 1 sec width time window started from the onset of S wave. Appropriate ε^2/a value is searched by nonlinear least square method in which the sum of squared residuals between calculated and observed envelopes is minimized.

3. RESULTS OF INFERERENCE OF INHOMOGENEITY

3.1 Inferred Ground Motion at Bed Rock

The observation records used for inferring underground structures are selected so that the variation of geometrical incident angles, which are calculated from epicentral distance and depth of the hypocenter, is within 20 degree. As a result, from four to eight records has been selected at each observation site. The logarithm averages of transmission functions and H/V spectral ratios from each earthquake record are set as targets of inversions. As an example Figure 2 shows the fitting of calculated and observation records. The estimated underground model produces better fitting than the PS logging model. At other two sites good fitting has also been obtained. The estimated underground models are shown in Table 2.

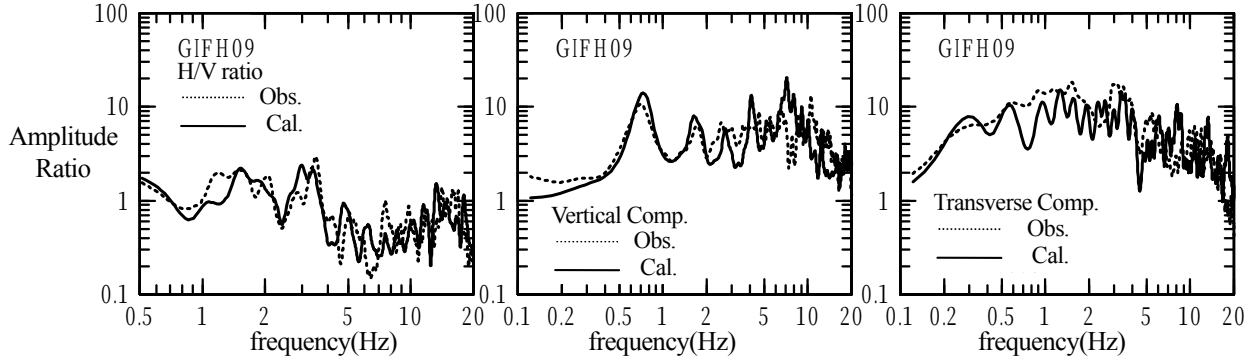

Figure 2 Fitting of observed spectral ratios and calculated ones based on the inferred underground model inferred by inversion analysis (GIFH09)

Table 2 Inferred Underground Structures by Inversion Analysis

Some examples of the estimated bed rock records based on the inferred underground model are shown in Figure 3. The waves are S wave transverse components of velocity records and band pass filter between 1 to 5 Hz was applied. The bed rock records show relatively short duration time and are simple in shape.

3.2 Inferred Inhomogeneous Parameters

Some examples of fitting results between calculated and observed MS envelopes are shown in Figure 4. Envelopes in this figure are normalized to each maximum amplitude. Inferred ε^2/a for each record is shown in each figure. The ε^2/a values have fluctuation as large as about one order. Relation between ε^2/a and hypocentral distance is shown in Figure 5 where ε^2/a decreases with increasing distance. As all three observation sites seem to obey the same distance dependency, this trend may originate from common characteristics of inhomgeneous structure in the crust.

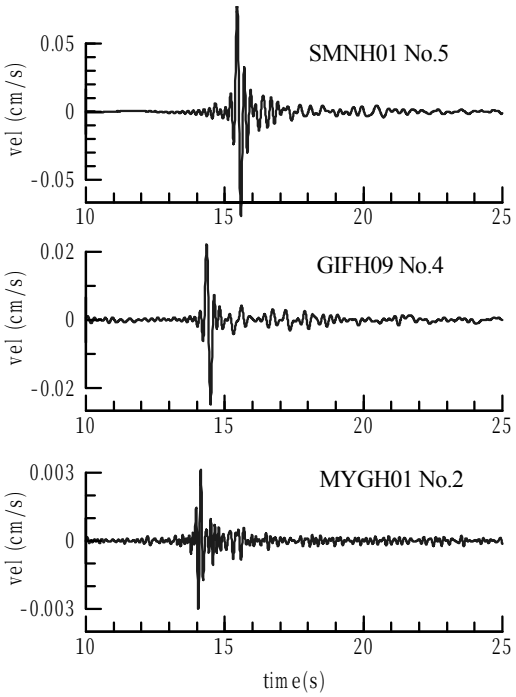

Figure 3 Examples of Inferred Ground Motion at Bedrock

In order to investigate the cause of the dependency of ε^2/a on distance comparison with results in past studies are done. Kosuga(2001) reviewed values of a and ε inferred in worldwide regions. In Figure 6 values of a and ε in the crust reviewed by Kosuga(2001) is plotted as symbols noted "past studies". Inferred ε^2/a in this study are also shown as straight lines. They are classified according to hypocentral distance (R). The ε^2/a values inferred from records with $R \geqq 10$km seem to have almost same distribution range as that of a and ε of previous studies. On the other hand the ε^2/a values inferred from records with R <10km are larger than previous studies. Larger value of ε^2/a can be seen in other studies. For example Yoshimoto et al.(1997) estimated ε^2/a as 8×10^{-3} km^{-1} in Nikko area, Japan by using records of small earthquakes with R less than about 15km. This value is larger than the usual values which are inferred by using records with R of tens or hundreds of kilometers. The ε^2/a by Yoshimoto et al.(1997) is near the value obtained from records with R<10km in this study. From these results it is indicated that earthquake records with smaller R may have stronger effects of scattering .

3.3 Inferred Model of Inhomogeneity

Kosuga(2001) founded that correlation distance (a) in the upper mantle becomes larger than in the crust based on reviewed results of past studies, although the strength of velocity fluctuation (ε) do not so differ in the upper mantle and in the crust. Flatte and Wu (1988) also indicated that the lower mantle has lager correlation distance than that of the upper crust based on the observation records at NORSAR which is a large horizontal array with aperture as large as about 100km. Yoshimoto et al.(1997) inferred a =300～800m, ε=0.05～0.08 based on the above mentioned ε^2/a value estimated in Nikko area. Yoshimoto et al.(1997)

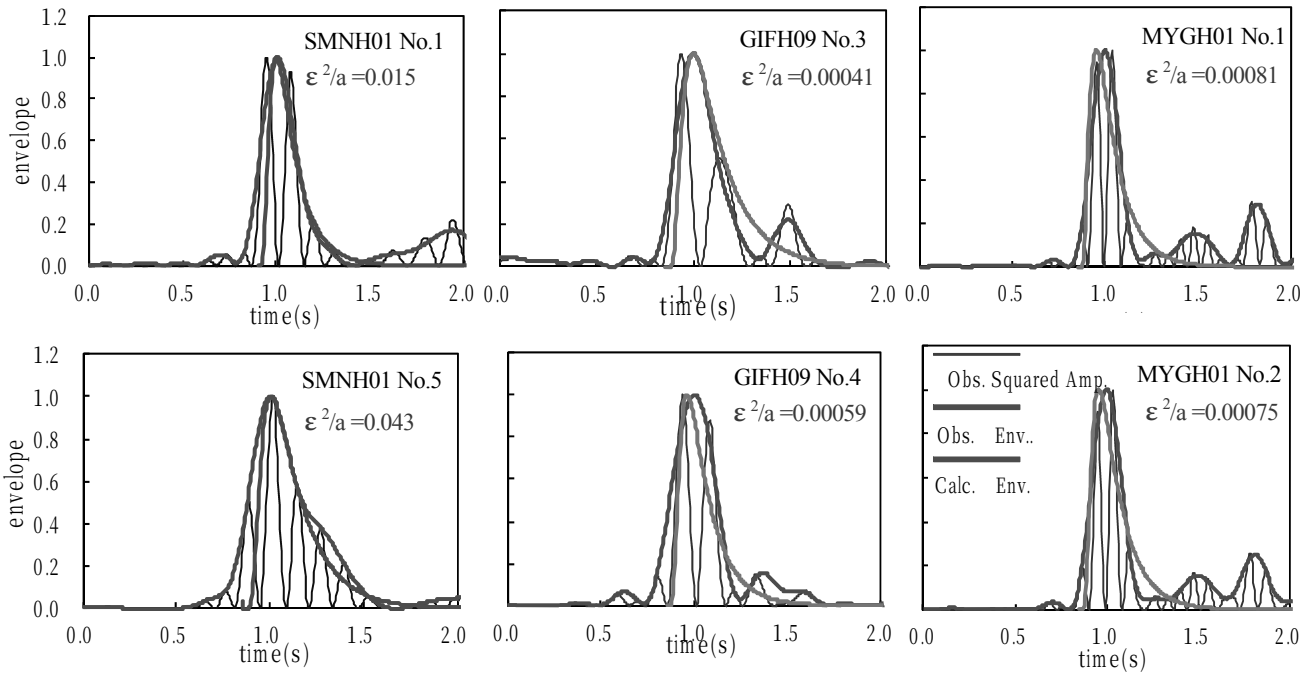

Figure 4 Examples of Fitting of Observed and Calculated Envelopes

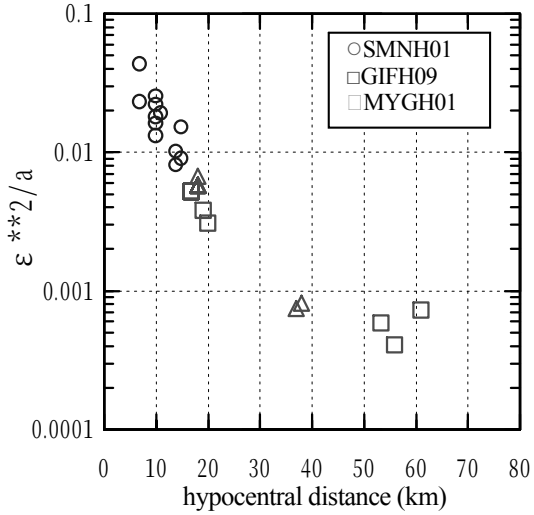

Figure 5 Relation between ε²/a and Hypocentral Distance

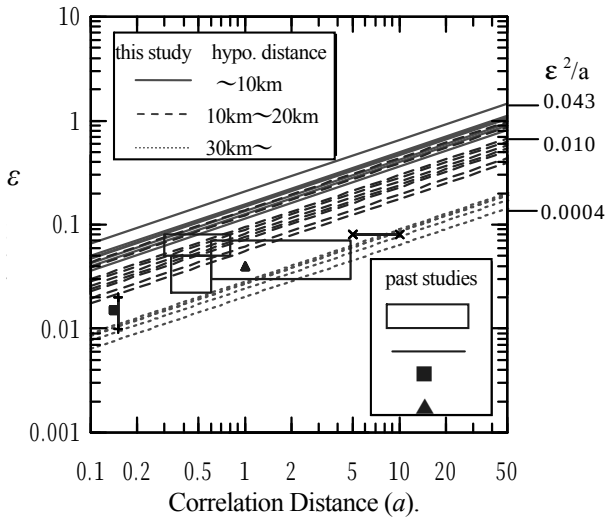

Figure 6 Comparison of Inferred a and ε in This Study with Values in Past Studies

pointed out that the cause of large ε^2/a may be strong inhomogeneity in the shallow part of the upper crust. Those results means that characteristics of inhomogeneity changed with depth and the inferred ε^2/a in this study with relatively smaller value may reflect deeper portion in the crust.

As to earthquake records in short distance the effect of path in the shallow crust with strong inhomogeneity may become larger because the ratio of path length passing in the region to the total distance becomes larger than that of records of far events. This can result in the dependence of ε^2/a on distance shown in Figure 5. To verify this assumption a simple examination was done as follows. The crust was modeled as Figure 7 in which the upper and the lower portion have different ε^2/a. The travel path from a hypocenter to an observation site is expressed as a straight line under the assumption that seismic velocity do not differ in the two regions. The ratio of length of path in the upper layer (r_1) to the total path length (R) was evaluated. The relation between r_1/R and ε^2/a is shown in Figure 8 supposing the thickness of the upper layer h_1 is 10km. Value of ε^2/a seems to increase with increasing r_1/R except for two values obtained at MYGH01. This means that the longer the seismic wave travel path in shallower part of the crust becomes, the stronger the effect of inhomogeneity. As the thickness of the upper layer h_1 is uncertain, several h_1 values were assumed. But the lenear relation between r_1/R and ε^2/a is better in the case of h_1=10km. Although h_1 cannot be inferred definitely the assumption that inhomogeneity of the shallow part of crust is greater than that of deeper part will be supported by the above result.

Figure 8 suggests value of ε^2/a used for numerical simulations. When seismic ground motion in relatively small distance are simulated the value of ε^2/a about 0.01 may be appropriate.

4. NUMERICAL SIMULATIONS

4.1 Method of Simulations

Preliminary numerical simulations were performed in order to study the influence of the strong heterogeneity on seismic ground motion variability. The finite difference method are applied assuming 3D inhomogeneous medium shown in Figure 9. The size of model is 45km×45km×10km corresponding to the shallow part of crust in which strong inhomogeneity has been inferred. The inhomogeneity in the medium is generated as following. The seismic velocity in the medium is expressed as

$$V(\boldsymbol{x}) = V_0(1 + n(\boldsymbol{x})) \qquad (4)$$

where $V(\boldsymbol{x})$ means velocity of Vp or Vs at position $\boldsymbol{x}$ in the 3D medium. V_0 is average velocity of V_P or Vs and $n(\boldsymbol{x})$ means fluctuation of velocity. In this study V_P, Vs were set as 6.7km/s, 3.7km/s respectively. $n(\boldsymbol{x})$ was generated from auto-correlation function (ACF) R(r) based on Hoshiba(2000). ACF of the Gaussian function type was assumed here as follows.

$$R(\boldsymbol{r}) = \langle n(\boldsymbol{x})n(\boldsymbol{x}+\boldsymbol{r}) \rangle = \varepsilon^2 exp(-|\boldsymbol{r}|^2/a^2) \qquad (5)$$

where $\boldsymbol{r}$ means distance vector between arbitrary two points in the medium and $\langle\ \rangle$ means averaging operation. After $R(\boldsymbol{r})$ are evaluated assuming ε and a, $n(\boldsymbol{x})$ can be produced by Fourier transforming of $R(f)$ assuming the phase is random. According to eq. (4) Vp, Vs value of each grid is assigned. Density was assumed not to have fluctuation and has constant value of 2.8g/cm^3. ε^2/a is set to 0.01 based on the result in this study shown in Figure 7 and Figure 8.

A point source was assumed at 5km depth with focal mechanism of vertical fault with pure strike slip. The source time function is assumed to be a smoothed ramp function with rise time τ. Hereafter $1/\tau$ is expressed as f_0 to be referred as central or predominant frequency of waves. The grid interval is 0.05km to make possible to calculate up to 8Hz waves.

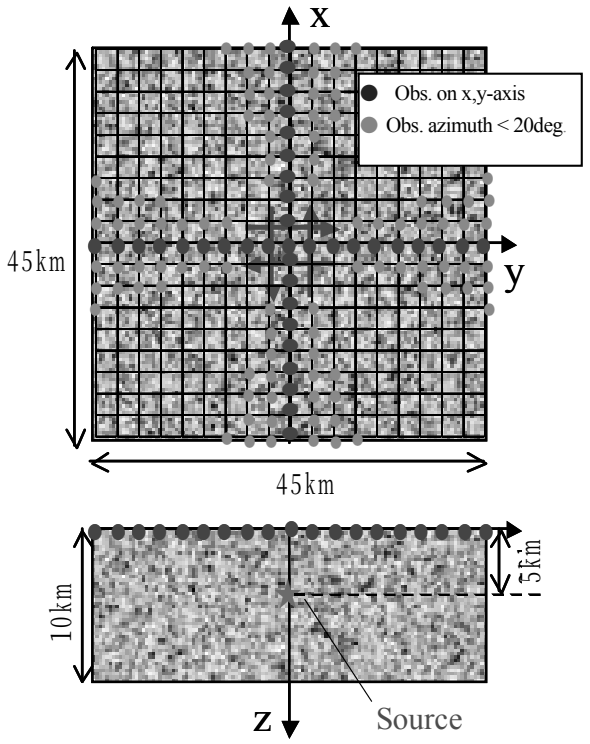

Figure 9 Numerical Simulation Model

4.2 Results of Simulations

Examples of calculated waves in the case of f_0=2Hz and 5Hz are shown in Figure 10 and 11. Simulated waves in homogeneous media are also shown for comparison. In these figures simulated waves at grids on y-axis are selected considering the radiation pattern of the source. In the case of assumed source mechanism, the x- and y-axis are in the direction of node of P wave radiation pattern. The amplitude of S wave is maximized on the contrary and only transverse component is generated in these directions. The calculated waves in homogeneous medium show such theoretical characteristics. Also the shape of waves in homogeneous medium does not change with increasing distance. On the other hand in the case of inhomogenous medium, not only x-component but also y- and z-component are generated. Also shown are later phases after main pulses of direct S waves. These are coda waves by scattering. The coda waves become more prominent in the case of f_0=5Hz than in the case of f_0=2Hz. In the case of f_0=5Hz the amplitude and duration of coda waves increase with distance clearly. These

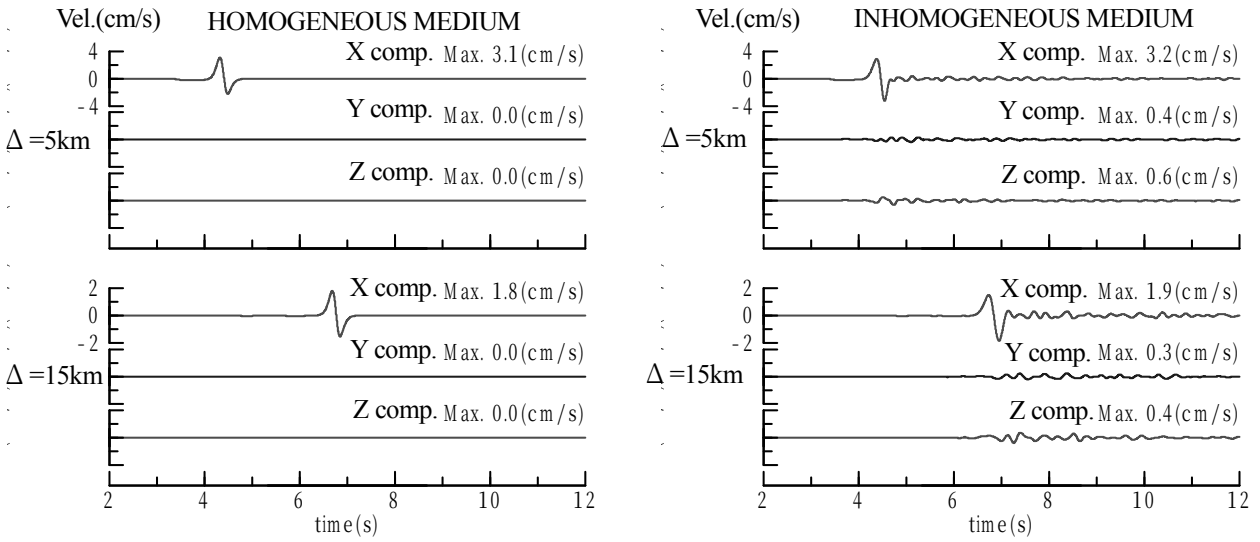

Figure 10 Examples of Calculated Velocity Waves (f_0 = 2Hz) Δ: Epicentral Distance

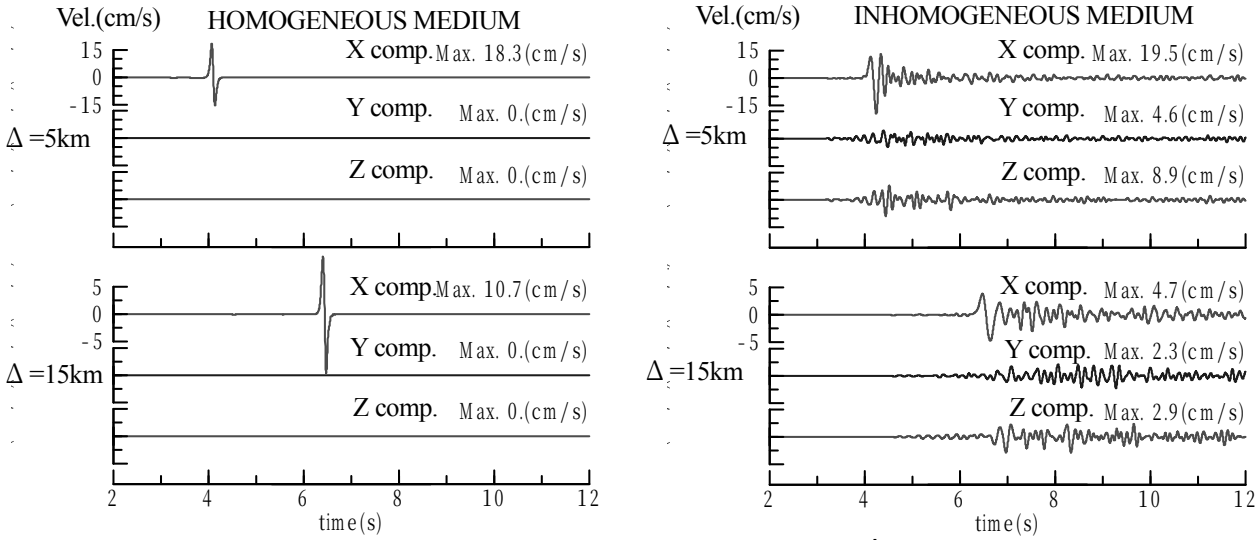

Figure 11 Examples of Calculated Velocity Waves (f_0 = 5Hz) Δ: Epicentral Distance

phenomena are also observed in real seismic records.

The amplitude of simulated wave in inhomogeneous medium differs from that of wave in homogeneous medium as shown in Figure 10 and 11. This means that inhomgeneity affects variability of seismic ground motion. In order to investigate the effect quantitatively the peak ground velocity (PGV) of simulated waves was evaluated and arranged. As mentioned above the effects of radiation pattern of the source is included in the waves. So in this study the ratio of PGV of simulated waves in inhomogeneous media to that of waves in homogeneous media was evaluated. As the difference of amplitude originated from source is canceled by this operation, the fluctuation of ratio means the effects in propagation path. In order to avoid sampling from grids located in the direction of near the node of S wave radiation, only the grids contained in the range where the azimuth angle from the origin is below 20 degree were selected as shown in Figure 9. Transverse component synthesized from two horizontal components was used to calculate the ratio.

The ratios were arranged as relation to hypocentral distance and are shown in Figure 12. In both cases of f_0=2 Hz and f_0=5Hz the ratios in an average decrease with increasing distance. The dependency is clearer in the 5Hz case and is thought to be scattering attenuation by inhomogeneity. As the fluctuation of ratios around the average attenuating trend corresponds to variability caused by path effect, we first regressed the linear decreasing trend by the least squared method. Then the residuals between the ratios in Figure 12 and the values by the regressed equation were calculated to evaluate the standard deviation of them. The common logarithm standard deviations (σ) in the case of f_0=2Hz and 5Hz are 0.09 and 0.17 respectively. Considering that the standard deviation of attenuation relations is σ=0.2 ~0.3 on an average, the σ of our simulations implies the possibility that the inhomogeity in propagation path has relatively large contribution to the total cause of variability of observed seismic ground motion.

As ε and a corresponding to the large ε^2/a value (0.01), which is inferred to reflect the characteristic of shallow part of the crust, were assumed in the whole propagation media, the σ's evaluated here might be somewhat overestimated. So we are planning simulations assuming the two layered model as Figure 7. By using such a model simulation may become more realistic and we can obtain basic data to study

dependence of σ on distance and frequency quantitatively.

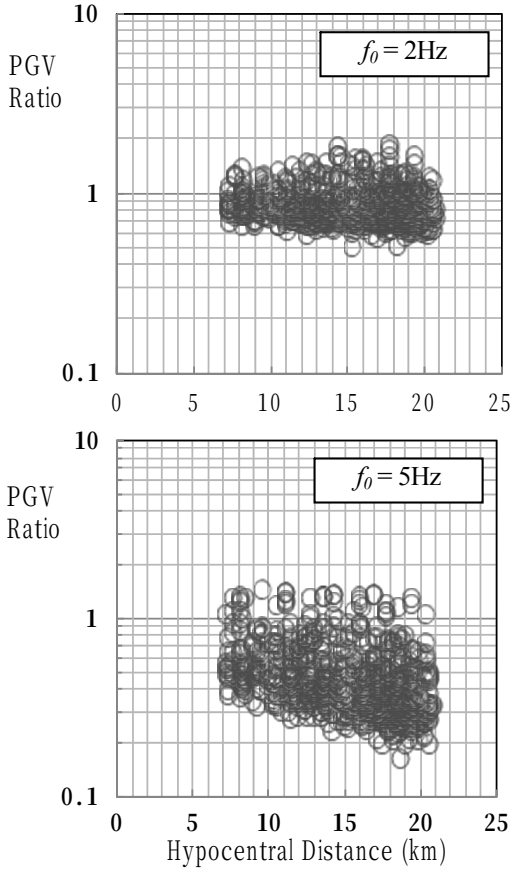

Figure 12 Relation between Ratios of PGV (Inhomogeneous/ homogeneous) and Hypocentral Distance.

5. CONCLUSIONS

Preliminary evaluation of variability of seismic ground motion caused by inhomogeneity in propagation path has been done by numerical simulations. First, strength (ε) and correlation length (a) of inhomogeneity of seismic velocity in propagation path were inferred based on KiK-net records to set up realistic models for numerical simulations for inland earthquakes. The estimated ε^2/a depends on distance and the values for short distance records are clearly greater than common values in previous studies. It may reflect the strong inhomogeneity in the shallow part of the upper crust. Then numerical simulations were performed assuming 3D random inhomogeneous media assuming inhomogneity with property based on the ε^2/a value estimated for short distance. The simulated waves explained characteristics of coda waves well. Based on the calculated waves, common logarithm standard deviation (σ) of fluctuation of peak ground velocity was evaluated. As for 2Hz and 5Hz waves σ estimated as about 0.1 ～ 0.2. The result implies the possibility that the inhomogneity in propagation path has relatively large contribution to the total cause of variability of observed seismic ground motion. In further study we are planning to accumulate simulation cases in order to evaluate dependence of the variability on distance and frequency..

Abstract: We reevaluated deep underground structures in the Tokyo Metropolitan Area, using dominant periods of H/V spectral ratios of coda waves observed by MeSO-net. At first, we verified the stability of H/V of earthquake ground motions by applying the time-frequency analysis and understanding the differences of H/V calculated by several earthquake recording data. The results of those processes showed that coda waves were mainly composed of surface waves. The variability of H/V of coda waves calculated by 9 earthquakes larger than Mj 6.5 was quite small. Consequently, we concluded that dominant periods of H/V of coda waves would be useful for creating a 3-D subsurface velocity structural model. Finally, we compared the dominant periods of H/V of coda waves obtained by MeSO-net with the velocity structures in the Tokyo Metropolitan Area proposed by Yamanaka and Yamada (2006).

1. INTRODUCTION

The high-density seismic observation network at more than 200 stations, called MeSO-net (Sakai and Hirata, 2009), has been being installed at an interval distance of about 5 km in the Tokyo Metropolitan Area. By comparing numerical predictions with earthquake ground motions observed by MeSO-net, we found that the previous 3-D underground velocity structural model in the Tokyo Metropolitan Area (Yamanaka and Yamada, 2006) was still not constrained enough to accurately predict the observed earthquake ground motions for long periods larger than 1 second. Therefore, to improve the 3-D underground velocity structural model especially for bedrock and/or a deep boundary between layers, we evaluated the relationship between dominant periods of H/V spectral ratios of earthquake ground motions and underground velocity structures in the Tokyo Metropolitan Area.

2. H/V SPECTRAL RATIO OF EARTHQUAKE GROUND MOTIONS

2.1 Data set

To evaluate the relationship between dominant periods of H/V spectral ratios of coda waves and deep underground structures, we used earthquake recording data at about 170 sites by MeSO-net in the Tokyo Metropolitan Area. For analyzing long periods of earthquake ground motions larger than 10 seconds, we selected 9 earthquakes larger than Mj 6.5 occurred in and around Japan. List of earthquakes used in this study is shown in Table 1. Locations of hypocenters of the earthquakes and MeSO-net are shown in Figure 1.

Table 1 Details of earthquakes used in this study

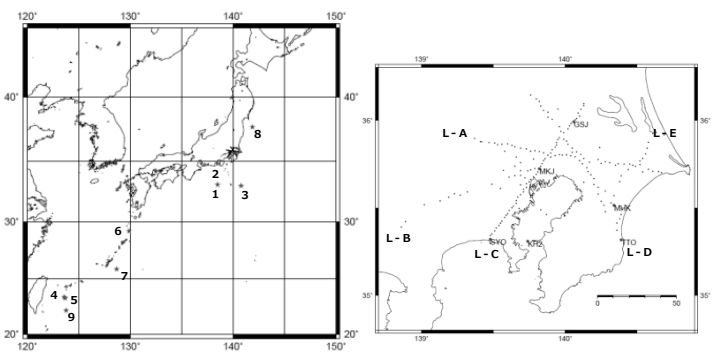

Figure 1 (Left) Hypocenters of earthquakes (Right) Locations of MeSO-net used in this study

2.2 Time-frequency analysis

To understand the discrepancy of H/V spectral ratios obtained by different wave types (e.g. body waves and surface waves), we verified time-variations of H/V spectral ratios, by performing the time-frequency analysis (Gabor transform with Gaussian time window of 20 seconds.). In this paper, we defined the division of geometric mean between horizontal components by a vertical component as H/V spectral ratio. Velocities and H/V spectral ratio at MKJ during off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5) are shown in Figure 2 and Figure 3, respectively.

In the early arrival from 100 to 200 seconds, a period less than 4 second is dominated for H/V spectral ratio in Figure 3. On the other hand, a period of 5 to 10 second is dominated in the later phase from 200 to 600 seconds. The discrepancy of those dominant periods is caused by the complexity of wave fields during earthquake ground motions. In generally, early arrivals consist of body waves and later phases consist of surface waves.

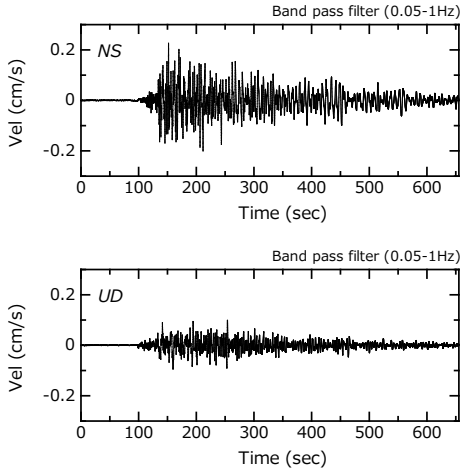

Figure 2 Velocities of NS and UD components by BWF between 1 and 20 seconds at MKJ during off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5)

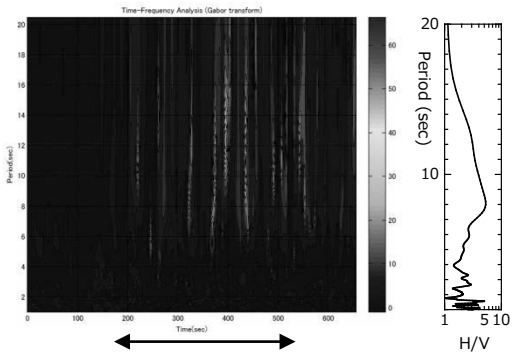

Figure 3 (Left) Gabor transform of H/V spectral ratio at MKJ using Gaussian time window of 20 seconds (Off the east coast of Hachijojima earthquake, 2009/8/13, Mj 6.5) (Right) H/V spectral ratio of coda waves in a duration shown with a closed arrow in the left figure

2.3 Similarity to H/V spectral ratio of microtremors

We compared H/V spectral ratios of coda waves with H/V spectral ratios of microtremors. As examples, H/V spectral ratios of coda waves and microtremos are shown in Figure 4. The similarity of both H/V spectral ratios means that coda waves used in this study are composed of surface waves as well as microtremors. However, the difference of the two H/V spectral ratios for periods larger than 5 seconds is due to the noise of vertical sensors.

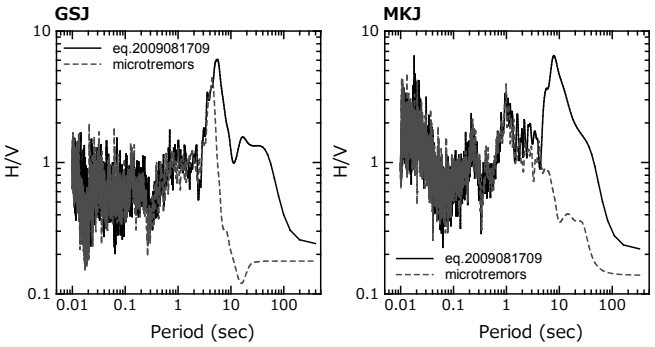

Figure 4 Comparison of H/V spectral ratios of coda waves (2009/8/17, Mj 6.7) with those of microtremors at GSJ and MKJ

2.4 Comparison with R/V spectral ratio

We compared the H/V spectral ratios of coda waves with R/V spectral ratios, as shown in Figure 5 using the earthquake recording data of off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5). Although the dominant periods of the H/V and R/V spectral rations are quite similar, the amplitudes have a slight difference for the peak because H/V spectral ratios have an influence from Rayleigh waves as well as Love waves. In the case of using H/V spectral ratios, we need to consider the contribution of Love waves despite less influence than Rayleigh waves.

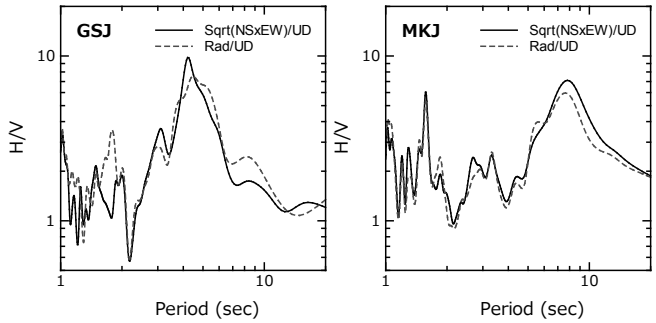

Figure 5 Comparison of H/V spectral ratios with R/V spectral ratios at GSJ and MKJ, during off the east coast of Hachijoima earthquake (2009/8/13, Mj 6.5)

2.5 Stability of H/V spectral ratios derived from different earthquakes

H/V spectral ratios averaged by 9 different earthquakes (See Table 1) are shown in Figure 6. Average of H/V spectral ratios has a quite small variability; therefore, it reflects the underground structure beneath the site. We could

accurately determine dominant periods of H/V spectral ratios at all the stations, using the average of H/V spectral ratios as shown in Figure 6. Theoretical ellipticities of fundamental mode Rayleigh waves calculated by the S-wave velocity models (Yamanaka and Yamada, 2006) are also shown in Figure 6. The agreement between the average of the H/V spectral ratios and the theoretical one at MKJ indicates that the structural model is well constraint at this site. On the other hand, the slight difference between the averaged and the theoretical H/V spectral ratios (e.g. GSJ and MHK) requires that the structural model beneath these sites will be improved.

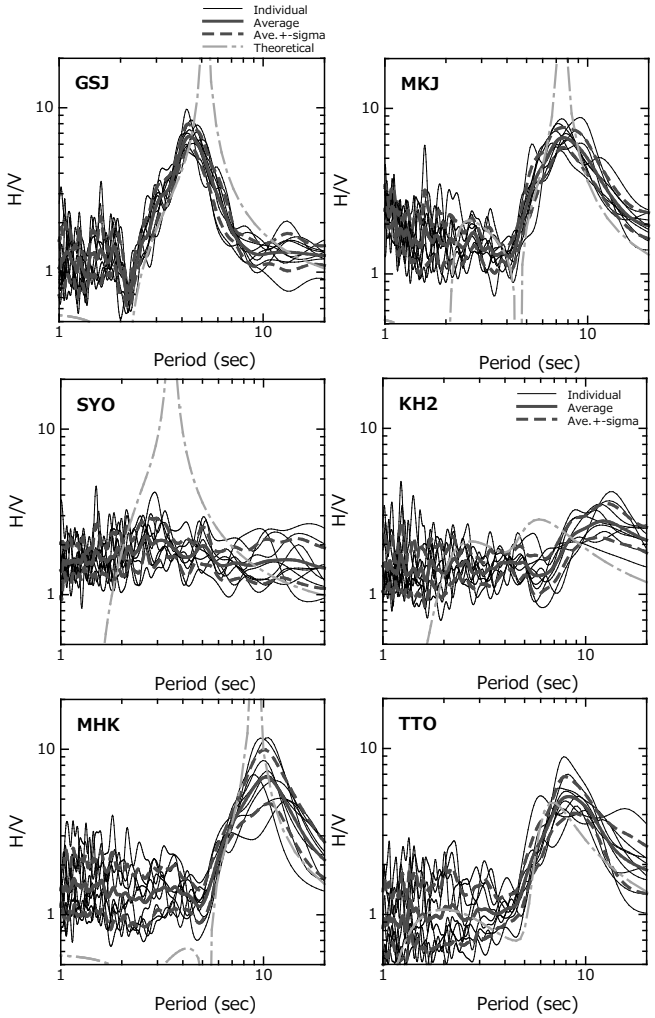

Figure 6 H/V spectral ratios at GSJ, MKJ,SYO, KH2, MHK and TTO (See Figure 1) (Black line: individual H/V, red line: averaged, red dot line: +- σ , green broken line: theoretical)

3. RELATIONSHIP BETWEEN H/V SPECTRAL RATIOS OF CODA WAVES AND DEEP UNDERGROUND STRUCTURES

Distribution of dominant periods of H/V spectral ratios using MeSO-net data is shown in Figure 7. Most of H/V spectral ratios in the Tokyo Metropolitan Area have periods larger than 5 seconds, due to deep underground structures (Yamanaka and Yamada, 2006). In particular, periods larger than 8 seconds are dominated in the west side of the Tokyo Bay and the north of the Boso Peninsula. This tendency is a good agreement with depths of seismic bedrock estimated by array microtremors observations (Yamanaka and Yamada, 2006).

In Figure 8, we compared dominant periods of H/V spectral ratios with theoretical dominant periods of fundamental mode Rayleigh waves calculated by using Yamanaka and Yamada's model, for 5 cross sections shown in Figure 1. Although both dominant periods in Figure 8 have the same tendency, they don't agree with each other in detail. In Line C, for example, the theoretical dominant periods by Yamanaka and Yamada's model underestimate those observed. The dominant periods of H/V spectral ratios matched well for sites where shallow basin structures are located; however, dominant periods of H/V spectral ratios didn't match well for sites where deep basin structures are located. Yamanaka and Yamada's model is based on phase velocities of Rayleigh waves estimated by array microtremors observations; therefore, the uncertainty of underground structural model is increased when a phase velocity is not obtained for long periods.

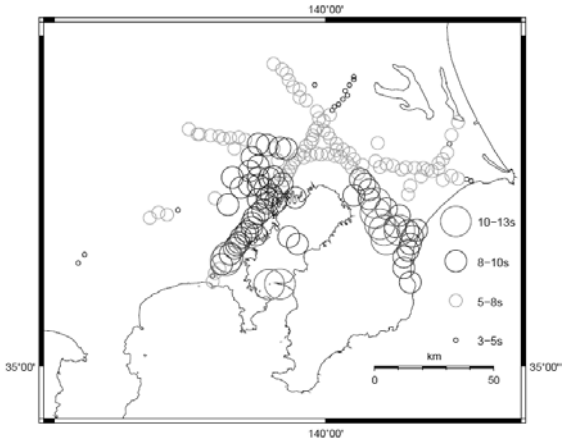

Figure 7 Distribution of dominant periods of H/V spectral ratios in MeSO-net

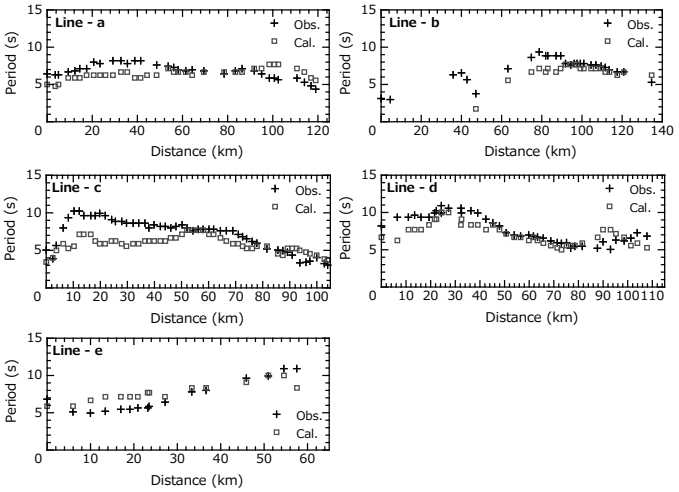

Figure 8 Comparison of dominant periods of H/V spectral ratios observed by MeSO-net with those calculated by Yamanaka and Yamada's model

4. DISCUSSIONS

We examined wave types of coda waves used for the calculations of H/V spectral ratio. Here, we focus on a duration of 312 to 335 seconds in which H/V spectral ratio is dominated during off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5; See Figure 3). H/V spectral ratios and those Fourier spectra from 312 to 335 seconds at MKJ are shown in Figure 9. The Fourier amplitudes of vertical motions from 322 to 328 seconds are decreasing at a period of around 8 seconds; therefore, H/V spectral ratio has a certain peak. Particle motions of NS - UD components from 317 to 327 seconds processed by a bandpass filter at periods between 8 and 20 seconds are retrograde (See Figure 10). On the other hand, particle motions processed by a bandpass filter at periods between 5 and 8 seconds are prograde. These wave motions strongly support that the vertical and radial motions are composed of Rayleigh waves propagating from the south to north as shown in Figure 11.

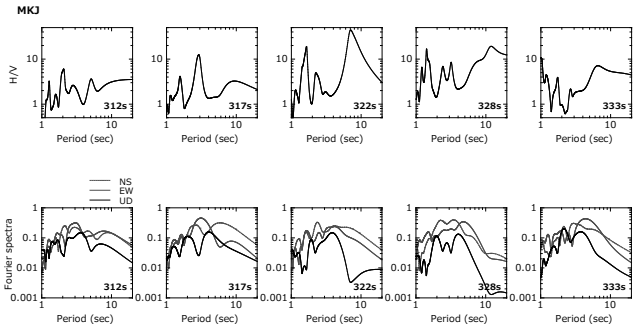

Figure 9 H/V spectral ratios and those Fourier spectra (312-333 second) at MKJ, during off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5)

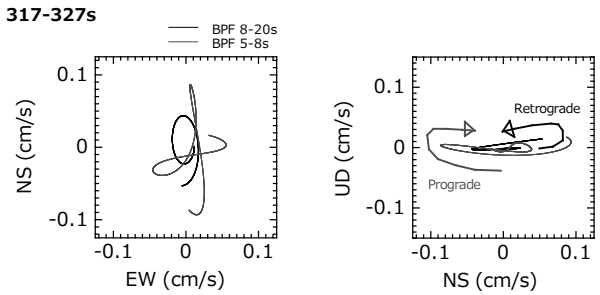

Figure 10 Particle motions among horizontal and vertical components at MKJ from 317 to 327 seconds during off the east coast of Hachijojima earthquake (2009/8/13, Mj 6.5)

5. CONCLUSIONS

Coda waves used in this study were mainly composed of surface waves consisting of both Rayleigh waves and Love waves. The variability of H/V spectral ratio of coda waves observed by 9 earthquakes larger than Mj 6.5 was quite small. Consequently, we concluded that dominant periods of H/V of coda waves would be useful for creating a 3-D underground velocity structural model to predict long period ground motions. In the case of using amplitudes of H/V of coda waves, we would need to include the amplitude of Love waves. In Yamanaka and Yamada's model, which is based on phase velocities of Rayleigh waves obtained by array microtremors observations, there are still uncertainties in the data obtained from deep basin structures when phase velocities for long periods are not obtained by array microtremors recording data.

As a next step, we aim to improve the velocity structural models in the Tokyo Metropolitan Area, by applying the inversion of ellipticities of Rayleigh waves for H/V of coda waves observed by MeSO-net. Also, we will simulate long periods of strong ground motions in the area, using the improved velocity structural models.

Abstract: In this study, we extend the application of the fault-structure system (FSS) analysis to seismic response estimation of a model of nuclear power plant (NPP). FSS is a system that can account for the variability of earthquake input and the corresponding seismic response. In FSS, an integrated analysis of the seismic wave propagation and NPP response is conducted, which include three-dimensional (3D) modeling of the fault rupture process, interaction of seismic wave with the complicated crust structure, effect of geologic setting within immediate vicinity of the NPP, and response of NPP structure. In solving the FSS, the Macro-Micro Analysis procedure (Ichimura and Hori, 2009a) is adopted to efficiently handle the resolution required for geologic- and engineering-length scale simulations. A 3D FEM code based on hybrid grid is developed to gain flexibility in handling mesh modeling and the resulting computational cost. A validation of the method is performed by a reproduction of an earthquake event on actual 3D crust structure. A scenario earthquake simulation is conducted for a fault-plane rupture close to the NPP model. Results show that by employing the FSS, a realistic response of the NPP can be obtained with respect to the scenario setting. Future targets for improvement are also discussed.

1. INTRODUCTION

Seismic response of large-scale structures such as nuclear power plants (NPP) is complicated due geometrical irregularities that conform to the function of different components of such facility. The use of numerical methods for analysis is widely-accepted, and improvements in computational resources are leading to development of more sophisticated analysis tools. Following this development, emphasis should also be placed on the earthquake input to the structure because this input is affected by the radiation characteristics of rupture of the source, the effect of geologic layers, subsurface velocity layers in the soft basin, and site effects such as surface topography. Thus, each earthquake scenario is unique in terms of phase and amplitude characteristics which are significant factors to account for in seismic response of structures such as NPPs.

The FSS is a system that can account for the variability of earthquake input and the corresponding seismic response. Though the FSS is a promising tool for analysis, it demands a heavy computational environment especially if considering 3D problems. It should be mentioned that different methods exist in the literature to address this difficulty (as examples, Domain Reduction Method (Bielak, et. al, 2003); Macro-Micro Analysis (MMA) (Ichimura and Hori, 2009a)). Among these methods, the MMA (Ichimura and Hori, 2009a) is one of the most promising analysis tool because of its rigorous mathematical foundation while maintaining robustness in implementation to actual problems. MMA efficiently solves the FSS by decomposing the problem into two scales, and satisfying the accuracy required in both scales in solving the problem. In this study, the extension of applicability of the MMA for NPP seismic analysis is examined.

2. METHODOLOGY

2.1 Equations for Macro-Micro Analysis

As earlier mentioned, the FSS includes 3D modeling of the earthquake source rupture, the wave propagation through the irregular crust, effect of geologic structure near the structure, and finally, the seismic response of the structure. It should be observed that two length scales are being considered when solving the FSS – the geologic and engineering, and the spatial dimensions would vary from about 10^5 meters for the domain size for seismic wave propagation to about 10^{-1} meters for the mesh to conform to structure component size. Thus, if to be solved directly (all

components are solved at once), the computational cost can increase considerably which may not be practical to run in any present computational environment.

The MMA addresses this difficulty by applying perturbation technique to the elastodynamic problem,

$$d_i\left(c_{ijkl}d_l\left(u_k\right)\right)-\rho\ddot{u}_j=0 \quad , \quad (1)$$

where c_{ijkl} is the component of elasticity tensor, ρ is mass density, u_k is displacement component, d_i is partial differentiation, and $\dot{(\ )}$ is time differentiation. The singular perturbation expansion method (Smith, 1985) expands the solution u_k of the wave equation as,

$$u_k \approx u_k^{(0)}+\varepsilon u_k^{(1)}+\ldots \quad , \quad (2)$$

where $u^{(0)}$ is solution at low resolution, $u^{(1)}$ is solution at high resolution, and $\varepsilon=X_i/x_i$ is a very small parameter (<<1) that relates the slow spatial variable, X to fast-changing variable, x.

The use of Equation (2) on Equation (1) results to two equations that first, computes the solution in the domain of the slow spatial variable, and then refines this solution using the properties near the structure:

$$D_i\left(C_{ijkl}D_l u_k^{(0)}\right)-R\ddot{u}_j^{(0)}=0 \quad , \quad (3)$$

$$d_i\left(c_{ijkl}\left(d_l u_k^{(1)}+d_l u_k^{(0)}\right)\right)-\rho\left(\ddot{u}_j^{(1)}+\ddot{u}_j^{(0)}\right)=0 \quad , \quad (4)$$

where D_i is differentiation with respect to X_i , R is the effective density, and C_{ijkl} is the equivalent elasticity tensor in the domain of the slow spatial variable. In MMA, Equation (3) is called the Macro analysis and Equation (4) is called the Micro analysis. The reader is referred to (Ichimura and Hori, 2006) for details of the derivation of Equations (3) and (4). Figure 1 shows the schematic of the MMA.

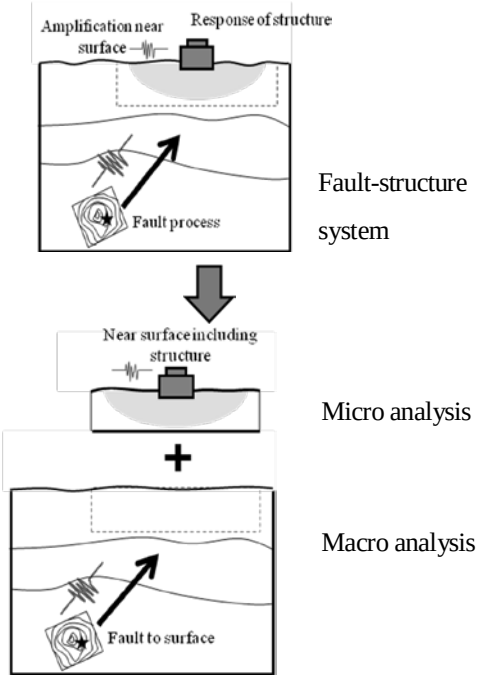

Figure 1. Schematic of MMA: decomposition of FSS to two-step procedure, Macro and Micro analysis.

2.2 Computing the Macro analysis

The "Macro" analysis is carried out to obtain the low resolution solution at geologic-length scale. This includes modeling the earthquake generation and propagation through the crust structure. Earthquake generation is modeled as double couple point source(s) with a specific source time function, rise time, magnitude and moment tensors. Modeling the propagation includes accounting for the irregular crust structure, basin velocity structures, and their respective layer properties (pressure and shear wave velocities, density, and quality factor). Following Equation (3), the spatial component is discretized using the Galerkin method and temporal component is discretized using Newmark-β (β=1/4) method to arrive at the following equation for implementation to computer code:

$$\left(\mathbf{K}+\frac{2}{\Delta t}\mathbf{C}+\frac{4}{\Delta t^2}\mathbf{M}\right)\mathbf{u}^{n+1}= \left(\frac{2}{\Delta t}\mathbf{C}+\frac{4}{\Delta t^2}\mathbf{M}\right)\mathbf{u}^{n}+\left(\mathbf{C}+\frac{4}{\Delta t}\mathbf{M}\right)\mathbf{v}^{n}+\mathbf{M}\mathbf{a}^{n}+\mathbf{f}^{n} \quad , \quad (5)$$

where **K**, **C**, **M**, **u**, **v**, **a**, **f**, n, Δt are stiffness, Rayleigh damping, mass matrices, displacement, velocity, acceleration, external force vectors, temporal counter, and time step size, respectively.

2.3 Computing the Micro analysis including NPP model

To include the site-specific response, the "Micro" analysis is carried out as described in Equation 4. Here, a small region near the structure is considered and the low resolution obtained in Macro analysis is refined to account for the settings near the structure to be analyzed. Such refinement of solution is a main point of perturbation methods. Discretization in space using the Galerkin method and in time using Newmark-β (β=1/4) method, we arrive at the equation similar to Equation (5) without the external force term.

2.3 FEM coding of the Macro and Micro Analysis

As mentioned, solving the FSS using the direct analysis can result to large computational cost. However, even though a significant reduction has been achieved in decomposition to two scales, the computation cost is still high. In the developed MMA code, several computing techniques were used in mesh modeling and time integration. Mesh modeling employs a background cell to efficiently place finite elements and reduce inefficient tetrahedral elements (elements with low aspect ratio). The background cell also determines the voxel (Koketsu, 2004) locations, and based on location in the layers, may invoke the octree technique (Bielak, 2005) to determine its efficient dimension. In the analysis,, the element-by-element (EBE) technique (Wenget and Hughes, 1985) is implemented to avoid global assembly of stiffness matrix. The EBE is implemented to the preconditioned gradient method (PCG) with a specified criterion for convergence.

For the details of the Macro and Micro analysis and implementation of the computating techniques mentioned, the reader is referred to the following related papers (Ichimura and Hori, 2006, Ichimura and Hori, 2007, Ichimura and Hori, 2009a, Ichimura and Hori, 2009b).

3. Application Examples

3.1 Validation of earthquake simulator: Reproduction of observed earthquake

To check the validity of the code to simulate earthquake as input to NPP, a reproduction of observed earthquake is conducted. A region that includes a large part of Tokyo, as shown in Figure 2 (with details in Table 1), is chosen as the simulation region, and layer properties are as derived by Tanaka et al. (2006). A recent earthquake is selected (F-NET) which was observed in several seismic stations (K-Net). This earthquake is modeled as a double-couple point source with settings as given in Table 2. Equation (5) is used to compute the response at seismic stations. The target accuracy is 0.5 Hz. Time step size is 0.01 seconds and 10 elements is used for one wavelength. The iterative solver is PCG method with convergence criteria of $1x10^{-6}$.

Table 1. Layer material properties used in reproduction of observed earthquake (Tanaka et al. 2006)

Layer	P-wave velocity (m/s)	S-wave velocity (m/s)	Density (kg/m3)	Quality factor
1	1850	500	1950	60
2	2560	1000	2150	150
3	3200	1700	2300	200
4	5800	3360	2700	500
5	6600	3700	2800	600
6	8040	4480	4400	800

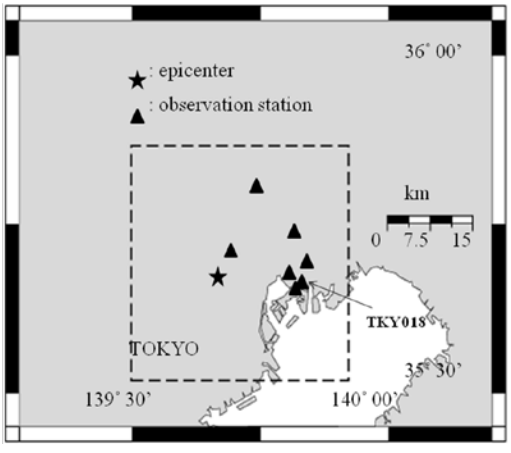

Figure 2. Target region, earthquake epicenter (shown as star), and observation points (shown as black triangels) for the reproduction of observed earthquake. Arrow points to Station TKY018.

Table 2. Observed earthquake properties (K-net)

Date	2010/05/09
Latitude	35.6757 N
Longitude	139.6613 E
Depth	26.73 km
Source time function	$M_o(2t^2/T_o^2)$ $0 \le t \le T_o/2$
	$M_o(1-2(t-T_o)^2/T_o^2)$ $T_o/2 \le t \le T_o$
	M_o $t \ge T_o$
Magnitude	Mw = 3.8
Strike, Dip, Rake	253°, 17°, 39°
Rise time, To	0.18 sec

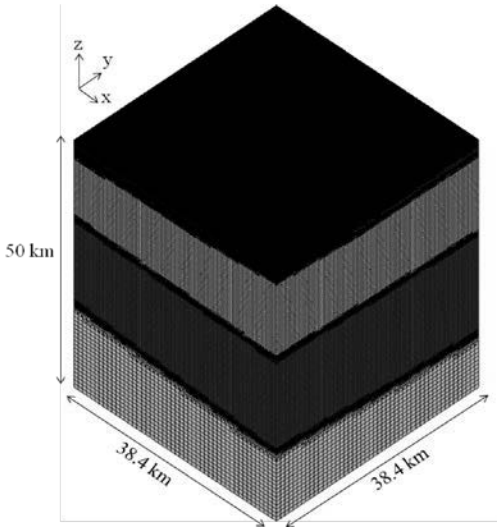

Figure 3. Resulting 3D model of the actual crust structure (Tanaka, 2006) using the modeling code of Macro analysis. The minimum element size is 100 m.

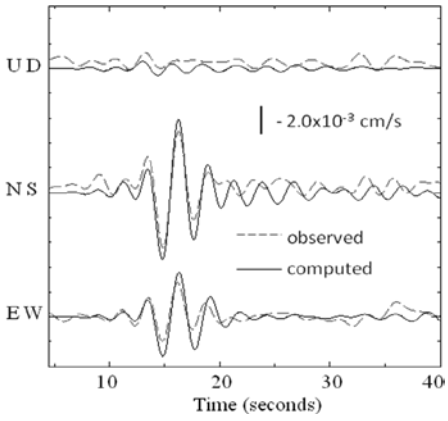

Figure 4. Comparison of observed and computed results at Station TKY 018. The results are band-pass filtered (0.1 – 0.5 Hz).

As observed in Figure 3, a good agreement between the observed and computed seismograms has been obtained. Similar agreement has also been obtained in the comparison for other seismic stations. This validates the applicability of the Macro analysis code for earthquake simulation from fault to surface in geologic-length scale.

3.2 Earthquake scenario example: Nuclear power plant seismic response estimation

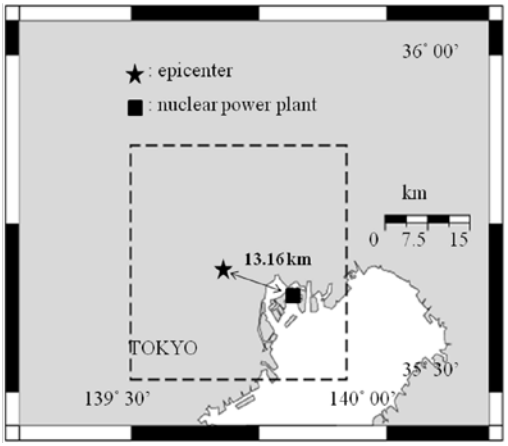

Figure 5. Target region, earthquake epicenter, and NPP (shown as star and square marks).

Table 3. Material properties

Material	P-wave velocity (m/s)	S-wave velocity (m/s)	Density (kg/m3)	Quality factor
Engineered fill	1500	400	1600	50
NPP	3373	2127	2500	200

Table 4. Scenario earthquake properties

Hypocenter depth	30.0 km
Rupture speed	2.0 km/s
Source time function	$M_o(2t^2/T_o^2)$ $0 \le t \le T_o/2$
	$M_o(1-2(t-T_o)^2/T_o^2)$ $T_o/2 \le t \le T_o$
	M_o $t \ge T_o$
Magnitude	$M_w = 5.3$
Strike, Dip, Rake	30^o, 45^o, 60^o
Rise time, To	1.0 sec

In this section, the MMA is applied to seismic response estimation of NPP model. The target accuracy is 0.5 Hz. The same simulation domain and crust layer properties as 3.1 are used. The time increment is 0.01 seconds and total simulation time is 40.96 seconds. The criterion used for numerical accuracy is ten (10) elements per wavelength for the target accuracy. Figure 5 shows the problem setting where the epicenter is about 13.16 km from the NPP. The rupture plane is about 1.2 km x 1.2 km in dimensions and dips at 45^0 from the horizontal plane (see Figure 8). The hypocenter depth is about 30 km and rupture propagation speed from the hypocenter is 2.0 km/s. In this scenario, the moment magnitude is about 75% of scenario for Kanto region as presented in CDPC report (2004).

Figures 6 and 7 show the Micro model (with location of soft soil and NPP) and the NPP meshed model, respectively. Tables 3 and 4 give the details of the material properties of the soft soil layer and NPP, and the properties of the scenario earthquake modeled as fault-plane rupture.

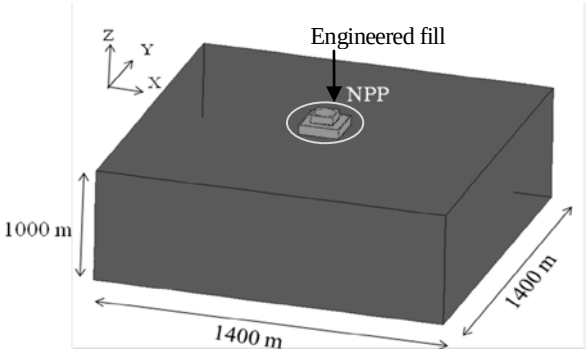

Figure 6. Micro model. NPP structure is at the center of the model. An engineered fill encloses the NPP at about 40 meters on each side.

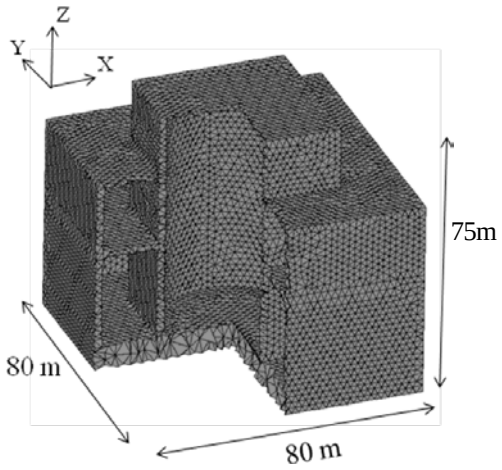

Figure 7. Model of NPP used in the simulation. Mesh size is 2.0 m. Embedment to soil is 36.0 meters from the base.

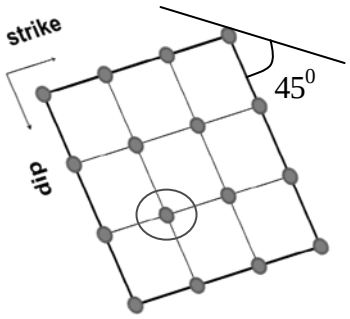

Figure 8. Fault-plane rupture modeled as 16 point sources with different rupture starting time. Distance between adjacent point sources is 400 m. Details are as given in Table 4. Red circle shows the hypocenter.

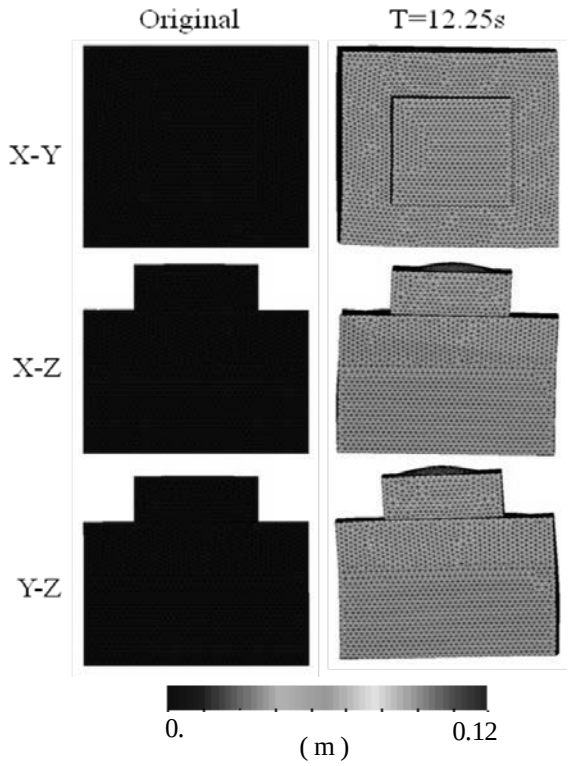

Figure 9. NPP structure deformation at time, T = 12.25 seconds (deformation x2000). Color bar shows displacement.

It is emphasized that the application of FSS for seismic analysis of NPP is advantageous because it can simulate the realistic behavior of this structure with respect to the given earthquake scenario and actual geologic and near vicinity settings. Because the analysis is based on 3D models, the 3D effect of the wavefield on the NPP structure is inherently accounted for. As shown in Figure 9, deformation of the NPP can be examined simultaneously from which critical locations in the structure can be determined. The capability to observe these deformations using analysis tools such as MMA is significant when designing new structures and analyzing existing ones.

To extend the applicability further for in-depth analysis of NPP structures, this study hopes to integrate fracture analysis based on particle discretization scheme (Hori et al. 2005). Moreover, to further reduce the computation time in modeling and analysis, hybrid-parallelization (shared and distributed memory) is presently being implemented to the MMA codes.

4. CONCLUSIONS

We have presented a FSS approach for seismic response estimation of NPP structures. FSS includes 3D modeling of the fault rupture process, interaction of seismic wave with the complicated crust structure, effect of geologic setting within immediate vicinity of the NPP, and response of NPP structure. To solve the FSS, a multiscale approach – Macro-Micro Analysis is used, allowing for feasibility of implementation to present available computational resource. To validate the earthquake input to the NPP model, a recent earthquake in Kanto region is reproduced. This is then extended to seismic response estimation of NPP under a scenario earthquake.

Abstract: Detailed analysis of the low frequency content of accelerations recorded in the near-field of four large Japanese earthquakes showed that it is possible to obtain realistic estimates of coseismic displacement time histories. Nearby GPS records are used as a check of the method. The displacements obtained for each earthquake by the two independent methods are given here in terms of maps of residual displacements, with an aim at stressing the usefulness of the proposed methodology.

1. INTRODUCTION

The determination of coseismic displacements from strong-motion seismometers is needed for various purposes including tsunami prediction, estimation of ground strain, design of structures and deep foundations. Deriving displacements from strong-motion seismometers records, rather than obtaining them from direct measurements such as from GPS stations, is interesting because of the large number of accelerometers already deployed, including in a wide range of places, such as the bottom of boreholes, within structures or on the seabed.

The methodology we use to estimate the displacement time-histories from strong-motion records was first described in Javelaud et al. (2005). A detailed description of the method including its limitations can be found in Javelaud et al. (2011).

It has so far been used in studies related to the evaluation of ground strain (Ohtake 2006 and 2007), estimation of the coseismic residual tilt of structures (Javelaud et al., 2006) and coseismic displacement time-histories (Javelaud et al., 2005, 2010 and 2011; Inoue et al., 2007; Furukawa et al., 2010a and 2010b).

In this paper, the displacements time-histories derived from accelerations recorded during four recent and large Japanese earthquakes are compared with those obtained by nearby GPS stations, as a check of the method. Map of residual displacement estimated for four large earthquakes are gathered here with an aim at showing the efficiency of the proposed methodology in different earthquake situations.

2. EARTHQUAKES STUDIED

The four Japanese earthquakes studied are the 2004 Niigata-ken Chuetsu earthquake, the 2007 Noto Hanto Earthquake, the 2007 Niigata-ken Chuetsu-oki Earthquake and the 2008 Iwate-Miyagi Nairiku Earthquake.

TABLE 1 MAIN CHARACTERISTICS OF THE EARTHQUAKES STUDIED

Earthquake	Fault type	Maximum acceleration recorded (cm/sec^2)	M_{JMA}
2004 Niigata-ken Chuetsu earthquake	Reverse	> 1000	6.8
2007 Noto Hanto Earthquake	Reverse	> 1300	6.9
2007 Niigata-ken Chuetsu-oki Earthquake	Reverse	> 700	6.9
2008 Iwate-Miyagi Nairiku Earthquake	Reverse	3866	7.2

TABLE 2 STUDIED EARTHQUAKES AND RELATED REFERENCES

Earthquake	General information	GPS
2004 Niigata-ken Chuetsu earthquake	Asano and Iwata (2009), Honda et al. (2005).	GSI (2004)
2007 Noto Hanto Earthquake	Hiramutsu et al. (2008)	GSI (2007,a)
2007 Niigata-ken Chuetsu-oki Earthquake	Tabuchi et al. (2008), Miyake et al. (2010)	GSI (2007,b)
2008 Iwate-Miyagi Nairiku Earthquake	Suzuki et al. (2010)	GSI (2008)

Brief summary of the studied earthquakes' characteristics are given in Table 1, while references about their mechanisms and source of the GPS residual displacement data are given in Table 2. The strong-motion records come from two networks, the Japanese nationwide K-Net and KiK-Net networks. A few records from the Japanese Meteorological Agency have also been used.

3. MAP OF RESIDUAL DISPLACEMENTS

Maps of residual displacement (Figure 1 to 4) were drawn for each earthquake (Murakami, 2008; Inoue et al., 2009; Javelaud et al., 2010; Furukawa et al., 2010) and the displacement derived from acceleration records compared with those obtained from GPS data.

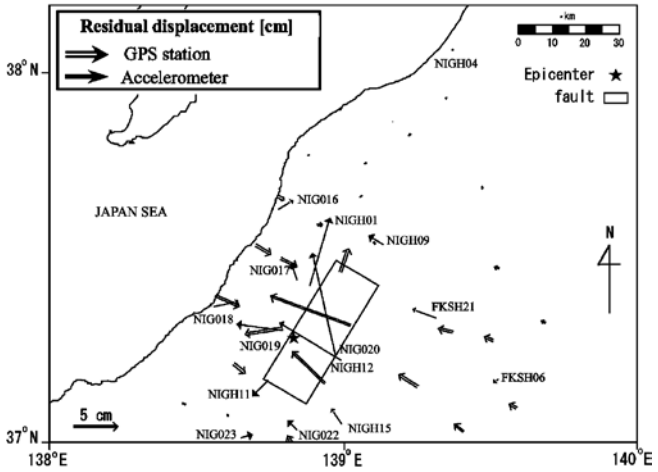

Figure 1 Comparison of coseismic residual displacement obtained from strong-motion seismometers and surrounding GPS stations during the 2004 Niigata-ken Chuetsu earthquake, Japan

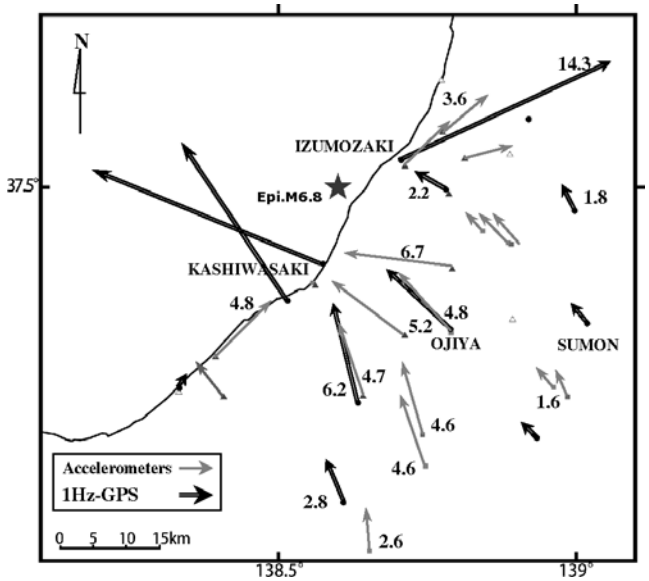

Figure 2 Comparison of coseismic residual displacement obtained from strong-motion seismometers and surrounding GPS stations during the 2007 Niigata-ken Chuetsu-Oki earthquake, Japan

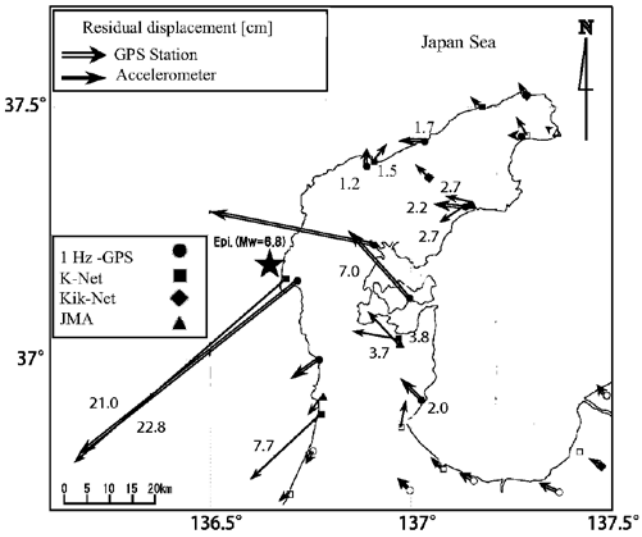

Figure 3 Comparison of coseismic residual displacement obtained from strong-motion seismometers and surrounding GPS stations during the 2007 Noto Hanto earthquake, Japan

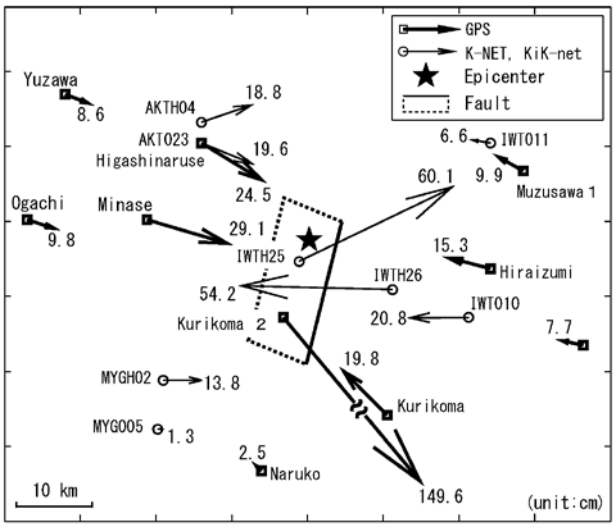

Figure 4 Comparison of coseismic residual displacement obtained from strong-motion seismometers and surrounding GPS stations during the 2008 Iwate-Miyagi Nairiku earthquake, Japan

The four maps above show the coseismic residual displacement obtained at both GPS stations and from acceleration records. In these four areas hit by large earthquakes, there are some collocated GPS and strong-motion stations: at those places, the residual displacements obtained by the two methods are very close in amplitudes and directions, which is an important result considering that the instruments are not sealed on a same concrete footing but at best distant by a few hundred meters. At other places, the residual displacements obtained by the two methods are consistent considering the distance between the instruments and the varying field of displacement.

4. DISCUSSION AND CONCLUSIONS

Estimating displacement time-histories from accelerations records is difficult because strong-motion records of translational accelerations are contaminated during the recording process by instrumental noise, mainly by 1/f semiconductor noise, and by the simultaneous record of the instrument's tilt.
This addition of noise to the translational accelerations includes the addition of long period noise, which makes the estimation of the displacement time histories by double integration difficult to perform and the results of double integration of accelerations series often uncertain.

The proposed methodology is described in detail elsewhere, such as in Javelaud et al.(2011), but could be summarized as follow:
In a first step, the records' low frequency content is visualized. To obtain the Fourier transform of the signal, computers perform their Discrete Fourier Transform (D.F.T.). This provides a discrete representation of the signals' Fourier content but not the continuous visualization necessary to obtain a detailed representation of their low frequency content. Long zero pads are therefore first added to the acceleration records so that the Discrete Fourier Transform performed by computer provides the Discrete Time Fourier Transform of the records (Oppenheim and Schafer, 2010), i.e. allows the user to visualize all the low frequency information that the acceleration records contains.
Then, the 1/f semiconductor noise is estimated from ambient vibration noise records or from records of small aftershocks that occurred short before or after the main event.
Also, any residual tilt shall be recorded after the main part of the shaking as a constant acceleration lasting until the end of the record. It shall therefore have a typical shape in the Fourier domain that should be distinguishable from the low frequency content of the acceleration record and from the 1/f semiconductor noise.

The importance of these three terms (translational acceleration, 1/f semiconductor noise and residual tilt) is evaluated before processing the acceleration time-histories:
- far from the epicenter, the 1/f semiconductor noise may dominate the acceleration record and so an estimate of the displacement can be obtained if the corner frequency at which the 1/f noise dominates the acceleration is small enough.
- in the near-field, removing the residual tilt is often all what is needed to obtain stable and reliable displacement time-histories. The effect of the oscillatory part of the tilt is indeed assumed to have little effect on the displacement time-histories. This assumption may not be valid in the very near-field of the largest earthquakes (Furukawa, 2010; Javelaud et al., 2011). Further studies (Furukawa, 2011) are currently performed to investigate these records with very large amplitude, reaching for example nearly 4000 cm/sec^2 during the 2008 Iwate-Miyagi Nairiku Earthquake.

We believe that the records obtained from the thousand of strong-motion seismometers already deployed in Japan can be also used immediately following earthquakes to obtain additional information such as quick estimations of the residual displacements but also to provide background data for the design of structures close to capable fault and more realistic tsunami prediction.

Abstract: The 2009 L'Aquila, Italy, earthquake (M_w 6.3) caused severe damage to the city of L'Aquila and tens of villages of the Abruzzo region, killing over 300 people. The mainshock was followed by a significant aftershock activity that extended more than 30 km in northwest-southeast direction. This earthquake provided an unprecedented for a normal faulting event amount of seismological records. During the mainshock, several of the near-fault stations located on the hanging wall of the causative fault experienced ground shakings that exceeded the level prescribed by the design spectra (e.g., Eurocode8) in the period up to 1 s. We studied the source process of the 2009 L'Aquila earthquake in both low- and broadband frequency ranges. The low-frequency (0.05-0.5 Hz) source model was determined by the waveform inversion of the near-field strong motion data, resulting in a slip distribution characterized by an asperity located about 8 km southeast from the hypocenter. The broadband (0.2-10.0 Hz) source characteristics were further determined by employing the empirical Green's function method. Here we discuss the comparison of the derived source characteristics and their influence on the spatial variability of the observed ground motions.

1. INTRODUCTION

The L'Aquila earthquake (Fig. 1) occurred on 6 April 2009 at 01:32:40 UTC in the Abruzzo region of Central Apennines, Italy. According to the Istituto Nazionale di Geofisica e Vulcanologia of Italy (INGV) the earthquake was generated by normal faulting on a fault system running parallel to the axis of the Apennine mountains and had a moment magnitude (M_w) of 6.3. The updated location of hypocenter was estimated to be 2 km westward from the city of L'Aquila at 42.3476°N, 13.3800°E, and depth of 9.46 km (INGV, 2009). This M_w 6.3 event caused severe damage to the city of L'Aquila and tens of villages of the Abruzzo region located in the middle Aterno Valley. Although this magnitude was not among the largest to have occurred in the Apennines, the 2009 L'Aquila earthquake can be considered one of the most disastrous events there (Tertulliani, 2009). As was estimated by the May of 2009, 305 person lost their lives and over 1500 were injured, and thousands of buildings and houses were destroyed and damaged. This represents the highest death toll due to an earthquake in European Union since the 1980 Irpinia event, and the highest economic loss due to the seismic activity since the 1999 Athens earthquake (Papanikolaou *et al.*, 2010). According to the damage estimates, 47% of houses in the epicentral area were damaged and 20% of those were heavily damaged. Most of the damage occurred within the city of L'Aquila, located close to the hypocenter, and the villages of Paganica and Onna, located further southeast.

The 6 April 2009 L'Aquila mainshock was a largest event in a seismic sequence that started a few months earlier. The mainshock was followed by a significant aftershock activity that extended over the length exceeding 30 km in northwest-southeast direction (Fig. 1).

The 2009 L'Aquila earthquake provided an unprecedented amount of seismological records form a normal faulting event, making the study of its source process an important issue for understanding and quantifying the seismic hazard due to normal faulting events. The mainshock and aftershocks have been recorded by several local and regional seismic networks. The records from the Italian strong-motion network (RAN), operated by the Department of Civil Protection were integrated into the ITalian Accelerometric Archive (ITACA) and made available over the internet. Fifty-eight strong motion stations in the distance range from 1.7 km to 277 km provided the high quality digital acceleration records of the mainshock. The near-fault stations at epicentral distances of 1.7 to 5.0 km) on the hanging wall side recorded largest horizontal PGA values ranging from 0.35 to 0.65 g. These stations are also characterized by vertical PGAs as large as the horizontal ones. The largest PGA of 662 cm/s^2 was recorded at the AQV station in the Aterno valley. Stations located on the foot wall side recorded only PGAs less than 0.15 g. According to some of the Italian seismologists this event represents the third largest earthquake recorded by strong-motion instruments in Italy, after the 1980 M_w 6.9 Irpinia and the 1976 M_w 6.4 Friuli earthquakes (Akinci *et al.*, 2010).

The comparison of the 5% damped velocity response

spectra estimated from the records of the 2009 L'Aquila mainshock recorded at the near-fault stations located on the hanging wall of the causative fault with the design spectra prescribed by the Eurocode 8 (EC8) showed that both the horizontal and vertical components generally exceeded the spectral ordinates of the design spectra (Fig. 2). This can explain the widespread damage of the buildings observed in the near-fault area.

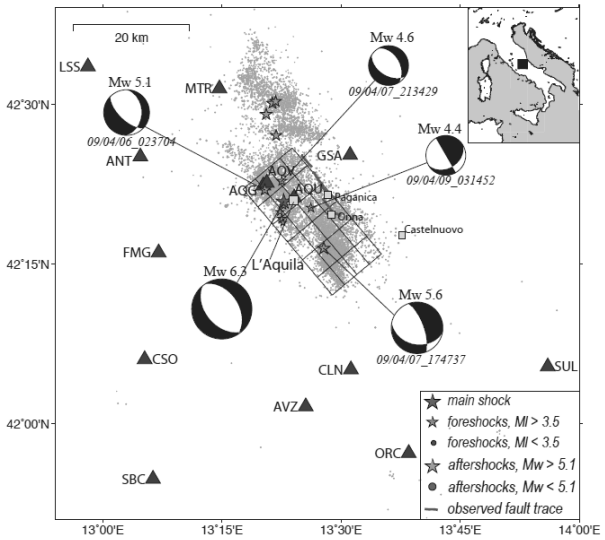

Figure 1. Map view of the L'Aquila area showing the distribution of the strong motion stations of RAN network that recoded the mainshock and are located within the epicentral distance of 50 km from the epicenter (blue triangles). The black rectangles represent the surface projection of the fault plane determined from the waveform inversion analysis.

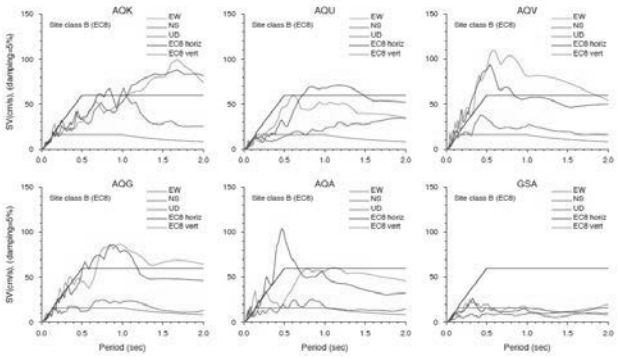

Figure 2. Comparison of three component recorded velocity response spectra (5% damping) with the pseudo-velocity response spectra prescribed by the EC8 for the horizontal and vertical components for 10% exceedance probability in 50 years.

2. SOURCE PROCESS INFERRED BY STRONG MOTION INVERSION

We developed a rupture model for the L'Aquila event in a frequency range of 0.05-0.5 Hz through the waveform inversion of near-field strong motion data applying the multiple-time-window linear waveform inversion method of Yoshida *et al.* (1996). We used three component velocity records from the stations located within the distance of 55 km from the epicenter (Fig. 1). To account for the geological complexity of the area, a set of 1-D stratified velocity models were determined for each station by the forward modeling of the available aftershock records (Fig. 1) assuming the finite duration point source approximation and calculating the theoretical Green's functions by the extended reflectivity method of Kohketsu (1985).

A number of studies including coseismic surface rupture observations (Falcucci *et al.*, 2009; Boncio *et al.*, 2010; EMERGEO Working Group, 2010), geodetic data (e.g., Atzori *et al.*, 2009; Anzidei *et al.*, 2009) and distribution of the relocated aftershocks (Chirabba *et al.*, 2009) confirmed that 2009 L'Aquila earthquake was a result of a normal faulting along the northwest-southeast oriented, southwest dipping Paganica fault. Taking into account these analyses we assumed that rupture occurred on a single fault plane dipping towards southwest, and adopted the location of the rupture starting point corresponding to the revised hypocenter of INGV. The orientation of the fault plane is based on the best fit solution Poiata *et al.* (2009). We set the fault plane dimensions of 24 km in length by 16 km in width by referring the aftershock distribution of INGV. The fault was then discretized into 6 × 4 subfaults, each with an area of 4 km in length by 4 km in width. Figure 1 illustrates the described fault settings by showing the surface projection of the assumed fault plane. The best values of the hypocenter depth and fault orientation (strike and dip angles) were determined during the strong motion inversion analysis through the grid search procedure. We estimated as well the rupture propagation velocity V_r minimizing the residuals between observed and synthetic velocity ground motions (Fig. 3).

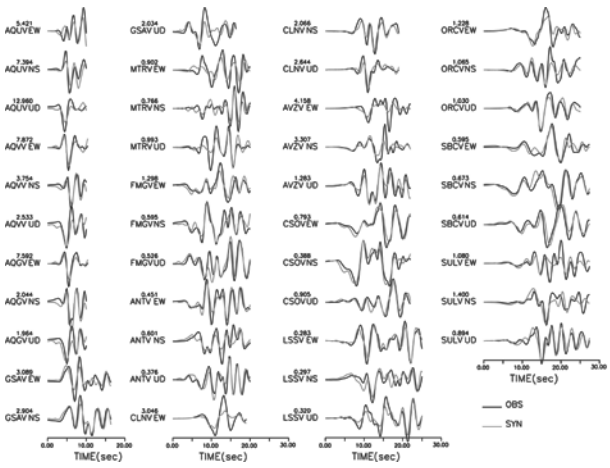

Figure 3. Comparison of the observed (black traces) and synthetic (red traces) ground velocities for the low-frequency strong motion source model. The numbers above the station codes indicate the maximum amplitudes of observation in cm/s.

The slip distribution of our best model from the strong motion inversion shows a major asperity located about 8 km southeast from the hypocenter beneath the town of Onna (Fig. 4e). The total seismic moment corresponding to the model is 0.373 x 10^{19} Nm (M_w 6.3) and the optimal depth of the rupture starting point is found to be 8.2 km. The overall source duration is around 14 s, and the rupture velocity is estimated at 2.0 km/s. The pure normal faulting mechanism of the strong motion model (Fig. 4d) and the precise fault orientation correspond to the values of strike and dip of 140° and 46°, respectively.

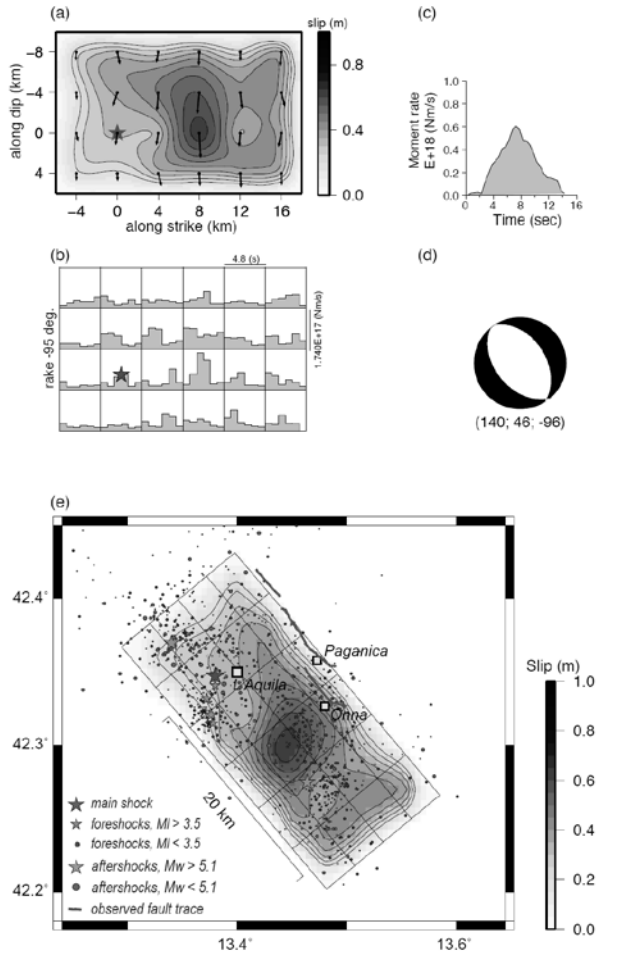

Figure 4. Results of the strong motion waveform inversion. (a) Slip distribution plotted at contour intervals of 0.05 m. The red star indicates the hypocenter. The arrows denote slip vectors of the hanging wall relative to the footwall. (b) Moment-rate functions of each subfault for the resultant direction of the rake angle. The red star indicates the hypocenter. (c) Total moment-rate function. (d) Focal mechanism solution corresponding to the slip distribution of (a). (e) Surface projection of the slip distribution (a) on the map. The contour interval is 0.05 m. The red star indicates the rupture starting point, orange and blue stars show the locations of the strongest foreshocks and aftershocks respectively; orange and blue dots the other foreshocks and aftershocks for a one week period following the mainshock. Red thick line show the location of the observed coseismic breakages modified after Boncio *et al.* (2010).

The source model and the location of the main asperity are in agreement with the results presented by other authors (Atzori *et al.*, 2009; Cirella *et al.*, 2009) as well as the aftershock distributions.

3. BROADBAND SOURCE MODELING USING THE EMPIRICAL GREEN'S FUNCTION METHOD

One of the principal goals of the source processes estimations is to provide the source model capable of reproducing broadband ground motions in the near source region with accuracy enough for engineering purposes. For frequencies higher than 1 Hz, the deterministic simulations of ground motions are limited by the deficit of the precise information about the velocity structure, and the complexity of the source description. A useful approach to overcome these difficulties is to estimate ground motions of an earthquake using the records of smaller events as the empirical Green's function.

We applied this empirical Green's function (EGF) method of Irikura (1986) to estimate the broadband source model for the 2009 L'Aquila mainshock in the frequency range of 0.2-10 Hz. For the source parameter estimation the aftershock form 7 April 2009 (21:34:29; one day from the mainshock) with the magnitude M_w 4.6 was selected as the empirical Green's function. The initial location of the SMGA was assumed based on the location of the asperity determined from the low-frequency inversion analysis. We further determined the parameters of the high-frequency SMGA such as: number and size of subfaults, rupture velocity, rise time of source time function and stress drop, by applying spectral fitting method (Miyake *et al.*, 1999) and forward modeling of the observed broadband ground motions for the selected mainshock-aftershock pair.

The size of the SMGA of the mainshock was found to be 8.0 km in length by 5.2 km in width with the rupture starting point located in its northwestern part. The rupture was estimated to have propagated predominantly towards the southeast and up-dip, in agreement with the result from the source inversion of strong motion data. The rupture velocity was determined to be 2.9 km/s. The validation of the estimated source parameters was made by comparison of the synthetic waveforms of acceleration, velocity, and displacement with the observed ones for four closest stations (Fig. 5) as well as five other stations located at larger epicentral distances. The estimated source model reproduced well the ground motion pulses in the velocity and displacement components of the stations located on the hanging wall side of the causative fault. The results of the analysis for 2009 L'Aquila earthquake indicate that a SMGA coincides with the asperity that was estimated from the low-frequency waveform inversion (Fig. 6).

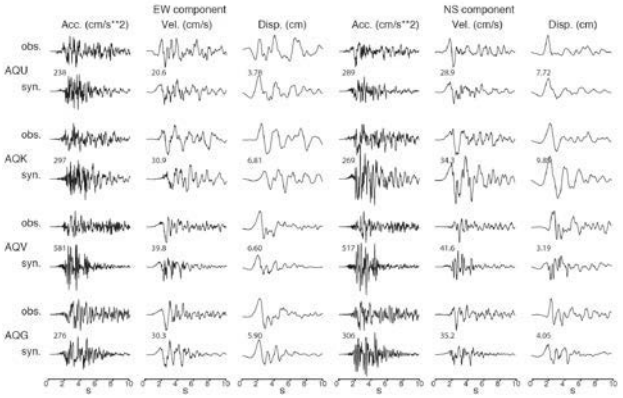

Figure 5. Comparison of the observed and synthetic broadband ground motions for four closest stations used for the estimation of the parameters of SMGA. The numbers aligned the station codes indicate the maximum amplitudes of observation.

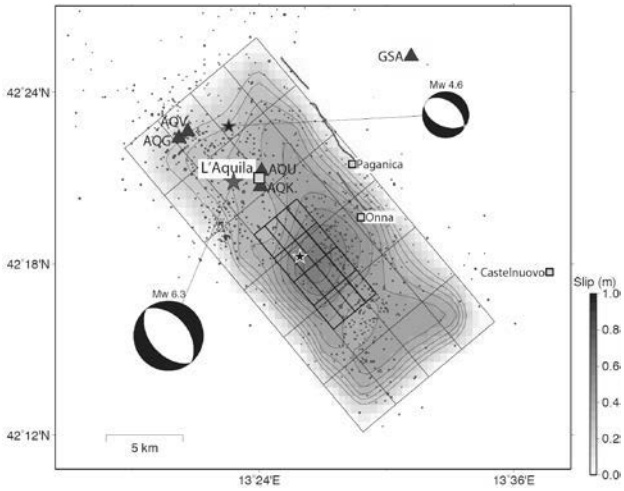

Figure 6. Map view of the near-source region of the 2009 L'Aquila earthquake showing the relative location for the surface projection of SGMA determined from the EGF analysis (black rectangles), and the slip distribution determined from the strong motion inversion. The red star represents the location of the mainshock and the black star with red contour represents the location of the EGF event. The focal mechanisms and seismic moments determined by INGV are also shown. The rest of the components are the same as shown in Fig. 1.

4. CONCLUSIONS

We presented a source model of the L'Aquila earthquake, determined from the waveform inversion of strong motion data in the frequency range of 0.05-0.5 Hz, and the broadband modeling using the EGF method in the frequency range of 0.2-10 Hz. The resulted source model; location of the main asperity and the SMGA (Figs. 4 and 6) are in agreement with the results presented by other authors (Cirella *et al.*, 2009; Atzori *et al*., 2009) as well as the aftershock distributions. We confirmed that the location of the main slip area southeast from the hypocenter is the robust feature of the inversion. This SMGA is in agreement with the existing empirical source scaling relationships for inland crustal earthquakes implying a stress drop of around 10 MPa (e.g., Miyake *et al.*, 2003). This feature is also in agreement with the study of Bindi *et al*. (2009), confirming that the 2009 L'Aquila earthquake provided a stress drop that corresponds to the events recorded in the Central and Southern Apennines.

The results of our analysis show as well correlation with the observed macroseismic intensities reported by INGV. The maximum MCS intensities of IX-X are reported southeast of the hypocentral location, with the value of X corresponding to the city of Onna.

Abstract: The Longitudinal valley is the convergent boundary of Eurasian Plate and Philippine Sea Plate. Located between the Central Range and Coastal Range, the valley was linear, narrow, and near the north-south direction. There are numerous earthquakes and many active faults here, and the underground active tectonics are very complicated. The previous studies provided us a better understanding of structures and seismotectonics in the Longitudinal valley. The fracture zone could be regarded as a low-velocity zone, and seismic energy will trapped in this low-velocity zone. In this study, the trapped waves were identified from the observed seismograms based on the characteristics list (Li *et al.* 1998, Ben-Zion 1998) and the amplitude, particle motion, and dominant frequency were also analyzed. Finally, the site effects in the Longitudinal valley were discussed in this study.

1. INTRODUCTION

Taiwan is located along the plate boundary between the Eurasian Plate and the Philippine Sea Plate. Collision between the two plates takes place along the Longitudinal valley (LV) with a highly convergence rate of 82 mm/yr. The Longitudinal valley is considered as the collision suture between the two plates. Its tectonic implications and seismicity have long been a primary research focus in the central eastern Taiwan. The crust beneath the Longitudinal valley was unusually thinner than that beneath other parts in Taiwan (Kim et al. 2005, Kim et al. 2006, Liang et al. 2007).

The LV is sandwiched between the Central Range and the Costal Range. It is shown in Figure 1. It is about 160 km long and less than 10 km wide in most places. And it's filled with Quaternary sediment. The geological condition in LV is relatively soft in contrast to the stiff eastern and western range. Li (2004) reported that a fracture zone may form a low-velocity zone and trap some waves inside the fault. From the regional geology setting, we want to know if the Longitudinal valley can trap waves just like a low-velocity zone.

The seismicity in central collision zone is relatively low in contrast to the very active northern and southern collision zone. The Longitudinal valley was reported with complex tectonics along different segment of the LV. We also collect the earthquakes data and stations' information to analyze the site effect in the area.

2. DATA AND METHOD

2.1 Data Source

Strong ground-motion data obtained by the Taiwan Strong-Motion Instrumentation Program (TSMIP) are used to investigate site effect. The TSMIP accelerograph network currently consists of more than 650 free-field stations. Seismic signals digitized at 24 bits and 200 samples per second for three-component stations. And the maximum range of records is ±2g. All the arrival time and earthquake-location files from 1999 to 2009 reported by the Central Weather Bureau (CWB) have been collected and analyzed in this study.

The Chengkung earthquake (M_L = 6.42) occurred on December 10, 2003 at a focal depth of 17.73 km, as reported by the CWB. The main shock occurred at 23.0667°N and 121.3982°E along the eastern coast of Taiwan near the town of Chengkung. This earthquake resulted in slight damage of buildings and constructions of nearby harbor facilities, leading to limited property loss. We collected 98 P-wave arrival times recorded by stations of Hualien and Taidong for this event. And we take this earthquake as a target to discuss the trapped wave. The selected earthquake and stations are plotted in Figure 2.

2.2 Trap Wave Analysis

The Chengkung earthquake and its aftershock sequence occurred along an east-dipping seismic zone beneath the Coastal Range in southern LV (Kim et al. 2006, Hao et al. 2007). Recent studies of strong ground motion and coseismic GPS observation suggested that the 2003 Chengkung earthquake sequence along this east-dipping

fault was most probably related to the Chihshang fault. And maybe seismic waves could be trapped in this east-dipping seismic zone.

Joints and cracks are distributed around the fault plane with a high density (Scholz et al. 1993). When the wavelengths of the seismic wave are longer than the scale of each crack, the total elastic property of the material can be considered as a homogeneous zone (O'conell and Budiansky 1974, Hudson 1980). Hence, the trapped waves that travel within the fault-zone can be expected. The fault-zone trapped waves have some characteristics (Li et al. 1998, Ben-Zion 1998):

(1) Large amplitude within a fault zone;
(2) Particle motion polarized into the fault-parallel direction;
(3) Propagating along the fault zone;
(4) Normal dispersion;
(5) Dominant frequency that almost corresponds to the frequency showing the minimum phase velocity.

We identify trapped waves from observed seismograms based on the characteristics listed above. An example of observation of fault-zone trapped wave is shown in Figure 3. We can find that the fault-zone trapped wave with large amplitude arrival after the S wave. From the cross seismic array, each seismogram is synchronized with the onset of the direct S-wave arrival. The amplitude of the trace in fracture zone is relatively large than others.

2.3 H/V ratio

The waveform data recorded by seismic station is mainly influenced by source effect, path effect and site effect. Traditionally, reference-site method was used to discuss the local site effect. Nakamura (1989) found that it can only use the Horizontal-to-Vertical (H/V) spectral ratio of surface station to get the site effect in the station location easily.

At the same time, Huang and Teng (1999) also confirmed that the amplification is similar to one when the reference station is the rock station. And Hsieh (2001) proved the H/V ratio of good rock station will approach a constant by analyzed several downhole accelerometer arrays in Taiwan. In general, H/V ratio of rock station is often affected by regional structure. The value is not stable but will slightly similar to a constant.

3. RESULTS

3.1 Trap Wave

The acceleration data of station HWA005 for Chengkung earthquake exhibits phase with large amplitudes after S waves in the Figure 4. And we further to analyze the particle motions for direct P wave and the waves after S arrival (Figure 5). We find that the particle motion of P wave shows basically a vertical movement. And the particle motion of the wave after S wave displays an east-west movement. That seems like the wave after S wave is a reflected wave due to tectonic. Accordingly, compared with the stations in the north of station HWA005 and found stations HWA017, HWA029 and HWA059 had same phenomenon that movement seems to shift from directly approach in the northeast-southwest (before 60 sec in Figure 6) to approximate in the east-west (after 60 sec in Figure 6). Stations HWA016, HWA020, and HWA052 also showed similar tendency. And stations HWA018, HWA031, HWA035, and HWA051 were not so clear. All stations' data were shown in Figure 6.

3.2 Dominant Frequency

After basic data processing, include baseline correction and filter, the H/V ratios of every station are calculated, and then picked out the dominant frequency for each station. The dominant frequency is the frequency has the greatest impact of site amplification.

In this study, we selected the dominant frequency based on:

(1) The frequency with high magnification;
(2) Some stations have several bands with magnification. In such cases, we may (a) choose the lower frequency band if the low- frequency with higher magnification; (b) choose the lower frequency band if several bands with similar magnification; (c) choose the high frequency band if the high-frequency with higher magnification.
(3) After pick out the dominant frequency of each station, we will compare with the dominant frequency of nearby station and revise.

In general, there is not much difference between adjacent stations. It is because the subsurface structure may not exist significant change. The sample of pick out dominant frequency is shown in Figure 7.

4. DISCUSSIONS AND CONCLUSIONS

From the results of analyzing the particle motions, we found some stations in the LV displayed that the direction of wave propagation changed by structure in 2003 Chenkung earthquake. The direction of wave shift from near northeast-southwest or north-south to approach east-west. Most of them were located in the north of station HWA005. But from the time domain, the amplitude of those stations didn't reveal as in Figure 3. The maximum amplitude is 25.073 gals in station HWA005. It is mainly because the complex structure beneath the LV. We suspect that the seismic wave propagated along the LV fault zone.

Stations in the south of HWA005 have large amplitude of P and S wave, but they didn't receive obvious fault zone trapped wave or resonant wave by alluvium. That may be mixed by strong S wave or the time was too short to produce trapped wave. On the other hand, the changes of direction in the station HWA005 and others to the north could be due to the thick alluvium beneath the stations. The seismic wave propagated along the fault zone to the alluvial plain of northern LV and trapped and resonated in there. The stations HWA031, HWA033, and HWA051 on the eastern of northern LV are near to the surface exposure of Luehmei

fault. Their particle motions almost similar. And stations on the western of northern LV show obvious change of direction of wave propagation. The wave resonance in alluvium may come from fault zone of LV, which located in the eastern boundary of northern LV. The seismic wave resonated by the alluvium, so the stations HWA005, HWA020, HWA052, HWA059, HWA017, HWA029, and HWA016 all had significant change of direction of wave propagation.

It is noticeable that HWA032 and HWA035 didn't show clear change of wave direction. From the drilling data of station HWA035, the structure nearby the station can be considered as a more rigid stratum. And from the drilling data of station HWA006 which near by HWA005, the structure in the vicinity of HWA006 is a softer stratum and has thicker alluvium. That may be the reason for the different results between the station HWA035 and HWA005. Another noticeable is the station HWA018. In addition to HWA018, stations had obvious change of wave propagation in that area. From the drilling data, the structure beneath the station has divided into upper and lower levels by a thin soft layer. It may be the cause of difference behavior in contrast to nearby station.

We further analysis particle motions of six stations. The results are shown in Figure 8. The direction of wave propagation was significantly different at before 60 seconds and after. Those are particularly clear at stations HWA005 and HWA038. The movement displays a northeast-southwest direction at the window before 60 seconds. After 60 seconds, the movement shift to about an east-west or north-south direction. The station closer to the epicenter shows unobvious tendency. Next we want to choose smaller earthquakes to analyze in the future. Hope the trapped wave can identify more clearly, and to link the geological structure.

Figure 9 compare the dominant frequency result and that from microtremor measurement by Huang (2009). Near the Hualien and Taidong cities, both have low dominant frequency. The Hualien and Taidong cities are alluvial plains, the resonance frequency is relatively lower than other places in the study area. The value of dominant frequency is less than 4 Hz. The dominant frequency value is about 3.5-5.5 Hz in most places of LV. The value of dominant frequency shows greater than 6.5 Hz in the southern part of LV. Because the lack of drilling data, we have to do further investigation to check the reason of high dominant frequency value. From the drilling data, we can find that the high value in the eastern of Coastal Range is mainly due to the thin alluvium. Huang's study use intensive microtremor measurements distributed in LV. So his result can provide better control inside of LV than our results. However, our station network has a bigger distribution range from LV to Coastal Range. Our results reveal that the dominant frequency value is greater than 4 Hz for the most part of eastern Coastal Range. The largest value is reach to 10~20Hz.

Abstract: The Jiasian earthquake occurred on March 4th, 2010 and it was a large earthquake (M_L 6.4) occurred on land in Taiwan. There were 96 people injured but no one died. It also caused a high speed rail car derail, soil liquefaction, and some structures damage. The event of the high speed train was noticed by public and it is the first case of high speed rail derailed due to earthquake in Taiwan.

We utilize the strong motion data from Jiasian earthquake and using the Horizontal-to-Vertical (H/V) spectral ratio method to analyze the site effect in the Chianan Plain. The dominant frequency contour from strong-motion data was compared with the results from dense microtremor measurement (Huang 2009), and they showed good agreement with each other. Finally, due to there's a train of Taiwan High Speed Rails went off the track in our study region. The strong-motion records near the accident location was analyzed and method was proposed to improve the alarm system.

1. INTRODUCTION

The March 4th, 2010 Jiasian, Taiwan earthquake is an inland shallow earthquake with magnitude M_L=6.4 and focal depth 22.6 km. It caused many structures damage, soil liquefaction, high speed rail car went off the rail and about 90 people injured.

Taiwan is located on the plate boundary between the Eurasian plate and the Philippine Sea plate, in a region of high seismicity (Figure 1). The subduction zone is active in the east and south of Taiwan, in the Ryukyu and Manila-Luzon arc-trench system. There are many earthquakes occurred every year in Taiwan. In the past, nearly a dozen destructive earthquakes have occurred in Taiwan, including the Meishan earthquake (M_L=7.1, 1906), the Hisnchu-Taichung earthquake (M_L=7.1, 1935), and the Chi-Chi earthquake (M_L=7.3, 1999). Most of people living in the western Taiwan, and is the important place of economy develop, so if a large earthquake happen in this region, it will have big influence in Taiwan.

The Jiasian earthquake data used in this study are from the free-field strong-motion stations operated by Central Weather Bureau (CWB). The Horizontal-to-Vertical (H/V) spectral ratio method was used to conduct the site effect analysis in this study for the Chianan Plain (Figure 2).

2. Data

From 1990, the dense earthquake monitoring network called Taiwan Strong Motion Instrumentation Program (TSMIP) was operated by CWB, Taiwan, and there are 688 free field strong-motion stations involved now. Furthermore, the Real-Time Digital stream output system (RTD) involved 109 stations were constructed by CWB since1995 for real time location and shake map (Figure 3). The average accelerograph station spacing is about 5 km except Central Mountain Range. Most of these accelerographs are run at 200 samples/sec with 16-bit resolution at least and the dynamic range at ± 2g.

In this study, we use the data in the Chianan Plain from the Jiasian earthquake. Totally, about 130 stations triggered by this event in this area are shown in Figure 2.

3. Method

The factors affect the ground motions are quit complex. The main factors are source, path, and local site effects. Spectral ratio analysis is a simple method for studying site effects. The spectral ratio from soil and rock station pair was used to analyze the resonance frequency of the soil layer and the amplification factor in traditionally.

Choosing a perfect rock station in a wide alluvium plain is difficult. If choose a wrong rock station, such as at mountain of the top or valley, it will be affected by the topography. Nakamura (1989) proposed a single station spectral ratio method, using microtremor data to study the resonance frequency of a shallow soil layer. Field and Jacob (1993) and Lachet and Bard (1994) evaluated this single

station spectral ratio method by using theoretical calculation. Lermo and Chávez-García (1993) applied this method to S waves. Because find the perfect reference stations is difficult in this region, we used a single station spectral ratio method in this study. Assuming S_H and S_V are the horizontal and the vertical spectra on the surface. The H/V ratio S_M :

$$S_M = \frac{S_H}{S_V} \quad (1)$$

To take advantage of equation (1), we may realize the site effect in Chianan Plain.

4. Result

4.1 Dominant frequency

Cutting a 5~10 sec time window of S wave to obtain H/V spectral ratio. After that, the dominant frequency and related amplitude value of the H/V spectrum are picked. The rules of dominant frequency selection were varied from person to person. In this study, the rules are as follows:

1. Choosing the highest of the H/V ratio to be the dominant frequency.
2. If the H/V ratio had the same peak value in the frequency of over two, we may choose the lower frequency.

To avoid the interference of noise the dominant frequency we choosed were between 0.4~20 Hz. Figure 4 is the example of H/V spectra. The left spectrum is the result of station CHY115. The dominant frequency is 2.38 Hz and the related H/V ratio is 41.07. The right spectrum is the result of station KAU087. The dominant frequency is 6.86 Hz and the related H/V ratio is 11.09.

Figure 5 shows the dominant frequency distribution in the Chianan Plain. The 0.3 to 3 Hz low frequency regions are located near the coastal plain. Most intermediate frequency band of 3 ~ 6.5 Hz are surrounding the basin and the regions near the tableland, hill, and mountain. Others are high dominant frequency areas, greater than 6.5 Hz. The regions are mainly at the mountain area where mainly are the rock stations.

4.2 Amplification Effects

Except the dominant frequency can picking from the H/V ratio, it also can be used to understand the spacial variation of the site amplification on different frequency bands. In order to avoid the unusual peak of the H/V ratio, the average H/V ratio in the 1 Hz frequency band were calculated. Figures 6a ~ 6d show the examples of the results for frequency 0.4~1 Hz, 2~3 Hz, 5~6 Hz, and 10~11Hz, respectively.

The higher amplification contours areas occurred on deeper alluvium at lower frequency band. At higher frequency band, the higher amplification contours areas occurred shift to near the piedmont (Figure 6). As the frequencies increase, the distributions of higher H/V ratio areas shifted toward the areas of shallow soil.

5. Discussions and Conclusions

5.1 Compare with The Result of Microtremor

Huang (2009) used the microtremor measurement to study the site effect in Taiwan area. We compared the results of strong-motion and microtremor by the distribution of dominant frequency (Figure 7). The lower frequencies are mainly along the regions of coast or the alluvial plain. Toward the mountain area, the dominant frequencies are higher. And the results of the two measurements are similar but the result of strong-motion is about 0.5~1 Hz higher (Figure 5 and Figure 7). In the Figures 5 and 7, the red triangles and the block crosses are the free-field strong-motion stations and microtremor stations, respectively. We may see that there are some strong-motion stations located near the mountain region, but microtremor stations were not. Therefore, the dominant frequencies of the strong-motion are higher in the nearby mountain region. The microtremor stations are denser than strong-motion stations in the plain area. Consequently, the map in Figure 5 seems higher in some areas. It may caused by local geological variations.

5.2 Damages versus Site Amplification

There were many structures destroyed in Jiasian earthquake. The majority are elementary and junior high schools. Therefore, the distribution of destructive schools are plotted to discuss the relationship between damages and site amplification.

It usually use 10 derived by storeys to estimate the resonance frequency of the structure. Figure 6a and Figure 8 are the site amplification at the frequencies of 1~2 Hz and 4~5 Hz, respectively. Damage structures are separated to two kinds by the stories of schools, the white symbols are 1~3 stories, yellow symbols are equal or greater than 4 stories, and the light blue symbols are the stories not known. The stars show the buildings are serious damage and the diamonds are only a little damage. The school buildings are serious damage near the epicenter area. Further more, the damaged schools are within the areas of high magnification. And the higher stories schools are damaged at the high amplification area of low frequencies, in contrast, to the lower stories schools are damaged at the high amplification area of higher frequencies. For example, Kaohsiung is an urban area, the most schools are higher (greater than or equal to 4), and the serious damaged schools are located in the high amplification areas of 1-2 Hz (Figure 9).

5.3 The Event of High Speed Rail Train Derailed

The event of the high speed train, TN#T110, was noticed by public and it is the first case of high speed train derailed due to earthquake in Taiwan. After the sensor received the seismic data, when the ground acceleration is equal or greater than 40 gal, then the alarm system of the Taiwan High Speed Rails will be triggered and started to

stop the train.

Because we did not have the strong-motion data of high speed rail, we selected the station CHY099 which near the alarm station to be as the alarm sensor's station of high speed rail. Based on the time of the high speed rail derailed, it shows the surface wave arrived (Figure 10). Seems the surface wave has some relationship with the train derailed, but it need more study.

Due to the earthquake alarm system are along the rail route, the time is short to brake when the train received the message that PGA ≥ 40 gal. Station CHY061 is the closest station to the epicenter (Figure 11), therefore assuming the earthquake warning system also setting at CHY061. Using the velocity structure (Lin 2009), we could obtain the P wave arrival time difference is 6.14 sec. The average response time of the alarm system from 6 trains of this event is 3.14 sec. If the brake time was stable, it will have 14.61 sec more to brake before station CHY099 received the PGA ≥ 40 gal message and the train velocity can be reduce from 298 km/hr to 245.90 km/hr. If the high speed rail can install the earthquake alarm system at the strong-motion stations in the future, it will increase much more time to brake the trains and decrease the probability of derail.

ESTIMATION OF SHALLOW S-WAVE VELOCITY STRUCTURE IN DAMASCUS CITY, SYRIA, USING MICROTREMOR EXPLORATION

Hussam Eldein Zaineh[1] and Hiroaki Yamanaka[2]

1) Doctoral Candidate, Dept. of Environmental Science and Technology, Tokyo Institute of Technology, Japan
2) Professor, Dept. of Environmental Science and Technology, Tokyo Institute of Technology, Japan
Zaineh.h.ab@m.titech.ac.jp, yamanaka@depe.titech.ac.jp

Abstract: Array measurements of microtremors were carried out at thirty sites in Damascus city, Syria to estimate S-wave velocity structures of shallow soil formations for site effect analysis. The microtremor data were recorded by 6 vertical-component seismometers distributed along the circumferences of two circles as well as one 3-component seismometer deployed in the center. The phase velocities were estimated at each site from the vertical components of recorded microtremor data by using Spatial Autocorrelation method (SPAC). Then, Genetic Simulated Annealing Algorithm technique was applied for inversion of the phase velocities to estimate the 1-D S-wave velocity structures beneath the considered sites. Inverted Vs profiles are not uniform in Damascus city and the results show a shallow soft layer (~200 m/s) appeared in the Eastern part of the city as well as the Central part along Barada River. This layer is controlling the amplification factors in the city and high amplification was mainly observed at the locations having this layer. The inversion results also show that the depth to the engineering bedrock (~750 m/s) is very shallow along foothills of Mt. Qasyoun in the north-west and along the foothills of Mt. El-Mane and Mt. El-Madani in the far south. Then the depth increases towards the center of the city and towards the east. The maximum depth to the engineering bedrock was observed in the southern part of Damascus. To validate the results of inversion, the spectral ratios between the horizontal and vertical components (H/V) of the recorded microtremor data at the central seismometer has been compared with the computed H/V ratios of the fundamental-mode Rayleigh-waves based on the respective Vs structure. The results showed a good agreement in the period range of (0.05s - 0.5s). In this period range, the clear H/V peaks in the central and eastern part of the city are due to the overall effect of the velocity contrast between layers in this area. Moreover, the average S-wave velocity for the top 10 m of soils (V_{S10}) shows a better correlation with the averaged site amplification in the period range (0.1s - 1.0s) than V_{S30} which indicates that V_{S10} can be a better proxy for site amplification in the case of Damascus city.

1. INTRODUCTION

Damascus city, located in the south-western part of Syria (Fig. 1a), is a capital city with a large trade, industry, culture and transport activities and more than five million people live in Damascus and its suburb. Serghaya Fault, as a branch of Dead Sea Fault System (DSFS), has a length of 200 km and located approximately along the Syrian-Lebanese border, about ~30 km north-west of Damascus (M. Meghraoui et al. 2003, F. Gomez et al. 2003). Serghaya Fault is considered as the main source of seismic potential for the city and through the last 2000 years, many destructive earthquakes occurred in the region and caused much causality in Damascus city and its vicinity; one of the most documented events occurred in 1759 with a magnitude of ~7.4 (Ambraseys and Barazangi, 1989). Historical records suggest that DSFS, which is quiescent at present, is capable of producing relatively large earthquakes (Ambraseys, 2009). Syrian Seismic Design Regulations, are officially established in 1995 and revised in 2004, require an information on S-wave velocity structure for estimating the site coefficient (S) as in the 1995 code or estimating the seismic coefficients (C_a and C_v) as in the 2004 code. Since Syrian cities have lack of information on subsurface structure (S-wave velocity structure), it is so complicated task to define the site classification according to the Syrian codes.

Globally, S-wave velocity has been recognized as one of the important soil properties in earthquake and civil engineering. Therefore, knowledge of geometry and shear wave velocities of soil deposits and basement is one of the key parameters controlling the amplification of seismic motion. Also, this knowledge is required for the solution of many significant problems in earthquake engineering such as design earthquake motions and soil-structure interaction and therefore most of the building codes required the knowledge of S-wave structure. Array technique using microtremors is an important exploration method which becomes very attractive and useful for microzonation and site effects studies in urbanized areas. This exploration method was established after the pioneering work done by Aki 1957. The wide spreading of the microtremor technique is due to its low cost compared with other

conventional geophysical prospecting, as well as its applicability even in big and crowded cities. Array records of long-and short-period microtremors have been applied successfully to delineate both the deep and shallow S-wave velocity structures of various sedimentary basins (e.g. Asten and Henstridge, 1984; Matsushima and Okada, 1990; Yamanaka et al., 1994; Kawase et al., 1998; Satoh et al., 2001; Scherbaum et al. 2003) located in highly populated urban areas, like Damascus city. In this exploration method, Rayleigh-wave phase velocities are estimated from vertical components of array records of microtremors, and then the subsurface structure is estimated by the Rayleigh-wave inversion.

The main objective of this study is to estimate the shallow S-wave velocity Structure in Damascus city. We also discuss site effects in the city using S-wave velocity profiles obtained from microtremor data.

2. TOPOGRAPHY AND GEOLOGY OF THE STUDIED AREA

Damascus city occupies the mostly part of Dimashq basin (Damascus basin). Dimashq basin is located to the south-western part of Syria and extends between 33°00´ to 33°50´ N and 36°00´ to 36°50´ E. The north-western part of the area was formed after many tectonic evolutions that affected the region and started in Mesozoic period. As a result, many folding structures are appeared (Palmyra subzone and Anti Liban subzone) as Mt. Qasyoun and Mt. El-Qalamoun which bounded Dimashq basin at the north-west (Ponikarov, 1963). Elevation points vary within the limits of 1.500 -1900 m and the relative elevations amount to 500-700 m. The south-eastern part of the area is quite different from the folded mountain system. It is the Drouz depression zone characterized by typically platform dislocations and intensive basaltic volcanism, with shallow-seated pre-Cambrian basement as Mt. El-Mane which bounded the basin at the far south (Ponikarov et al., 1963). The highest point is about 1000 m and relative elevation here amount to 300-400 m. Actually, the basin is filled by deposits of the surrounded heights and deposits carried by Barada River (Nahr Barada) which flows through the basin and forms the lowland of the basin (The geological map of Syria, explanatory notes, Dimashq sheet, 1963).

The geological map of Damascus (Fig. 1b) shows different type of geological formations. Cretaceous (Turonian, C_r) and Paleogene (Middle Eocene, P_g) formations appeared in the north-west of the city along Mt. Qasyoun and Mt. El-Qalamoun. The outcropping basalt rock (Middle Miocene, B_N) appeared in the far south along Mt. El-Mane and Mt. El-Madani. While the main part of the city lies on the sedimentary basin (Dimashq basin) represented mainly by the upper quaternary deposits (Q_3) (Geological map of Syria, Dimashq sheet, 1963) as well as the recent alluvial deposits (Q_4) which have very limited areal exposure along Barada River (Geological Map of Syria, North of Damascus sheet, 1998). In general, the upper quaternary deposits (Q_3) represented by Proluvial and Lacustrine formations which are the most dominant exposures. Lacustrine deposits appear in the further east of Damascus and form the basin of El-Oteibeh Lake. While Proluvial deposits forms the fan of Damascus in the intermountain area, (Geological Map of Syria, Dimashq sheet, 1963).

3. ARRAY MEASUREMENT OF MICROTREMORS

The site locations for the array measurement of microtremors are shown in Figure 1b. We conducted array measurements at 30 sites in the city of Damascus. The selection of these sites is based on the geological conditions of the city as well as the results of microtremor H/V spectral ratios (*Zaineh et al. 2009*). Measurements at 26 sites were conducted at Dimashq Basin (Q_3 zone). Namely, UNV, MRJ, OD1, OD2, OD3, NEC and ABS sites are located at the central part of Damascus. DAS, HRS and QBN sites are located in the north. BBL and MDN sites are located at the south-central of Damascus while LWN, DAR and SEH sites are located at the western part. All these sites have short to medium peak period of H/V spectral ratios. JRM, ZML, DOM, BSW, JSR, ZBD and HTT sites are situated at the eastern part while HOS, FJR, SBN and ISS sites are located in the south. These sites, also conducted at Damascus basin (Q_3 zone), have medium to long peak period of H/V. The remaining measurements (MZH, QSN and SFR) were conducted along Mt. Qasyoun where paleogene and cretaceous formations appeared (these sites have almost a flat H/V spectral ratio curves), as well as one measurement (TOT) at the south east of the city (location of TOTH seismic station) where young basalt rocks are outcropping (Fig. 1b).

All measurements were taken using circular array configuration which consists of 7 recording stations. For each array measurement, a 3-components accelerometer (#1 in Fig. 2) was deployed in the center and 6 vertical accelerometers were distributed along the circumference of two circles. Stations #2, #3 and #4 distributed along the circumference of the inner circle while #5, #6 and #7

distributed along the outer one. Both of these circles have the same center and the radius of inner circle is half of the outer one as it shown in Figure 2. Two array measurements of 7 stations were carried out in each site (large and small arrays) for better resolution with a duration of 20 minutes for each. The size of large array varies from 12 meters to 40 meters depending on the available open space at the selected site. The small array (1.5 m the smallest one) was deployed for better resolution at the up most soil layers, while the large one is for deeper soil layers. A simultaneous recording at 7 stations was carried out for about 20 minutes for each array. The microtremor data were recorded by 24 bit A/D wireless portable recorders with 100 samples per second attached to 7 accelerometers manufactured by Mitsutoyo (Japan) having flat characteristic period range of 0.01 sec to 14 sec.

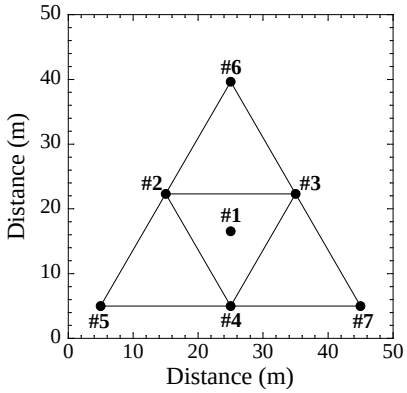

Figure 2. Large Array Configuration at HTT site.

4. DATA PROCESSING

4.1 Estimation of Phase Velocity

For the estimation of phase velocity, each observed vertical-component records were divided into time segments of 81.92 sec in length after removing the locally generated noise. We estimate the phase velocities of Rayleigh waves by Spatial Autocorrelation (SPAC) method (*e.g. Okada, 2003*). The SPAC method requires ambient-noise records obtained in a circular array of stations with one station at the center. This geometry allows the computation of the cross-correlation between many station pairs at the same inter-station distance, *r*, and sampling many different azimuths at the recording site. The correlation coefficients, $\rho(r, \omega)$ as a function of frequency (ω), are computed as the normalized cross-correlation between all station pairs separated a distance *r* and averaged over all azimuths, θ. Assuming stationary of microtremors, Aki (1957) showed that

$$\rho(r,\omega) = \frac{1}{2\pi \emptyset(r=0,\omega)} \int_0^{2\pi} \emptyset(r,\theta,\omega)\, d\theta$$

$$= J_0\left(\frac{r\omega}{c(\omega)}\right) \qquad (1)$$

where $\emptyset(r=0, \omega)$ is the average autocorrelation function at the center of the array, $\emptyset(r, \theta, \omega)$ is the cross-correlation function between the records obtained at coordinates (r, θ) and the record obtained at the center of the circle, $c(\omega)$ is the phase velocity at frequency ω at the site, and $J_0(\cdot)$ is the Bessel function of first kind and order zero. In this equation, the only unknown parameter is the phase velocity, $c(\omega)$, which can be obtained from the inversion of the correlation coefficients. Further details about SPAC method can be found in the literature *(e.g. Okada, 1987, 2003; Morikawa et al. 2004; Chavez-Garcia et al. 2005).*

The observed phase velocity dispersion curves show big differences from site to site and they can be categorized to three different groups ***a, b,*** and ***c*** (Fig. 3). *Group* ***a*** represents the sites located in the central and eastern part of Damascus. The value of observed phase velocities for these sites ranged from 200 m/s to 700 m/s and the phase velocity curves have narrow period range from 0.03 s to 0.2 s except for HTT site which has a wider period range up to 0.5 s (Fig. 3a). *Group* ***b*** represents the sites located in the south and south-central of the city. The phase velocity curves of these sites have a wider period range (0.03 s to 0.5 s) than group ***a*** (Fig. 3b). The sites in these two groups are located at the same geological formation (Q_3 zone). While *group* ***c*** represents the sites located along Mt. Qasyoun with different geological formations (Q_3, C_r *and* P_g) as well as TOT site located at the south-eastern part of Damascus in the region of outcropping basalt (B_N). *Group* ***c*** sites (Fig. 3c) have high phase velocities (up to 1000 m/s) with more narrow period range from 0.03s to 0.15s. Figures 3a and b show the variations of the observed phase velocities for the sites located at the same geological formations while figure 3c shows the variation of the observed phase velocities for the sites located at different geological formations. The results show that the value of phase velocity decreases from the foothills of Mt. Qasyoun toward the east and the south. The period range of the observed phase velocity curves decreases in the same direction too. These clear differences are an indication of a significant variation in the shallow soil formations in Damascus city.

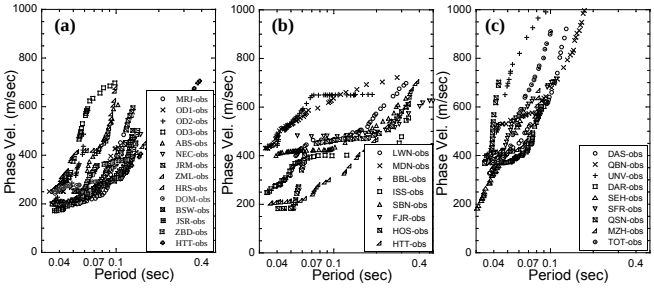

Figure 3. Comparison of the observed Rayleigh wave phase velocities for ***a*** sites located at the central and east, ***b*** sites located at the south and south-central; and ***c*** sites located in the north-west of Damascus along Mt. Qasyoun as well as TOT site in the south-east.

4.2 Inversion of Phase-Velocity Data

The phase-velocity data were inverted by Genetic Simulated Annealing Algorithm technique, which is a hybrid inversion technique introduced by H. Yamanaka, (2007) as global optimizing method. In this technique, a 1-D soil profile is searched by minimizing the misfit between

observed and inverted phase velocities. 10 inversions with 100 generations were conducted using different seeds of random numbers where good model with smaller misfit survive more in the next generation while bad models are replaced by newly generated ones and so on, (*Yamanaka and Ishida, 1996; H. Yamanaka, 2007).*

Open circles and solid lines in Figure 4 show the observed and inverted phase velocities for the models in Figure 3. The sites are shown in Figures 4 a-1 to a-3, belong to the group ***a*** in Figure 3 and located at central and eastern part of the city. The sites in b-1 to b-3 belong to the group ***b*** and located at south and central-south while the sites in c-1 to c-3 belong to the group ***c*** and located in the north-west along Mt. Qasyoun. It is confirmed that the misfit between the observed and inverted phase velocities is fairly good for all the sites. Thus we succeeded to estimate the shallow structure down to the engineering basement with an S-wave velocity of ~750 m/sec for all the sites. While deeper structure (~1250m/sec) was estimated only in few sites that belong to the groups ***b*** and ***c*** (UNV, QBN, DAS etc.).

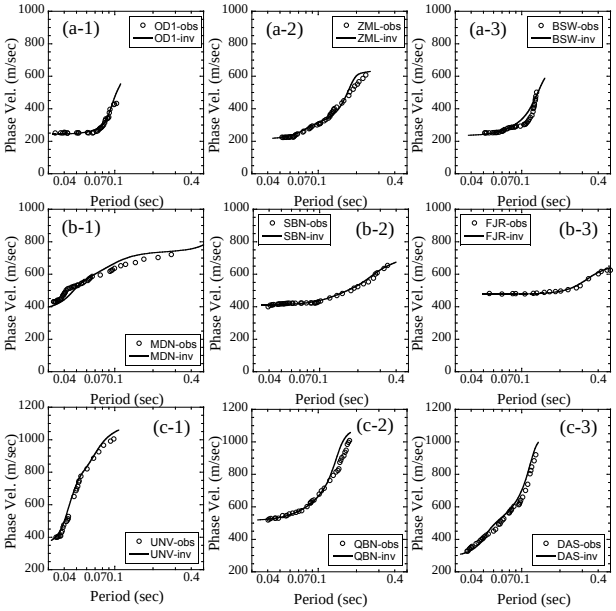

Figure 4. Comparison between the inverted phase velocity (circles) and observed one for some sites belong to different groups.

5. RESULTS

5.1 S-Wave Velocity Structure

As it is mentioned previously, subsurface structural model corresponding to the minimum misfit between the observed and inverted phase velocities was selected as inverted 1-D soil profile for each site. The results show that the shallow soils are not uniform in Damascus city and there is a wide variation in both S-wave velocity and thickness of shallow soil layers. According to our results, the city can be divided into three regions as following (Fig. 5):

*Center and east region (**a** region)* (Fig. 5a), the features of the S-wave velocity structure in this region is as following:

- The first layer is a shallow soft layer with a very low S-wave velocity (~ 200 m/s) with the thickness ranged from ~ 5 m in the center (MRJ, OD2 and OD3) and becomes about ~10 m in the eastern part of the city.
- The second layer has a low velocity (~350 m/s) with thickness ranged from ~7 m in the central part and becomes ~20 m in the eastern part (BSW, ZBD and HTT). The second layer (~ 350 m/s) is disappeared in OD1, OD2 and OD3 sites while it is replaced by higher velocity layer (~500 m/s) in HRS and HTT sites.
- The third layer is the engineering bedrock with S-wave velocity of ~750 m/s.

Generally, the depth to the engineering bedrock is increasing from 10 m in the central part along Barada River and becomes about 30 m in the eastern part as it is shown in Figure 6.

*South and central-south region (**b** region)* (Fig. 5b), the features of the S-wave velocity structure in this region is as following:

- FJR and SBN sites has a thick layer with a high S-wave velocity (~500m/s) overlain the engineering bedrock.
- HOS and ISS sites has a very thin soft layer (~200m/s) and a thick high velocity layer (~500m/s) overlain the engineering bedrock.
- MDN and LWN sites have a thin low velocity layer (~350m/s) overlain the high velocity layer (~500m/s) and the engineering bedrock.
- BBL site has a thin low velocity layer (~350m/s) overlain the engineering bedrock.

The depth to the engineering bedrock is increasing from 20 m in the central-southern part (MDN and BBL) towards the southern part and becomes at relatively deeper depth (~80 m) underneath ISS, FJR and HOS sites as it is shown in Figure 6.

*Foothills region (**c** region)* (Fig. 5c), this region located along Mt. Qasyoun (north-west) and along Mt. El-Madani and Mt. El-Mane (far south), the engineering bedrock in the north-west area is covered by one low velocity layer (~ 350 m/s) as in DAR, MZH, UNV and QSN sites, or by two layers (~350 m/s and ~500 m/s) as in DAS and SFR sites while in QBN site, the engineering bedrock is covered by a high velocity layer (~500 m/s). SEH site has a very thin soft layer (~200m/s) overlain the engineering bedrock. While TOT site in the south-east of Damascus, has a thin low velocity layer (~350 m/s) overlain the engineering bedrock. Generally, the subsurface distribution of the S-wave velocity revealed the engineering bedrock at a relatively shallow depth (less than 10 m) in this region as it is shown in Figure 6.

Figure 6 shows the contour maps for the depth to the engineering bedrock presented on the elevation map of Damascus city. Circles, squares, and triangles denote the sites of ***a, b,*** and ***c*** regions respectively. Generally, the depth is less than 10 m in the foothills region (***c** region*) along Mt. Qasyoun in the north-west and along Mt. El-Madani and Mt. El-Mane in the far south. The depth increases towards the basin from 10 m in the central part of the city to 30 m in the east and becomes at a relatively deeper depth (~80 m) underneath ISS, FJR and HOS sites in the south.

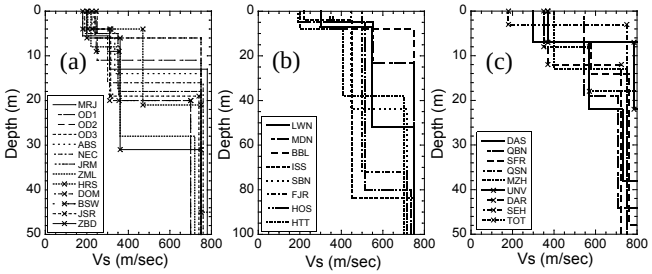

Figure 5. Comparison of the inverted 1-D soil profiles for **a** sites located at central and east, **b** sites located at the south and south-central, and **c** sites located in the north-west as well as TOT site located in the south-east of Damascus.

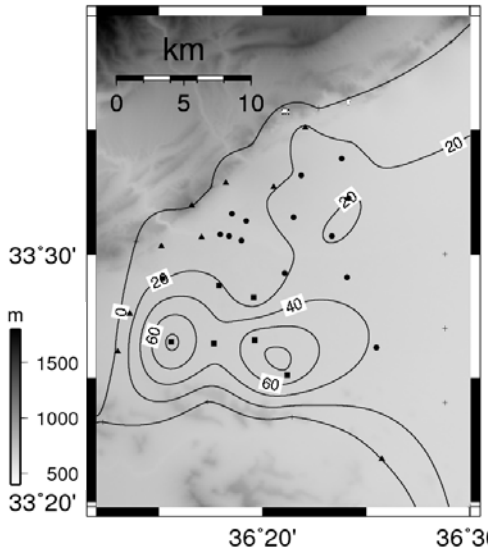

Figure 6. Contour Map for the depth to the engineering bedrock (m) presented on the elevation map. Circles, squares, and triangles denote sites of ***a, b*** , and ***c*** regions respectively

5.2 Site Amplification Factor

Using the inverted 1-D soil profiles (Fig. 5), site amplification factor was calculated by following one-dimensional shear wave propagation theory (*Schnabel et al., 1972*) for vertically incident S-wave. Here we consider the engineering bedrock as a half space since this layer has appeared in all soil profiles. Figure 7 compares the theoretical amplification factors for ***a*** sites located at the central and eastern region, ***b*** sites located in the south and south-central region, and ***c*** sites located in the foothills region. Figure 8(a) shows the contour map of the averaged site amplification for period range from 0.1 s to 1.0 s presented on the elevation map of Damascus city and Figure 8(b) shows the contour map for the fundamental predominant periods of the site amplification factors.

Regarding our results, ***a*** region (Fig. 7a) has the highest site amplification among the regions due to the presence of the soft layer (~200 m/s) near the surface which controlling the site amplification in this region. While the fundamental predominant periods of the amplification factors in this region, increases from 0.15 sec in the central part of the city to 0.3 sec in the east (circles in the Fig.8). For ***b*** region (Fig. 7b), the overall site amplification in this region is higher than it in ***c*** region. The fundamental period of the amplification factors in ***b*** region, increases from 0.15 sec in the central-south to 0.6 sec in the southern part of the city underneath ISS, FJR and HOS sites (squares in the Fig. 8). While ***c*** region (Fig. 7c), has the lowest site amplification and the shortest predominant periods (less than 0.15 sec) of the amplification factors among the regions (triangles in Fig. 8).

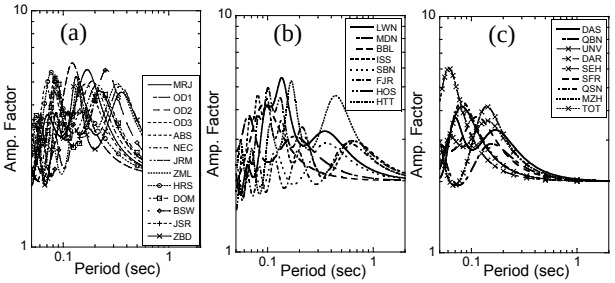

Figure 7. Comparison of the theoretical amplification factors for ***a*** sites located in the central and eastern region, ***b*** sites located in the south and south-central region, and ***c*** sites located in the foothills region.

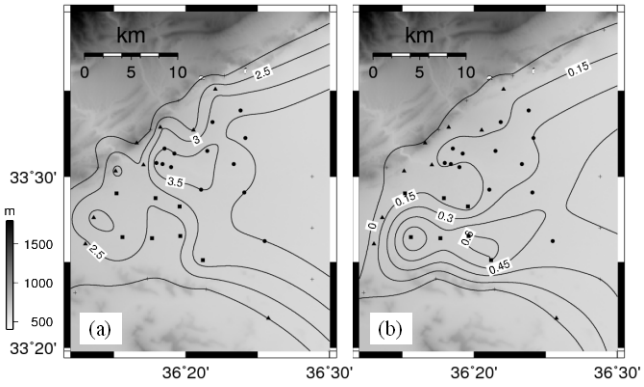

Figure 8(a). Contour map of the averaged site amplification for period range (0.1 s – 1.0 s) presented on the elevation map. (b). Contour Map for the fundamental period of the amplification factors (sec). Circles, squares, and triangles denote sites of ***a, b,*** and ***c*** regions respectively

5.3 Horizontal-to-Vertical Spectral Ratio

The horizontal-to-vertical $(H/V)_o$ spectral ratios at all measurement sites were determined from the observed microtremor data recorded at the 3-components accelerometer (#1 in Fig. 2) deployed in the center of each array measurement. These values are next compared with the computed $(H/V)_c$ spectral ratios of the fundamental-mode Rayleigh waves based on the obtained S-wave velocity structure. Solid and dotted lines in Figure 9 show the observed and computed H/V spectral ratios for the 1-D soil profiles in Figure 5. Figures 9 (1) to (3) show the results of some ***a*** sites located in the central and eastern part of Damascus (region ***a***). Figures 9 (4) to (6) show the results of some ***b*** sites situated in the south and central-south (region ***b***) while Figures 9 (7) to (9) show the results of some ***c*** sites located in the north-west along Mt. Qasyoun (region ***c***). The results of these Figures show that the overall peak period characteristics of the observed $(H/V)_o$ are in close agreement with the computed $(H/V)_c$ in the period range

from 0.05 sec to about 0.5 sec. Generally, the sites of ***a*** region exhibit a clear peak due to the high velocity contrast in these sites while the sites of ***b*** and ***c*** regions have almost a flat H/V spectral ratio of the observed and computed one in the period range of 0.05 sec to about 0.5 sec. As an exception, SEH, ISS, and HOS sites (located in ***b*** and ***c*** regions) exhibit a short period peak (less than 0.1 s) because of the high velocity contrast due to the presence of a thin soft layer (~200 m/s) near the surface. The mismatch between $(H/V)_o$ and $(H/V)_c$ for longer period range (period > 0.5 sec) can be attributed due to the lack of deep soil layers in our soil models, thereby indicating the limitation of the method used in this study.

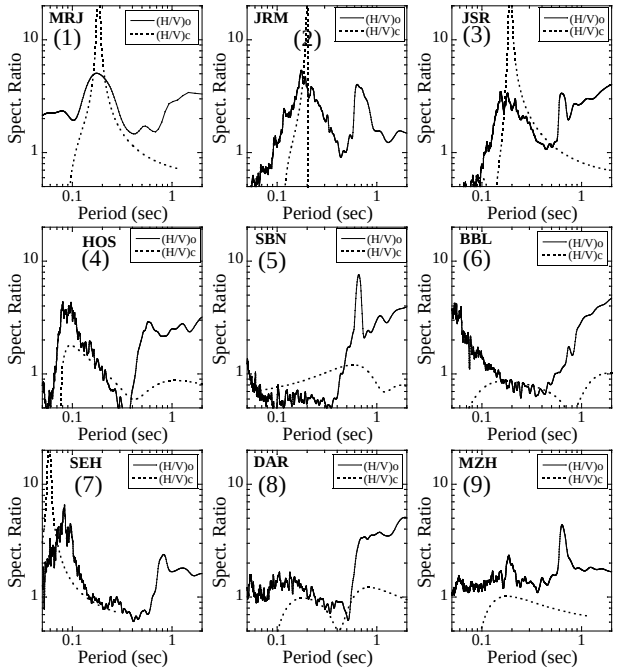

Figure 9. The comparison of the observed $(H/V)_o$ spectral ratios of microtremor data (solid line) with the computed $(H/V)_c$ spectral ratios of the fundamental-mode Rayleigh waves (dotted line)

6. DISCUSSION

6.1 V_{S30} and V_{S10} *vs.* Site Amplification

The average of shear-wave velocity from the surface to 30 m depth (V_{S30}) is adopted as international standard for soil classification. It was proposed in the United States under the National Earthquake Hazard Reduction Program (NEHRP). In fact, many U.S. building codes now require V_{S30} for site classification and Syrian building code 2004 which based on UBC97 has the same requirement of V_{S30} for site classification. Since the NEHRP classification was based on data from the western United States (*Borcherdt 1992, 1994*), we should confirm the validity of the NEHRP site classification in the case of Damascus city. Therefore, V_{S30} was compared with the averaged site amplification for a period range from 0.1s to 1.0s. Figure 10(a) shows the correlation between the V_{S30} and the averaged site amplification. A slight correlation with a scattered relationship was observed between the V_{S30} and the averaged site amplification and almost all our sites are belonging to the same class (class C) according to the NEHRP classification (Table 1). Then, we compared between the V_{S10} (the average of shear wave velocity for the top 10 meters of soils) with the averaged site amplification for the same period range. Figure 10(b) shows the correlation between the V_{S10} and the averaged site amplification. In the case of V_{S10}, a much better correlation was observed with the averaged site amplification which illustrate that V_{S10} can be a better proxy for the site amplification than V_{S30} with less economic and logistic efforts. The fact that V_{S10} could be a better proxy for the site amplification than V_{S30} in Damascus city can be interpreted due to the shallow low velocity layer (~200 m/s) which controlling the site amplification as it is mentioned previously. Table 1 reports Latitude, Longitude, Elevation, V_{S30}, V_{S10}, NEHRB Class, Geological index, Site predominant period of the site amplification, and the averaged site amplification for period range from 0.1s to 1.0s.

6.2 Comparison with Geological Data

As it is mentioned previously, the basin of Damascus is filled mainly by the deposits of the surrounded heights represented by the proluvial deposits which form Dimashq fan as well as the lacustrine deposits which form the basin of El-Oteibeh Lake in the far east of the basin. Dimashq fan is characterized by a monotonous lithological composition, i.e., yellow-grey loams with intercalations of angular predominantly lime-stone pebbles near the mountain ridges. But, further from the mountain ridges and closer to the central part, proluvium is represented by loess-like loams which are laterally replaced by lacustrine deposits. In the outer portion of Dimashq fan, on the boundary with the lacustrine plain (Fig. 1b), alternation of the lacustrine deposits with proluvial pebble-beds and loams were observed in many wells (*Geological map of Syria, 1963*). In addition, the recent alluvial deposits (Q_4) have very limited areal exposure along Barada River which flows through the basin (*Geological map of Syria, 1998*). This, illustrate that the quaternary deposits in the eastern part of the basin as well as the central part along Barada River are different from other locations near to the mountain ridges. Also our results show that the low S-wave velocity layers were mainly observed in the eastern part of Damascus city as well as the central part along Barada River. Figure 11 shows the comparisons in general sense between the 1-D soil profiles obtained from inversion (right) with the nearest geological borehole profile (left) for different 4 locations in the city. The distance between both profiles in MRJ site (Fig. 11(a)) is about 200 m; the last layer in the geotechnical borehole profile (Dense Conglomerates with SPT number of 59) represents the engineering bedrock in our results (with S-wave velocity of ~750 m/s). In NEC site (Fig. 11(b)), the distance between the two profiles is about 1000 m; the engineering bedrock is represented by the lower quaternary layer (Clay & Sand) in the geological profile. For MZH site (Fig. 11(c)), the distance is about 1500 m between the two profiles and the engineering bedrock is represented by the cretaceous layer (limestone). While for SEH site (Fig. 11(d)), the engineering bedrock is represented by the fractured basalt layer and the distance between the inverted 1-D soil profile and the geological one is about 800m. Generally, there is a very good agreement between the inverted profiles and geological profiles which confirm the validity of our results.

7. CONCLUSIONS

Array measurements of Microtremors were performed at thirty sites to estimate the S-wave velocity structure of shallow soil formations in the city of Damascus, Syria. As a result we succeeded to estimate the shallow structures down to the engineering bedrock with an S-wave velocity of ~750 m/sec.

The inversion results show that the engineering basement is located at a shallow depth (less than 10 m) for sites located in the foothills region along Mt. Qasyoun in the north-west and along Mt. El-Madani and Mt. El-Mane in the far south. The depth increases gradually toward the center of the basin (~15 m) and toward the east (~30 m) and becomes at a relatively deeper depth (~80 m) underneath ISS, FJR and HOS sites in the south.

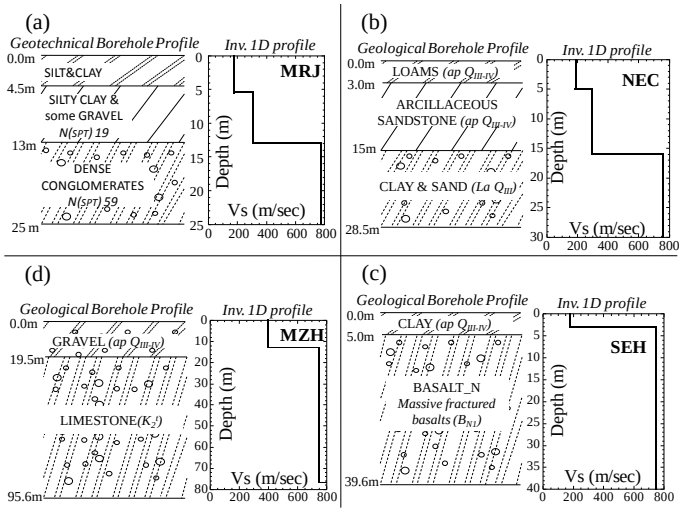

Figure 11. Comparisons between the inverted 1-D soil profile and nearest geological borehole profile at different 4 sites in Damascus city; (a) and (b) represent MRJ and NEC sites respectively, located in the center and east region; (c) represents MZH site located in the foothills region along Mt. Qasyoun; and (d) represents SEH site located in the foothills region along Mt. El-Madani.

The shallow structure is not uniform in Damascus city and there is a wide variation in both S-wave velocity and thickness of shallow soil layers. The results show a shallow soft layer (~200 m/s) appeared in the central and eastern region (***a*** region). This layer is controlling the amplification factors in the city and high amplification was mainly observed at the sites having this layer.

To validate the S-wave structures obtained from the inversion, the spectral ratios between the horizontal and vertical components (H/V) of the recorded microtremor data has been compared with the computed H/V ratios of the fundamental-mode Rayleigh-waves based on the respective Vs structure. The results show a good agreement in the period range from 0.05s to 0.5s. The mismatch outside this period range (period>0.5s) can be attributed due to the lack of deep soil layers in our soil models.

To validate the NEHRP site classification in the case of Damascus city, the average of shear wave velocity for the top 30 m of soils (V_{S30}) has been compared with the averaged site amplification. The results show a slight correlation with a scattered relationship between the V_{S30} and the averaged site amplification. In the other hand, the V_{S10} show a much better correlation with the averaged site amplification that suggest V_{S10} as a better proxy for site amplification than V_{S30} in the case of Damascus city with less economic and logistic efforts due to the fact that site amplification is controlled by a very shallow low velocity layer near the surface.

Abstract: Surface waves generated by a subsurface point load in a transversely isotropic elastic medium with elastic constants and mass density varying exponentially with depth are studied in this paper. The axis normal to the free surface is the axis of symmetry. The surface wave in this case is dispersive which is in contrast to the homogeneous case in which the Rayleigh surface wave is non-dispersive. The elastodynamic reciprocity theorem, which provides an integral relation between two elastodynamic states of same body, has been used to determine the unknown coefficients in the expressions for the displacement and stress components. Numerical results for beryl rock have been presented.

1. INTRODUCTION

Studies have shown that Rayleigh surface waves recorded during earthquakes or underground explosions are dispersive in nature, a characteristic which is different from the context of a homogeneous half-space given by Lord Rayleigh. Numerous studies were carried out with many number of layers to refine the model, until the inhomogeneous nature of the half-space as a continuous variation of the material properties was considered practical (Ewing et al. 1957). The aim of this paper is to obtain the analytical solution for seismic wave propagation in an inhomogeneous transversely isotropic elastic half-space. Rayleigh surface wave being the most devastating wave during an earthquake, the focus of this study is to analyze the surface waves generated due to a time-harmonic subsurface horizontal point load at a depth $x_3 = z_0$ from the free surface (see Figure 1).

The elastodynamic reciprocity theorem was used to determine the surface waves generated by a subsurface point load of arbitrary direction in an isotropic, homogeneous, elastic half-space in Achenbach (2000b). The same theory has been used by Achenbach (2000a) for axisymmetric wave motion generated by point load excitation in an isotropic elastic layer, by Achenbach and Xu (1999) to determine displacements excited by a point load of arbitrary direction in an isotropic elastic layer and by Kulkarni and Achenbach (2008) to determine surface waves generated by a line load in an inhomogeneous transversely isotropic half-space. Recently, this theorem was used by Kayestha et al. (2010) to study axisymmetric surface waves generated due to a time-harmonic vertically applied point load in a transversely isotropic, inhomogeneous elastic half-space.

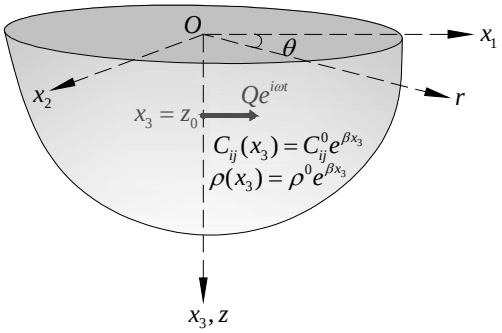

Figure 1 Inhomogeneous transversely isotropic elastic half-space subjected to a subsurface time-harmonic horizontal point load.

In the present paper too, the elastodynamic reciprocity theorem has been used to study surface waves generated by a subsurface harmonic horizontal point load in an inhomogeneous transversely isotropic elastic half-space. This method makes it possible to solve the point load generated surface wave field with an analytical approach, which provides explicit expressions for components of displacements and stresses. Numerical results for beryl rock have been presented.

2. GOVERNING EQUATIONS

For a transversely isotropic elastic solid the stress

components are given in terms of the displacement gradients as (see Ting 1996),

$$\begin{aligned}
\sigma_{11} &= C_{11}(x_3)\frac{\partial u_1}{\partial x_1} + C_{12}(x_3)\frac{\partial u_2}{\partial x_2} + C_{13}(x_3)\frac{\partial u_3}{\partial x_3},\\
\sigma_{22} &= C_{12}(x_3)\frac{\partial u_1}{\partial x_1} + C_{11}(x_3)\frac{\partial u_2}{\partial x_2} + C_{13}(x_3)\frac{\partial u_3}{\partial x_3},\\
\sigma_{33} &= C_{13}(x_3)\frac{\partial u_1}{\partial x_1} + C_{13}(x_3)\frac{\partial u_2}{\partial x_2} + C_{33}(x_3)\frac{\partial u_3}{\partial x_3},\\
\sigma_{23} &= C_{44}(x_3)\left(\frac{\partial u_2}{\partial x_3} + \frac{\partial u_3}{\partial x_2}\right),\\
\sigma_{13} &= C_{44}(x_3)\left(\frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1}\right),\\
\sigma_{12} &= C_{66}(x_3)\left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1}\right),
\end{aligned} \tag{1}$$

where $C_{66}(x_3) = \left[C_{11}(x_3) - C_{12}(x_3)\right]/2$ and σ_{ij}, u_i are components of stress tensor and displacement vector, respectively. Since the elastic half-space is inhomogeneous, elastic constants C_{ij} depend on depth x_3. The equations of motion in the absence of body forces can be written as

$$\sigma_{ij,j} = \rho(x_3)\ddot{u}_i, \tag{2}$$

where ρ is the mass density which also varies with the depth x_3.

3. SURFACE WAVES

For time-harmonic motion displacement components can be expressed in general forms as (Achenbach 1998)

$$\begin{aligned}
u_\alpha(x_1,x_2,x_3,t) &= \frac{1}{k}V(x_3)\frac{\partial \phi}{\partial x_\alpha}(x_1,x_2)e^{i\omega t}, \quad (\alpha = 1,2),\\
u_3(x_1,x_2,x_3,t) &= W(x_3)\phi(x_1,x_2)e^{i\omega t},
\end{aligned} \tag{3}$$

where x_1 and x_2 are Cartesian coordinates, $k = \omega/c$ is wavenumber and $\phi(x_1,x_2)$ is a dimensionless function which is the solution of Helmholtz's equation,

$$\frac{\partial^2 \phi}{\partial x_1^2} + \frac{\partial^2 \phi}{\partial x_2^2} + k^2\phi = 0. \tag{4}$$

In what follows the time-harmonic factor $e^{i\omega t}$ is omitted. Substituting the stress components from Eq. (1) and the displacement components from Eq. (3) in the equations of motion given in Eq. (2), results in two coupled ordinary differential equations given by

$$\begin{aligned}
&-kC_{11}V(x_3) + \left(C_{13} + C_{44}\right)\frac{dW}{dx_3} + \frac{1}{k}C_{44}\frac{d^2V}{dx_3^2}\\
&+\frac{\rho\omega^2}{k}V(x_3) + \frac{dC_{44}}{dx_3}\left[\frac{1}{k}\frac{dV}{dx_3} + W(x_3)\right] = 0,
\end{aligned} \tag{5}$$

$$\begin{aligned}
&-k^2\left[\frac{1}{k}\left(C_{44} + C_{13}\right)\frac{dV}{dx_3} + C_{44}W(x_3)\right] + C_{33}\frac{d^2W}{dx_3^2}\\
&+\rho\omega^2 W(x_3) - k\frac{dC_{13}}{dx_3}V(x_3) + \frac{dC_{33}}{dx_3}\frac{dW}{dx_3} = 0.
\end{aligned} \tag{6}$$

Elastic constants and mass density are assumed to vary exponentially with depth and are expressed as $C_{ij}(x_3) = C_{ij}^0 e^{\beta x_3}$ and $\rho(x_3) = \rho^0 e^{\beta x_3}$, where β is the parameter representing the inhomogeneous behavior of the half-space. For surface waves propagating in the half-space defined by $x_3 \geq 0$ seeking solutions of Eqs. (5) and (6) in a general form given by $V(x_3) = \bar{V}e^{-px_3}$ and $W(x_3) = \bar{W}e^{-px_3}$ and substituting the expressions of elastic constants and mass density results in two homogeneous equations yields

$$\begin{aligned}
&\left[-kC_{11}^0 + \frac{\rho^0\omega^2}{k} - \beta\frac{p}{k}C_{44}^0 + \frac{p^2}{k}C_{44}^0\right]\bar{V}\\
&+\left[\beta C_{44}^0 - p\left(C_{13}^0 + C_{44}^0\right)\right]\bar{W} = 0,
\end{aligned} \tag{7}$$

$$\begin{aligned}
&-\left[\beta k C_{13}^0 - kp\left(C_{13}^0 + C_{44}^0\right)\right]\bar{V}\\
&-\left[k^2C_{44}^0 - \rho^0\omega^2 + \beta p C_{33}^0 - p^2C_{33}^0\right]\bar{W} = 0.
\end{aligned} \tag{8}$$

In order for non-trivial solution to exist, determinant of the coefficients must vanish, which yields the characteristic equation

$$M_1\gamma^4 + M_2\gamma^2 + M_3 = 0, \tag{9}$$

where

$$\begin{aligned}
&M_1 = C_{33}^0C_{44}^0,\ M_2 = \Gamma - \frac{\beta^2}{2k^2}C_{33}^0C_{44}^0,\\
&M_3 = RS - \frac{\beta^2}{4k^2}\left[C_{44}^0\left(\rho^0c^2 - C_{44}^0\right) + \right.\\
&\left. C_{33}^0\left(\rho^0c^2 - C_{11}^0\right) + \left(C_{44}^0 - C_{13}^0\right)^2\right] + \frac{\beta^4}{16k^4}C_{44}^0C_{33}^0,
\end{aligned} \tag{10}$$

in which

$\Gamma = \left(C_{13}^0 + C_{44}^0\right)^2 + \left(\rho^0c^2 + C_{11}^0\right)C_{33}^0 + \left(\rho^0c^2 + C_{44}^0\right)C_{44}^0$,
$R = \rho^0c^2 - C_{11}^0$, $S = \rho^0c^2 - C_{44}^0$ and $\gamma = p/k - \beta/(2k)$.

For the characteristic equation, there exist two positive real roots of γ for certain restricted range of β/k and are given by

$$\gamma_1 = s_1 - \frac{1}{2}\frac{\beta}{k}, \quad \gamma_2 = s_2 - \frac{1}{2}\frac{\beta}{k}, \tag{11}$$

where s_1 and s_2 correspond to two solutions for p/k. The corresponding forms of $V(x_3)$ and $W(x_3)$ then can be written as

$$V(x_3) = V_1 e^{-s_1 k x_3} + V_2 e^{-s_2 k x_3}, \tag{12}$$

$$W(x_3) = m_1 V_1 e^{-s_1 k x_3} + m_2 V_2 e^{-s_2 k x_3}, \tag{13}$$

where

$$m_i = \frac{\gamma_i^2 C_{44}^0 + \rho^0 c^2 - C_{11}^0 - \frac{1}{4}\frac{\beta^2}{k^2} C_{44}^0}{(C_{13}^0 + C_{44}^0)\gamma_i - \frac{1}{2}\frac{\beta}{k}(C_{44}^0 - C_{13}^0)}, \quad i = 1, 2. \tag{14}$$

The relevant components of stress $\sigma_{ij}(x_1, x_2, x_3)$ can be expressed as

$$\begin{aligned}
\sigma_{33} &= e^{\beta x_3}\left(-C_{13}^0 k V(x_3) + C_{33}^0 \frac{dW(x_3)}{dx_3}\right)\phi, \\
\sigma_{13} &= e^{\beta x_3} C_{44}^0 \left(\frac{1}{k}\frac{dV(x_3)}{dx_3} + W(x_3)\right)\frac{\partial \phi}{\partial x_1}, \\
\sigma_{23} &= e^{\beta x_3} C_{44}^0 \left(\frac{1}{k}\frac{dV(x_3)}{dx_3} + W(x_3)\right)\frac{\partial \phi}{\partial x_2}.
\end{aligned} \tag{15}$$

The traction free boundary conditions on the surface $x_3 = 0$ are

$$\sigma_{33}(x_1, x_2, 0) = \sigma_{13}(x_1, x_2, 0) = \sigma_{23}(x_1, x_2, 0) = 0. \tag{16}$$

Substituting Eq. (15) in Eq. (16) yields

$$\begin{aligned}
&(m_1 - m_2)\left(s_1 s_2 C_{33}^0 + C_{13}^0\right) \\
&\quad + (s_2 - s_1)\left(C_{13}^0 + m_1 m_2 C_{33}^0\right) = 0.
\end{aligned} \tag{17}$$

This equation is dispersive due to the appearance of the dispersion parameter β/k in m_i and s_i $(i = 1, 2)$. In order to ensure that surface waves decay exponentially with depth, ratios of β/k has to be restricted. The ratios for which Eq. (9) has exactly two positive real roots satisfies the decay conditions, so if γ_1 and γ_2 denote these two roots, then they both satisfy the condition

$$\gamma_i > \frac{1}{2}\left|\frac{\beta}{k}\right|, \tag{18}$$

which ascertain that both the displacements and stresses decay to zero as $x_3 \to \infty$. Thus, the displacement components of surface waves traveling in the inhomogeneous transversely isotropic half-space are

$$\begin{aligned}
u_\alpha &= \frac{D}{k}\left(e^{-s_1 k x_3} - \frac{s_1 - m_1}{s_2 - m_2} e^{-s_2 k x_3}\right)\frac{\partial \phi(x_1, x_2)}{\partial x_\alpha} e^{i\omega t}, \\
u_z &= D\left(m_1 e^{-s_1 k x_3} - m_2 \frac{s_1 - m_1}{s_2 - m_2} e^{-s_2 k x_3}\right)\phi(x_1, x_2) e^{i\omega t},
\end{aligned} \tag{19}$$

where $\alpha = 1, 2$ and D is an unknown multiplying constant of length dimension.

4. SURFACE WAVES GENERATED BY A HORIZONTAL POINT-LOAD EXCITATION

The time-harmonic horizontal point-load Q parallel to the free surface is applied at $x_1 = x_2 = 0$, $x_3 = z_0$ as shown in Figure 1. In this case, unlike Kayestha et al. (2010), the problem is no longer axially symmetric and the θ dependence also needs to be considered during the analysis. Solutions for displacement components in general form are based on Eq. (19). For analysis, cylindrical coordinate system $(x_1 = r\cos\theta,\ x_2 = r\sin\theta,\ x_3 = z)$ has been introduced as x_3-axis is perpendicular to the plane of symmetry. In cylindrical coordinate system, Eq. (19) can be re-written as

$$\begin{aligned}
u_r(r, z) &= \frac{D}{k} u(z)\frac{\partial \phi(r)}{\partial r}, \\
u_z(r, z) &= D w(z)\phi(r),
\end{aligned} \tag{20}$$

where

$$u(z) = \left(e^{-s_1 k z} - \frac{s_1 - m_1}{s_2 - m_2} e^{-s_2 k z}\right),$$

$$w(z) = \left(m_1 e^{-s_1 k z} - m_2 \frac{s_1 - m_1}{s_2 - m_2} e^{-s_2 k z}\right), r = \left(x_1^2 + x_2^2\right)^{1/2}$$ and

Eq. (4) becomes

$$\frac{\partial^2 \phi(r)}{\partial r^2} + \frac{1}{r}\frac{\partial \phi(r)}{\partial r} + k^2 \phi(r) = 0. \tag{21}$$

The solution for $\phi(r, \theta)$ of Eq. (21) can be written as (see Achenbach, 2003)

$$\phi(r, \theta) = \Psi(kr)\cos\theta. \tag{22}$$

Equation (21) then takes the form

$$\frac{d^2\Psi}{dr^2}+\frac{1}{r}\frac{d\Psi}{dr}+\left(k^2-\frac{1}{r^2}\right)\Psi=0. \tag{23}$$

From the asymptotic expansion of Hankel functions, the relevant solution of $\Psi(r)$ for outgoing and incoming waves can be given as

$$\Psi(kr)=H_1^{(2)}(kr), \tag{24}$$

and

$$\Psi(kr)=H_1^{(1)}(kr), \tag{25}$$

respectively. Using Eqs. (22) and (24) the corresponding components of displacement and stress can thus be written as

$$u_r=\frac{1}{k}Du(z)H_1^{(2)\prime}(kr)\cos\theta, \tag{26}$$

$$u_z=Dw(z)H_1^{(2)}(kr)\cos\theta, \tag{27}$$

$$u_\theta=-\frac{1}{kr}Du(z)H_1^{(2)}(kr)\sin\theta, \tag{28}$$

$$\sigma_{rr}=De^{\beta z}\left[\Delta_1\left(\frac{1}{kr^2}H_1^{(2)}(kr)-\frac{1}{kr}H_1^{(2)\prime}(kr)\right)+\Delta_2H_1^{(2)}(kr)\right]\cos\theta, \tag{29}$$

$$\sigma_{zz}=De^{\beta z}\Delta_3H_1^{(2)}(kr)\cos\theta, \tag{30}$$

$$\sigma_{rz}=\frac{D}{k}e^{\beta z}\Delta_4H_1^{(2)\prime}(kr)\cos\theta, \tag{31}$$

$$\sigma_{\theta\theta}=-De^{\beta z}\left[\Delta_1\left(\frac{1}{kr^2}H_1^{(2)}(kr)-\frac{1}{kr}H_1^{(2)\prime}(kr)\right)-\Delta_5H_1^{(2)}(kr)\right]\cos\theta, \tag{32}$$

$$\sigma_{\theta z}=-\frac{D}{kr}e^{\beta z}\Delta_4H_1^{(2)}(kr)\sin\theta, \tag{33}$$

$$\sigma_{r\theta}=De^{\beta z}\Delta_1\left(\frac{1}{kr^2}H_1^{(2)}(kr)-\frac{1}{kr}H_1^{(2)\prime}(kr)\right)\sin\theta, \tag{34}$$

where the prime denotes differentiation with respect to the argument and

$$\Delta_1=2C_{66}^0u(z),$$

$$\Delta_2=\left(C_{13}^0\frac{dw(z)}{dz}-kC_{11}^0u(z)\right),$$

$$\Delta_3=\left(C_{33}^0\frac{dw(z)}{dz}-kC_{13}^0u(z)\right),$$

$$\Delta_4=C_{44}^0\left(\frac{du(z)}{dz}+kw(z)\right),$$

$$\Delta_5=\left(C_{13}^0\frac{dw(z)}{dz}-kC_{12}^0u(z)\right). \tag{35}$$

5. USE OF ELASTODYNAMIC RECIPROCITY

Elastodynamic reciprocity has been used to obtain the unknown constant D introduced in Eq. (19). Considering two distinct time-harmonic states A and B of same frequency, reciprocity relation can be written as

$$\int_V\left(f_i^Au_i^B-f_i^Bu_i^A\right)dV=\int_S\left(u_i^A\sigma_{ij}^B-u_i^B\sigma_{ij}^A\right)n_j\,dS, \tag{36}$$

where f_i^A, f_i^B are body forces, u_i^A, u_i^B are displacement components and $\sigma_{ij}^A, \sigma_{ij}^B$ are stress components in states A and B, respectively, while n_j are the components of the outward normal to boundary S. For state A, displacement and stress components due to the point-load can be given as in Eqs. (26)-(34) but with $k_R=\omega/c_R$, where c_R is the Rayleigh surface wave speed. For state B, a virtual wave system consisting of the sum of outgoing and incoming waves is considered. Thus, the final displacement components after obtaining the constant D is given by,

$$u_r=-\frac{1}{4i}\frac{Qu^R(z_0)}{I}u^R(z)H_1^{(2)\prime}(k_Rr)\cos\theta, \tag{37}$$

$$u_\theta=\frac{1}{4i}\frac{Qu^R(z_0)}{Ir}u^R(z)H_1^{(2)}(k_Rr)\sin\theta, \tag{38}$$

$$u_z=-\frac{k_R}{4i}\frac{Qu^R(z_0)}{I}w^R(z)H_1^{(2)}(k_Rr)\cos\theta, \tag{39}$$

$$\sigma_{rr}=-\frac{k_R}{4i}\frac{Qu^R(z_0)e^{\beta z}}{I}\left[\Delta_1\left(\frac{1}{k_Rr^2}H_1^{(2)}(k_Rr)-\frac{1}{k_Rr}H_1^{(2)\prime}(k_Rr)\right)+\Delta_2H_1^{(2)}(k_Rr)\right]\cos\theta, \tag{40}$$

$$\sigma_{rz}=-\frac{1}{4i}\frac{Qu^R(z_0)}{I}e^{\beta z}\Delta_4H_1^{(2)\prime}(k_Rr)\cos\theta, \tag{41}$$

$$\sigma_{zz} = -\frac{k_R}{4i}\frac{Qu^R(z_0)}{I}e^{\beta z}\Delta_3 H_1^{(2)}(k_R r)\cos\theta, \tag{42}$$

$$\sigma_{\theta z} = \frac{1}{4i}\frac{Qu^R(z_0)}{I\,r}e^{\beta z}\Delta_4 H_1^{(2)}(k_R r)\sin\theta, \tag{43}$$

$$\sigma_{r\theta} = -\frac{k_R}{4i}\frac{Qu^R(z_0)}{I}e^{\beta z}\Delta_1 \left(\frac{1}{k_R r^2}H_1^{(2)}(k_R r) - \frac{1}{k_R r}H_1^{(2)\prime}(k_R r)\right)\sin\theta, \tag{44}$$

where $D = -\frac{k_R}{4i}\frac{Qu^R(z_0)}{I}$,

$I = \int_0^\infty e^{\beta z}\left[u^R(z)\Delta_2 - w^R(z)\Delta_4\right]dz$, $u^R(z)$ and $w^R(z)$ are defined just after Eq. (20).

6. NUMERICAL RESULTS

In this section numerical results are given for beryl rock (see Table 1). The dispersion curve for beryl rock obtained from Eq. (17) is shown in Figure 2(a). In addition, the positive real roots γ_1 and γ_2 of Eq. (9) are also plotted as a function of β/k. From a detailed calculation, it has been found that in the range $-2.210 \le \beta/k \le 0.164$, Eq. (9) have exactly two positive roots and thus Figure 2(a) shows the plot of non-dimensional surface wave speed c/c_T where $c_T^2 = C_{44}^0/\rho^0$, in this range of β/k. In addition, Figure 2(b) shows a variation of γ_1 and γ_2 with β/k which satisfies the condition given in Eq. (18) ensuring exponential decay of both the stresses and displacements, as the roots γ_1 and γ_2 are above the limit $\beta/2k$.

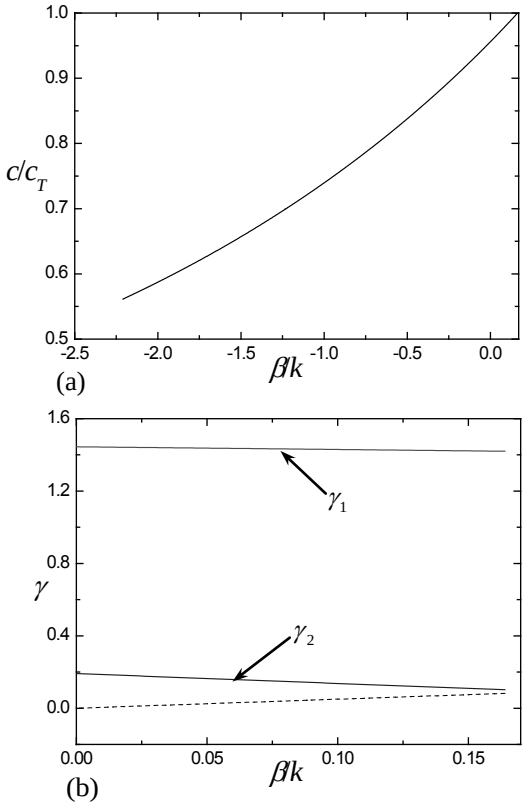

Figure 2 Beryl rock: Variations with the dispersion parameter β/k of (a) the surface wave speed and (b) the parameters γ_1 and γ_2 appearing in Eq. (9) (the dashed line is plot of $\gamma = \beta/2k$).

Table 1 Material constants

Material	$\bar{C}_{11}$	$\bar{C}_{13}$	$\bar{C}_{33}$	$C_{44}\times10^4$ (N/mm^2)	ρ (g/cm^3)
Beryl rock[a]	4.13	1.01	3.62	1.00	2.63

[a] Rajpakse and Wang (1993), $\bar{C}_{ij} = C_{ij}/C_{44}$.

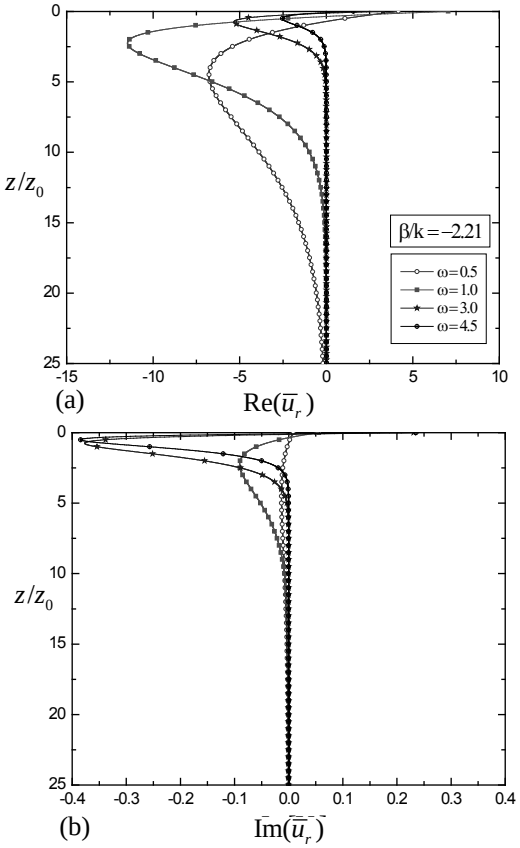

Figure 3 Normalized radial displacement $\bar{u}_r(0.1, z)$ along z-axis for $\beta/k = -2.21$, (a) real part and (b) imaginary part.

Figures (3) and (4) show the variation of radial displacement $\bar{u}_r = z_0 u_r C_{44}^0/Q$ along the depth direction at different non-dimensional frequencies ω for the inhomogeneous parameter $\beta = -2.21k$ and $\beta = 0.1k$,

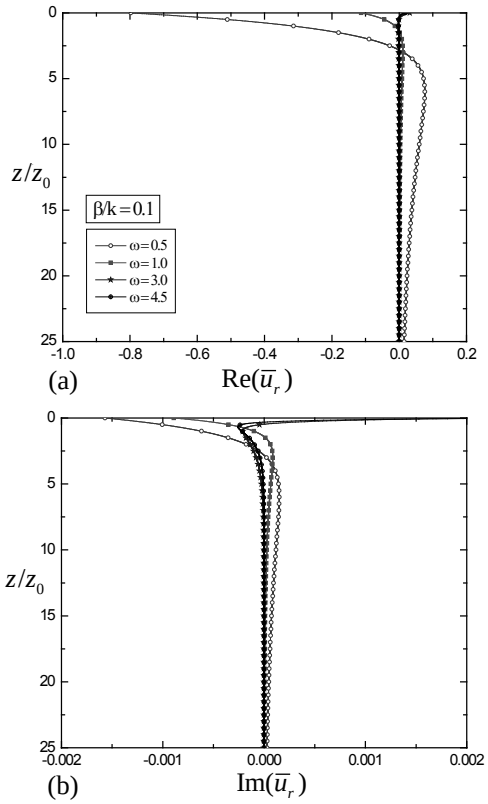

Figure 4 Normalized radial displacement $\bar{u}_r(0.1, z)$ along z-axis for $\beta/k = 0.1$, (a) real part and (b) imaginary part.

respectively. When the value of β is negative as seen in Figure (3), density and stiffness of the material decreases with depth thus resulting in less resisting capacity of the material. Besides, for positive value of β shown in Figure (4) density and stiffness increases with depth resulting in higher resisting capacity of the material. Thus, comparing Figures (3) and (4) it can be seen that the absolute values of displacements are much larger in Figure (3) than in Figure (4). In Figures (3) and (4), the displacement profile show changes in sign with the increasing depth; however, this feature is not clearly visible in Figure (4).

Since the half-space is subjected to time-harmonic radial loading at a depth of $z/z_0 = 1$, a distinct feature of displacement profile can be seen in Figure (3). Displacement profile in Figure (3) shows large absolute displacement values around the periphery of loaded point. For frequency $\omega = 3.0$, the peak displacement is noted exactly at $z/z_0 = 1$, however, for other frequencies it is noted at other depths. It can be seen that the displacement decays rapidly with increasing depth in both Figures (3) and (4). Thus from Figures (3) and (4), it can be noted that the degree of anisotropy of the material has significant influence on both real and imaginary parts.

Figures (5) and (6) show the variation of normalized vertical displacement $\bar{u}_z = z_0 u_z C_{44}^0 / Q$ along the depth direction at different non-dimensional frequencies ω for the inhomogeneous parameter $\beta = -2.21k$ and

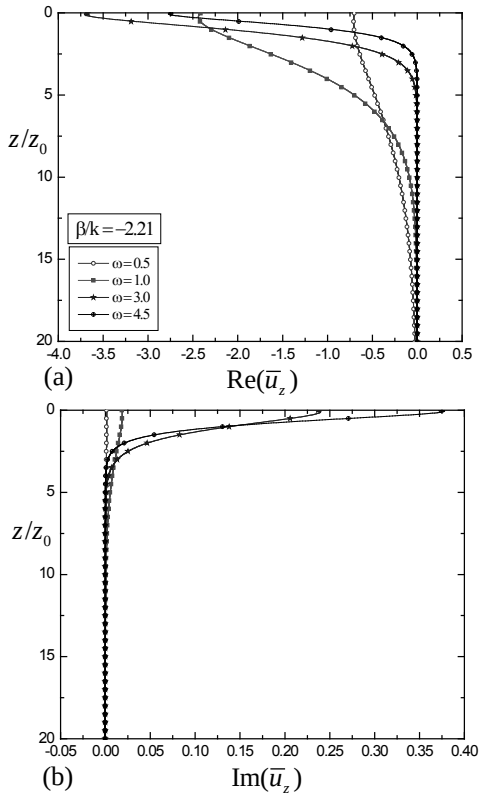

Figure 5 Normalized vertical displacement $\bar{u}_z(0.1, z)$ along z-axis for $\beta/k = -2.21$, (a) real part and (b) imaginary part.

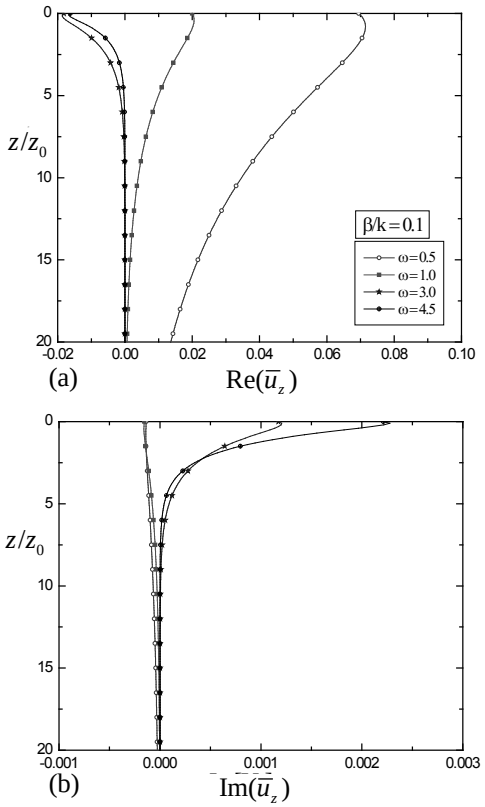

Figure 6 Normalized vertical displacement $\bar{u}_z(0.1, z)$ along z-axis for $\beta/k = 0.1$, (a) real part and (b) imaginary part.

$\beta = 0.1k$, respectively. As mentioned earlier, in this case too absolute values of displacements in Figure (5) are much larger than Figure (6) for both real and imaginary parts. The nature of displacement profile is similar to Rayleigh surface waves which is an expected feature for vertical displacement profile. The influence of frequency also has significant effect on the displacement profile. $\mathrm{Im}(\overline{u}_z)$ increases with an increase of frequency in both Figures (5) and (6), however, the variation of $\mathrm{Re}(\overline{u}_z)$ with ω is quite complicated. It can be seen in vertical displacement profile that the degree of anisotropy of the material has significant influence on both real and imaginary parts as was observed in radial displacement profile.

7. SUMMARY AND CONCLUSIONS

Explicit analytical solutions and numerical results are presented for displacement components of an inhomogeneous transversely isotropic elastic half-space subjected to a time-harmonic horizontal subsurface point-load. Elastodynamic reciprocity theorem is used in conjunction with an appropriately selected auxiliary elastodynamic solution to determine surface wave motions. It has been noted that the degree of inhomogeneity influence the results of displacement components significantly. The decay of the displacements with increasing depth is in general smooth.

Abstract: This paper presents the shear-wave (S-wave) velocity structures and site amplification of 32 sites covering all geologic settings in Metro Manila. We applied the passive microtremor array measurement using spatial autocorrelation (SPAC) to cover large area within a short period of time. An expanding double circular array composed of seven vertical portable seismometers is set up to measure Rayleigh type ground surface motions of microtremors and to come up with surface wave phase velocities in the form of dispersion curve. We used hybrid genetic algorithms for the inversion of surface waves to provide Vs structures. Thus, a 3D depth configuration of engineering bedrock is shown to evaluate the deepest alluvium deposits in the metropolis. The engineering bedrock is defined for this study to have S-wave of about 600 m/s. A one-dimensional analysis was applied to evaluate amplification using the revealed S-wave velocity profiles. The obtained variation in the site amplification factors and formulated regression equation provided information on the site response in the Metro Manila.

1. INTRODUCTION

Identification of velocity structures has been the interest of earthquake engineers to be able to evaluate theoretically the strong ground motions and site responses. Being able to model the dynamic characteristics of the underground structures are beneficial inputs to ground shaking hazard analysis. In the study of local site response in a metropolis, knowledge of sedimentary layers is important and a detailed approach requires sufficient distribution of boreholes with information regarding S-wave velocities.

Metro Manila, the capital of the Philippines is composed of 16 cities and one municipality. It has been considered as high risk to large earthquakes due to its surrounding active faults and trenches. Metro Manila is transected by 135 km long right lateral strike slip fault that is capable of producing a single earthquake event with a magnitude range of 7.3-7.7 (Rimando and Knuepfer, 2006). This fault (West Valley Fault) traverses the boundary of the Central Plateau and Marikina Valley with a sharp offset of several ten meters in elevation. Based on geomorphologic features (Gervasio, 1968), Metro Manila is divided into three categories; the Coastal Lowland, Central Plateau and Marikina Valley. The Coastal Lowland and Marikina Valley have deep quaternary alluvium sediments from the deposition of rivers, deltaic deposits and coastal deposits, whereas the Central Plateau covers tuffaceous sediments and pyroclastic flow deposits.

In this study, we conducted short period microtremor array measurements in 32 sites to make a detailed investigation of the shallow sedimentary layers by covering the major geologic settings in Metro Manila. Essential procedures require the extraction of Rayleigh waves from microtremors in the form of phase velocity dispersion curves by using Spatial Autocorrelation (SPAC) method and applied a hybrid genetic algorithms method for the inversion to infer the shallow S-wave velocity structures.

2. MICROTREMOR MEASUREMENT

Array observations of microtremors were carried out at 32 sites within Metro Manila on September 2009 and March 2010 (Fig. 1), totaling to nine surveyed days at an average of 3 to 4 sites per day. The surveyed sites were government establishments, private lands and school grounds that have open fields for easy deployment of circular arrays. The instruments used in the survey are portable accelerometers. Seven vertical sensors were used featuring Mitsutoyo 6A1 products with a period range of 0.01 to 14 s, with attached 24-bit analog-to-digital recorder that takes 100 samples per seconds. Each sensor was paired by a data recorder that transmits data to a laptop using wireless network. A software package installed in the laptop controls the setting and the duration of the recording. This set up enable easy viewing of real-time waveforms and quick assessment of sensors' sensitivities. The arrangements of six sensors were placed in the vertices of two equilateral triangles inscribed in a circle with the 7th sensor at the center. The sizes of the array were

selected according to the availability of the space at the site and limitation of signals from the wireless network. Due to this reason, the circular arrays were set up with a maximum length of sides of the triangle at 32 m. Two recording set-ups were deployed at each site by changing from the largest to smallest circular array. The shortest length of the side of the triangle for the smallest array that allows us to achieve a better definition of shallow layers is 1.5 m. The time for one recording took 30 to 40 minutes long.

3. SPATIAL AUTOCORRELATION (SPAC)

The SPAC method by Aki (1957) and Okada (1987) was employed in the processing of microtremor array data in order to identify phase velocity dispersion curve. The SPAC method analyzes ambient vibration records from an array of stations. The SPAC method in practice requires a circular array consisting of 3 or more circumferential stations and one at the center (Okada, 2006). Hence, for practical use, it is sufficient enough in SPAC applications to provide phase velocities by arranging 3 sensors in the tip of equilateral triangle inscribe in a circle and one sensor at the center (Kudo *et al.*, 2002). By setting up the array of vertical components of microtremor instrument, the phase velocities of Rayleigh waves could be estimated by computing the SPAC coefficients calculated from various combinations of station distances as a function of frequency, and averaged azimuthally for the selected time segments. Thus, cross correlation functions is computed between pairs of stations, and averaged for different station pairs at the same inter-station distance.

The SPAC coefficients can be directly calculated in a frequency domain using the Fourier Transform of the observed microseism, denoted by equation

$$\rho(r,\omega) = \frac{1}{2\pi}\int_0^{2\pi} \frac{R_e[S_{CX}(\omega,r,\theta)]}{\sqrt{S_C(\omega)\cdot S_X(\omega,r,\theta)}}\,d\theta \qquad (1)$$

where $R_e[\ ]$ stands for the real part of a complex value, and $S_C(\omega)$ and $S_X(\omega,r,\theta)$ are the power spectral densities of microtremors at sites C(0,0) and X (r,θ) respectively, and $S_{CX}(\omega,r,\theta)$ is the cross spectrum between ground motions at these two sites.

Further details of the SPAC method can be found in literatures (e.g. Okada, 1987, 2006; Kudo *et al.*, 2002; Chavez-Garcia *et al.*, 2005).

4. ANALYSIS AND INTERPRETATION

Phase velocities of Rayleigh waves are estimated from vertical components of microtremors. The SPAC coefficients were calculated for various combinations of station distances, as a function of frequency, and averaged azimuthally for the selected time segments. The SPAC coefficients provide a good average in the phase velocity of propagating waves in the array for a fixed distance between two stations at various frequencies.

Ideally, the larger the circular microtremor array the deeper sediments and most likely higher phase velocity will be deduced, but because of limitations in the area and accessibility, some sites could be surveyed only for a relatively small array with low expectation of reaching bedrock at sites having deep alluvium cover. For example the site L4 in Fig. 2 has a phase velocity that reaches only to a maximum of 350 m/s. In order to deal with dispersion curves that did not reach the engineering bedrock (Vs~600 m/s) we considered the input parameters of nearby sites that have phase velocity of engineering bedrock and with same geologic composition.

As shown in Fig. 2 dispersion curves of phase velocity in Coastal Lowland are distinct to have been covered by soft layer of alluvium. The Central Plateau shows abrupt steep slope on dispersion curves and in most cases the phase velocity start with a value higher than 200 m/s which clearly exhibits the top hard soil layer. Other steep dispersion curves of phase velocity in Central Plateau that have less than 200 m/s justify that a thin layer of soft sediment exist underlain by hard soil.

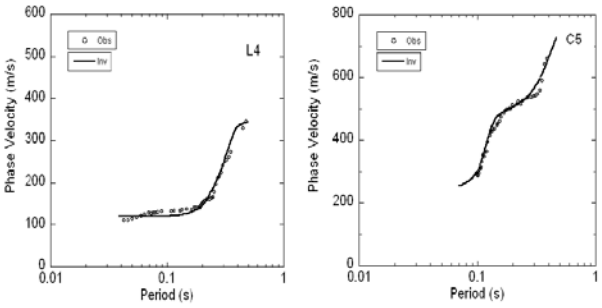

Figure 2 Comparison between observed phase velocity of microtremors (circular dotted line) and inverted surface wave phase velocity using hybrid genetic algorithms (solid line). Site L4 and C5 are located in Coastal Lowland and Central Plateau, respectively.

4.1 Inversion of surface waves using hybrid genetic algorithms

In order to extract the subsurface structural model from surface wave dispersion curve we applied Hybrid Genetic Algorithms (HGAs) as an inversion technique. SPAC utilizes the Rayleigh wave's surface propagation and considering that it propagates in a horizontally layered half-space. Dispersion curve of Rayleigh wave phase velocity is inverted into a 1-D shear wave velocity profile using HGAs based on the method of Takekoshi and Yamanaka (2009). In the HGAs inversion, subsurface structural models are searched by minimizing the misfits that is defined by L1-norm of differences between observed and inverted phase velocities. We conducted 10 inversions with 100 generations using different seeds of random numbers where good model with smaller misfit survive more in the next generation while bad models are replaced by newly generated models. The searched horizontally-layered models were considered to be an isotropic, homogenous unit characterized by four parameters: thickness (h), density (ρ), P-wave velocity (Vp) and shear-wave velocity (Vs). The unknown parameters in the HGAs inversion are S-wave velocity and thickness. The density is fixed while the P-wave is derived using an empirical relation with S-wave. In the inversion we searched for an optimal combination of S-wave velocity and thickness for each layer and they are digitized as 8-bit binary strings.

4.2 Shear wave velocity structures

The inferred S-wave velocity profiles at 32 sites in Metro Manila using the HGA's inversion of the phase velocity from SPAC of microtremors are presented here. The four major classifications based on geomorphic characteristics are enumerated as follows: Coastal Lowland, Central Plateau, Marikina Valley and Basement area. This study defines the engineering bedrock as having S-wave velocity of about 600 m/s. This assumption considered all the S-wave velocities that fall within the range of 500 m/s to 900 m/s as engineering bedrock.

Coastal Lowland (L) has a geological classification of Quaternary alluvium. As shown in Fig. 3, sites L1 and L2 have thin (~5 m) low velocity (Vs~90 m/s) layers existing near the surface, but high-velocity (Vs~600 m/s) layers are prevalent along shallow depth. The existence of the low velocity layers in these areas are considered to be from coastal deposits and some reclaimed land at close proximity to the coast. Because of high velocity contrast between the layers, it is possible to have high site amplification in these areas. The sites L4 and L5 located in Manila City, have the deepest sedimentary layers of 52 and 60 m, respectively. These results further contribute details to the study of Daligdig and Besana (1993) who discussed and mapped out the distribution of alluvial cover in the Manila area where the thickest accumulation of fine sediments exceeds 20 m. Documented damages of buildings during the 1968 Casiguran Earthquake could be seen in this area, as well as in areas nearby Pasig River where a distinct clustering of damaged buildings was noted (Omote *et al.*, 1969). Sites L3, L6, and L7 have thin (~3 to 11 m) low velocity (Vs~78 to 135 m/s) layer underlain by another layer (2 to 18 m) above the bedrock (Vs~600 m/s).

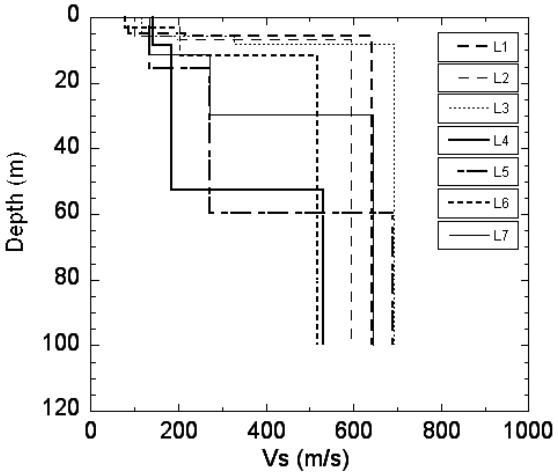

Figure 3 Inferred shear-wave velocity structures at Coastal Lowland by applying HGAs in the inversion of observed phase velocity dispersion curves.

The Marikina Valley (V) has the same geological classification as Coastal Lowland. From north where V1 is located in the upper stream of Marikina River to site V7 in the south shows clear variations of thicknesses in the near-surface layer from 19 to 64 m, respectively. Site V1 has a Quaternary alluvium thickness of 19 m with low velocity (Vs~200 m/s) layer underlain by engineering bedrock (Vs~600 to 800 m/s). The existence of layers with high velocities can be compared to the one identified by Matsuda *et al.* (2000) who used N-value of more than 50 that were obtained from Standard Penetration Test (SPT) of 80 borehole records in Marikina Valley. Also, the depth of around 30 m of N>50 in Manggahan, Pasig City is congruent with the microtremor array observations derived in this study.

The area of Central Plateau that covers the majority of Metro Manila is composed of tuffaceous sediments and pyroclastic flow deposits. It has high elevation compared to Coastal Lowland and Marikina Valley. Due to its composition, Central Plateau has layers with high velocity (Vs~500 to 1100 m/s) at shallow depth. The lower S-wave velocity sediment in Central Plateau reaches to a maximum depth of 20 m before engineering bedrock (Vs~600 m/s) is located. Sites C6, C7 and C9, which are located near the boundary of geologic contact between Quaternary alluvium deposits and tuffaceous sediments, have engineering bedrock at depths 10, 13, and 12 m, respectively. In these sites Quaternary alluvium deposits are thin and then become thicker towards the coast of Manila Bay. The site C15 is located in the southern part of the Central Plateau. It has soft sediments at 12 m underlain by a thicker layer with high velocity of about 500 m/s.

Basement area (B) or Basement complex is mainly mountainous area to the east of Metro Manila. Three sites were measured in this area namely B1, B2 and B3 at elevations of 25 m, 44 m and 198 m, respectively. B1 is a rock site located near the boundary of Marikina Valley consisting of a thin (~10 m) low velocity (Vs~200 m/s) uppermost layer underlain by a 15 m thick, second layer that has S-wave velocity of 470 m/s and, a third layer of high velocity (Vs~730 m/s). In site B2, it shows to have a thin (~17 m) low velocity (Vs~140 m/s) layer near the surface and a high velocity (Vs~1900 m/s) underlying at shallow depth. Site B2 is near to the borehole site with a basement (Vs~2000 m/s) at the depth of 20 m (Yamanaka *et al.*, 2002). Site B3 has thin (~5 m) low velocity (Vs~160 to 330 m/s) layer followed by a high velocity (Vs~2700 m/s). Site B3 is significant for the study of deep sediments in Metro Manila because it inferred the seismic basement rock that has S-wave velocities of 2700 to 3000 m/s.

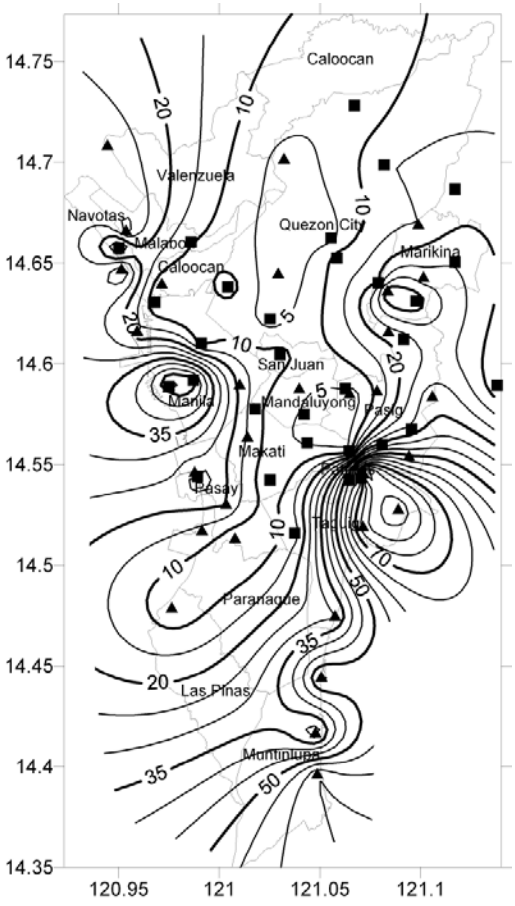

Figure 4 Three-dimensional (3-D) map of engineering bedrock (Vs~600 m/s) in and around Metro Manila from the combined data of microtremor observations (square) and boreholes (triangle).

The engineering bedrock in Metro Manila is summarized by a three-dimensional (3-D) contour map of engineering bedrock depths, with S-wave velocity of about 600 m/s. Further addition of borehole data from Metro Manila Earthquake Impact Reduction Studies (MMEIRS, 2004) lead to the refinement of 3-D contour map of engineering bedrock in Metro Manila. The deepest engineering bedrocks are found in Manila and Taguig-Pateros areas as shown in Fig. 4. Those areas have alluvium sediments with a depth of 50 – 90 m. The deep Quaternary alluvium on these two basins was deposited by the Pasig River that crosses the Central Plateau and connects the two basins. While in Marikina Valley the majority of deposition in the southern part came from Marikina River.

4.3 Site amplifications

This study calculated the 1-D amplification factors of S-waves propagating vertically in the shear-wave velocity profiles. As shown in Fig. 5 the amplification factors of Coastal Lowland and Marikina Valley have a dominant peak in the range of 0.20 to 1.15 s. The thinner upper layer of low velocity in sites L1 and L2 corresponds to the predominant peak at 0.24 s. Hence, the thicker low velocity layer of site L4 leads to the dominant peak at 1.15 s. Therefore, the thicker the sediment the longer period is expected. The same case also appeared in the amplification factors of Marikina Valley that it has a very clear variations of thicknesses on the upper layer from site V1 (north) to site V7 (south). Site V1 has a dominant peak at 0.3 s while V7 has a dominant peak at 1.2 s. Coastal Lowland and Marikina Valley are susceptible to high amplifications for earthquake events having period ranges from 0.24 to 1.0 s. The maximum amplification amplitude for Coastal Lowland reaches 8.1 at period of 0.24 s and in Marikina Valley to have amplification of 7.9 at the period of 1.2 s.

In Central Plateau, it is expected that the amplification levels are generally low than those from Coastal Lowland and Marikina Valley because of its tuffaceous characteristics. Central Plateau has a low period of less than 0.20 s, making it a distinct characteristic of a stable site to have engineering bedrock. The average amplification deduced for Central Plateau in this study is 6.0 at the period of 0.1 s. It is clearly pointed out that the amplifications of Coastal Lowland and Marikina Valley have a difference factor of 2 compared to the amplification of Central Plateau. Thus, considering the Central Plateau as a reference site, the intensity level of ground shaking in Coastal Lowland and Marikina Valley could be increased by factor of two when there is a significant earthquake event that will strike Metro Manila.

The Basement area (B) has similar characteristics of Central Plateau, but relatively smaller in amplification. In Basement area, the maximum amplification that was identified is 4.5 at period 0.17 s from site B1 which is located near the boundary of Marikina Valley. Site B3 has an amplitude of 4 at period of 0.1 s. Site B3 is significant compared to all microtremor sites in this study because it has a shear wave velocity layer reaching almost 3000 m/s which is categorized as basement complex or seismological bedrock. This site B3 can be used as a stable reference site for understanding site response and future understanding of much deeper sediments in Metro Manila.

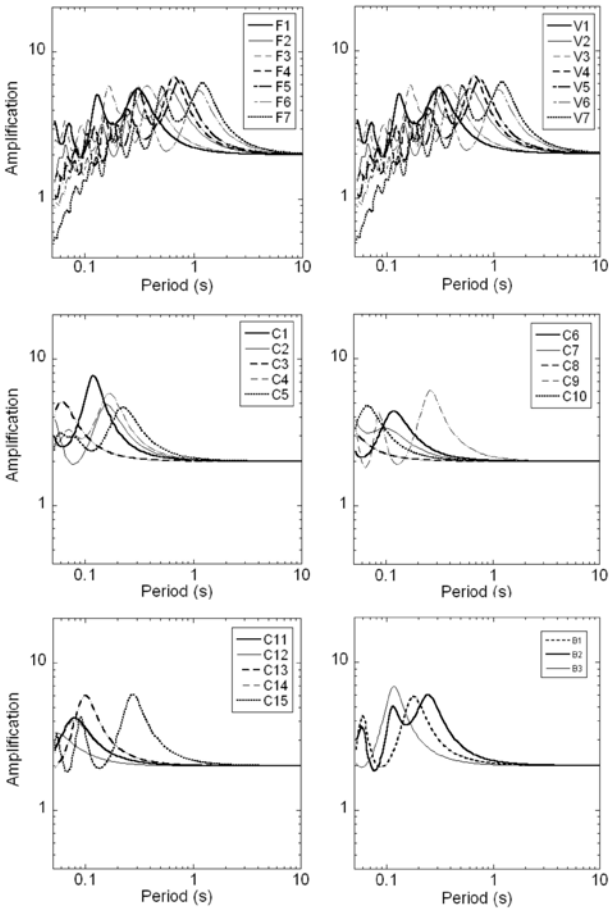

Figure 5 Amplifications of different geomorphic classifications in Metro Manila with the reference of engineering bedrock (Vs~600 m/s) as a half space model at the bottom layer.

4.4 Relationship of amplifications to Vs30

The most common parameter adopted worldwide for the seismic code, also in the National Structural Code of the Philippines (NSCP) (ASEP, 2001), is the average shear-wave velocity in the top 30 m of subsoil (Vs30). For this study, we derived regression equation of the calculated site amplification based on the Vs30

$$Ave.Amp = (687/Vs_{30})^{0.476} \quad (2)$$

where $Ave.Amp$ is the average amplification of a site and Vs_{30} is the average shear-wave velocity of the upper 30 m from the ground.

Focusing on the S-wave velocity of surface deposits that play a significant role in site amplification, comparison was made to other regression equation as shown in Fig. 6. Borcherdt (1994) developed a method to estimate site amplification from the average shear-wave velocity in the upper 30 m that is characterized by short (0.1-0.5 s) and mid-period (0.4-2.0 s) amplification. Also, Borcherdt work has been incorporated into the 1997 Uniform Building Code. As show in Fig. 6, our result coincides with the short period amplification of Borcherdt (1994). As compared to earthquake records, it is expected that the result of amplification for shallow S-wave velocity profiles is relatively low compared to the results derived by Fujimoto and Midorikawa (2006) because their amplification includes the effect of deeper profiles. However, the reference engineering bedrock in this study has S-wave velocity of around 600 m/s. Recently, Yamanaka *et al.* (2010) derived different correlation equation with respect to different periods using strong motion records in Metro Manila. As shown in Fig. 6, it would imply that the amplification in short period (0.14 s) of Yamanaka *et al*. (2010) shows higher amplification values compared to the result of this study. But interestingly, comparing the regression equation, the difference in amplification is almost twice and parallel to each other. More likely, this is the effect of basement rock that lies underneath Metro Manila having S-wave velocity of 3000 m/s. For a much deeper sedimentary layers amplification computation, the identified seismic basement rock (Vs~3000 m/s) of site B3 will be a suitable reference site. The effect of identified higher S-wave velocity value for basement rock will have an increase in amplitude value in amplification and will also give amplification in the longer periods because it is underlain by deeper sedimentary layers.

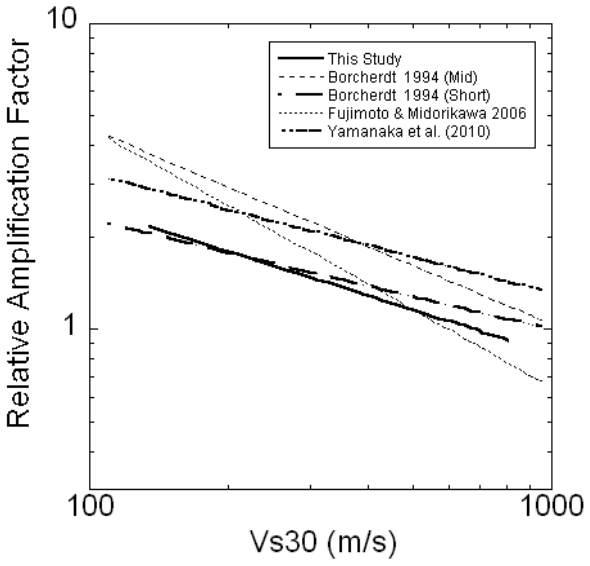

Figure 6 Comparison of result from this study using microtremor observation to various authors who used strong motion records to derived correlations between Vs30 and relative amplification factors.

5. CONCLUSIONS

Presented in this article are the wide area of coverage for microtremor surveys and the shallow S-wave velocity profiles of 32 sites covering all geologic conditions in Metro Manila. The results for the inferred S-wave velocity profiles are consistent with the investigations of the available borehole data, which significantly contributes to the

refinement of map of the depth of engineering bedrock. It is possible that some observed differences in interface depth and S-wave velocity estimation are affected by a significant distances between the borehole and microtremor sites. The deepest Quaternary alluvium in Coastal Lowland and Marikina Valley was located in Manila and Pateros-Taguig area making it distinct and critical areas for site response. We propose to classify these two catch basins as a separate group from Coastal Lowland and Marikina Valley and to be characterized as important areas considering site effects. Therefore, the four classifications namely: Coastal Lowland; Central Plateau; Marikina Valley; and Basement area, will be classified to six characteristics including these two deep alluvium basins. The area of boundary for these two separated classes will be at contour depth of 30 and 50 m in Coastal Lowland and Marikina Valley, respectively. In Marikina Valley, the identified area with deep alluvium corresponds to landfill classification as the Delta.

Site amplifications are provided to better understand the effect of geologic condition and thickness of Quaternary alluvium to the predominant period of amplifications. The Coastal Lowland and Marikina Valley show a predominant periods in the range of 0.2 to 1.2 s, while the Central Plateau and Basement area exhibit predominant periods about 0.2 s and below. Thus, site amplification is computed using the engineering bedrock of Central Plateau with S-wave velocity of about 600 m/s as a reference. The analysis with respect to the Vs30 was also evaluated and the different site classes in reference to NEHRP were obtained. A correlation between average amplification and Vs30 shows good agreement with the Borcherdt's (1994) short period regression, but as compared to the regression for earthquake records it shows a low level of amplification. Hence, this difference will be further assessed in the future by identifying the deeper sedimentary layers underlain by basement bedrock (Vs~3000 m/s). This paper presented briefly the result of local site effect focusing on the shallow velocity structures, especially Vs30 which has greater effect in engineering structures.

Abstract: It has already been demonstrated that an estimate of the Green's function can be obtained from the cross correlation of long-term ambient noises between two stations, and it can be possible to extract interstation surface wave group velocity. We had observation of microtremors in the southern Kanto basin including IZU peninsula, to validate the existing three dimensional S-wave velocity model of deep sediments. Obtained data were processed for estimating the Green's functions by cross correlation between two stations. The result shows that the estimated Green's functions propagate by the different velocities because of the complexity of geology of this area. Furthermore, they have specific azimuthal dependence. Finally, we estimated the Rayleigh and Love wave velocity from the estimated Green's function assuming a straight path. The result was compared with the theoretical ones calculated from 2D models of an existing basin model of the deep sedimentary layers. The result compares favorably with theoretical ones in the basin area. However, there are significant differences in the IZU peninsula.

1. INTRODUCTION

It is known that long-period strong ground motion is amplified in a large sedimentary basin. Tokyo metropolitan area locates over Kanto basin with a scale of about 200× 200km large and a depth is more than 4km. Therefore it is important to estimate amplification effects in the large and deep basin. Accordingly, some subsurface structure models were proposed to predict strong ground motion including Kanto basin (e.g. Yamanaka & Yamada, 2006). Although They carried out validation of their models by simulating observed ground motion during small events, they still have difficulty to validate such models due to uncertainty of source and subsurface structure out of the basin.

Seismic interferometory is used for estimating Green's function between two sites. This method is one of passive imaging method because it doesn't need special sources (e.g. earthquake or artificial source). Main data processing is cross correlating long-term ambient noises at two sites (Snieder, 2004).

Recent studies showed possiblily to retrieve surface wave of Green's function from long-term ambient noises (e.g. Shapillo and Campillo, 2004). As shown in Shapiro et al. (2005), it is also possible to use estimated traveltimes from cross correlations for a Rayleigh wave tomographic inversion.

In this study, we applied seismic interferometory to estimate and validate its subsurface model for the Kanto basin. First we conducted observation of long-term ambient noises around Kanto basin and Izu peninsula. Observed microtremor data are processed with a procedure based on seismic interferometory and we estimated traveltime of each Green's functions at the periods of 2-6s. Traveltimes were used for estimating averaged group velocities between two observation sites. We compared group velocities and theoretical ones calculated from Yamanaka and Yamada (2006). The observed group velocities are well explained by the theoretical ones in the Kanto basin, but we found discrepancy in the Izu peninsula. To understand subsurface structure regionally, we conducted surface wave tomography.

2. ESTIMATING GROUP VELOCITIES

2.1 Extracting Green's Function

In order to apply seismic interferometory, we started long-term continuous observation of ambient noises from March 2008 in the southern Kanto region as shown in Figure 1. We have already got cross correlation functions from the data of these observation. Data procedure is described in Yamanaka et al. (2010) precisely. Here we roughly show about data processing. First, in order to extract surface waves, band-pass filter is applied to the data with the period of 2 – 6s. Then, one-bit data clipping is used to reduce the influence of nonstationaly event like earthquake (e.g. Gerstoft et al., 2006). Finally we cross correlate the data at two sites. Since Love and Rayleigh waves appear in the horizontal component, we rotated the horizontal components into the radial(R) and transverse(T) components. Figure 2

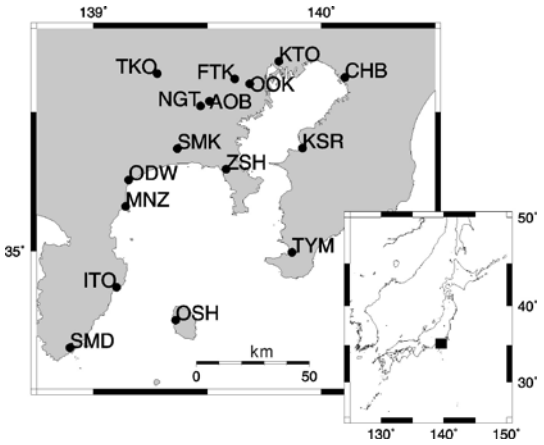

Fig.1. Observation Sites.

shows an example of cross correlation functions. As there are three components data at each site, we can get nine cross correlations after all. When source distribution is spatially uniform, positive waveform and negative waveform will be same (Snieder, 2004), but estimated Green's functions are not always symmetry. Fig. 3 shows all cross correlations against the inter-station distances and azimuths. This also show asymmetry of cross correlations. Gerstoft et al. (2006) showed most of the noise originates from microseisms from the direction of the ocean in California, U.S.A.. Our results also suggest this azimuthal dependence caused microseisms from ocean.

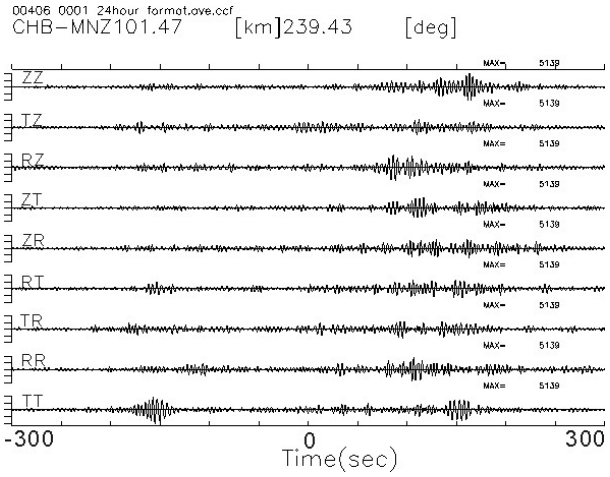

Fig.2. An example of cross correlations at 9 components. Z, R and T means Vertical, Radial and Transeverse, respectively.

2.2 Estimation of Group Velocity

We estimate group velocities using a multiple-filter technique (Dziewonski et al., 1969). The positive and negative cross correlations are firstly averaged to enhance Signal to Noise Ratio and then narrow bandpass filtered. We can see dispersive wave-trains in the cross correlation on vertical, radial, and transverse components (Fig.4). This result shows that we can get the Rayleigh and Love wave Green's function from ambient noises. Then we estimated

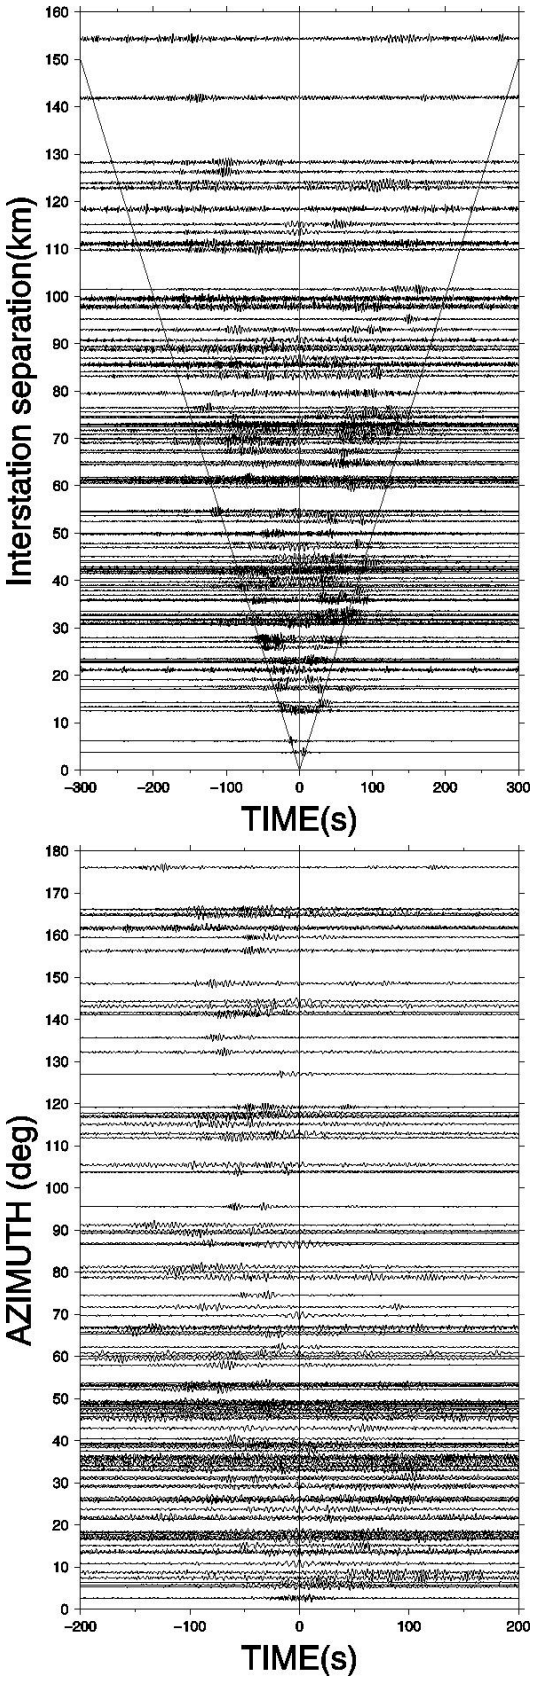

Fig.3. All cross correlations against distance (top) and azimuth (bottom). Vecolity of 1.5 km/s is shown in the top figure.

traveltime of fundamental mode of Rayleigh and Love wave, respectively. Rayleigh and Love wave's group velocity are estimated by assuming straight ray path.

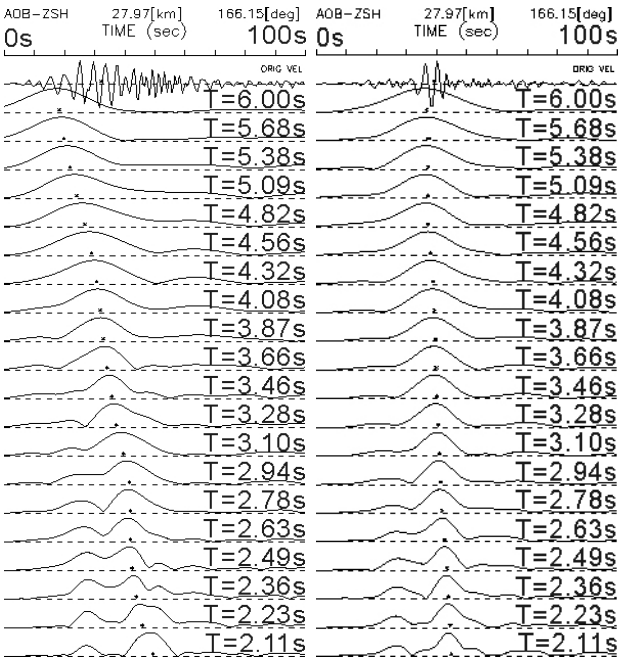

Fig. 4. The result of multiple filter analysis. Wave-form at top shows original cross correlation. ZZ (left) and TT (right) component are shown.

2.3 Comparing observed and calculated group velocity

We compared the observed group velocity and theoretical one calculated from Yamanaka and Yamada (2006). Two-dimensional model along two sites is divided into 500m segments. Each segment were assumed lateral model. Theoretical fundamental group velocities of Rayleigh and Love waves are calculated at each segment. Finally, theoretical averaged group velocity is obtained from those group velocities.

Figure 5 showes good agreement between observed and theoretical group velocities of the Rayleigh and Love waves in the Kanto basin. However the comparisons in the other area shows discrepancy between them. For example, Figure 6 shows group velocity between SMD and MNZ crossing Izu peninsula. This result clarifies inappropriateness of subsurface structure model in this region. In this way, we can validate two dimensional model not using earthquake nor artificial source.

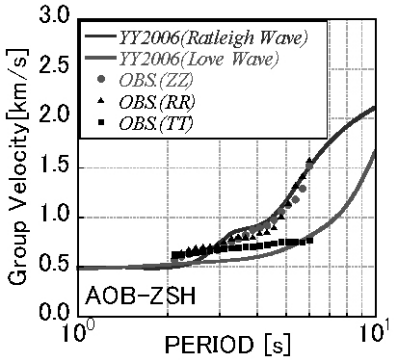

Fig. 5 Comparison of observed and theoretical group velocity (AOB-ZSH)

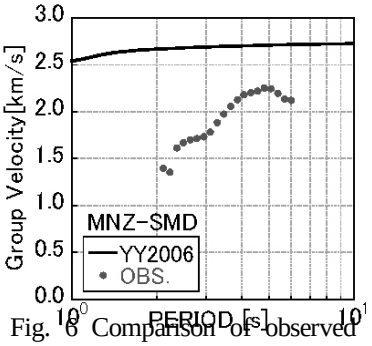

Fig. 6 Comparison of observed and theoretical group velocity (MNZ-SMD)

3. TOMOGRAPHIC INVERSION

3.1 Surface wave tomography

In this section, we consider about three-dimensional model. As shown by Bensen et al. (2008), if we have a lot of observation sites, we can conduct tomographic inversion based on seismic interferometory. Southern Kanto area is divided into 0.125° ×0.125° cells having constant group velocity in tomographic inversion, as indicated in Figure 7. the propergation paths are assumed to be completely straight paths. In order to construct tomography map, we applied a back projection technique using slowness at each period as an unknown parameter. Traveltimes are estimated in section 2 and an initial model is made based on those traveltimes. The nonlinear tomographic inversion is solved by iteratively conducting linear inversion, Simultaneous Iterative Reconstruction Technique (SIRT). Iteration is continued until residual becomes the minimum.

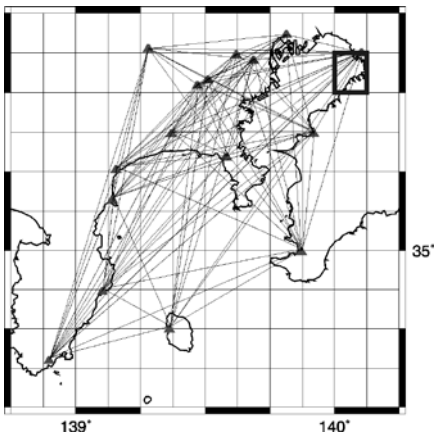

Fig. 7 Cell dividing and ray path coverage for tomographic inversion. Rectangular area shows tomographic inverted area in Fig.10,

3.2 Results

Figure 8 shows Rayleigh wave tomography map at period of 6s. This map clearly shows regional difference of group velocity. We can identify high velocity area such as Kanto mountain, Izu and Miura peninsula. We can also find low velocity area such as Tokyo, Sagami bay and Central Kanto basin. This result compares favorably with Section 2.

We conducted this surface wave tomography among the period of 2- 6s including Love waves (Fig.9). Estimated group velocities at each cell are used for tomographic inversion.

Rayleigh wave group velocity and Love wave group velocity are simultaneously inverted using Genetic Algorithm (Yamanaka and Ishida, 1996) to estimate a one-dimensional S-wave velocity at each cell subsurface model. The determined model including Chiba-city is shown in Figure 10. The comparison between the observed and theoretical phase velocities is shown in Figure 11. The theoretical phase velocity well explains the observed one.

4. CONCLUSIONS

Seismic interferometory using continuous microtremor data were applied in the Kanto basin and Izu peninsula. More than 150days observed data were used for extracting Green's functions. We used the multiple filter analysis for estimating group velocities at period of 2-6s. observed and theoretical group velocity comperes favarly, but we found discrepancy in Izu peninsula. We conducted tomographic inversion using SIRT. The result showed regional differences of group velocities.

Abstract: On May 12, 2008, there was an Ms 8.0 earthquake occurred in Wenchuan, China region. The earthquake inflicted severe damage in China, especially in the near-fault region. The mainshock was recorded by over four hundreds strong motion stations in whole China, and there were over sixty stations near Longmenshan fault. In this study, the method which was modified from Wu and Wu (2007) was used to correct the baseline of each strong motion record for near fault stations. After three-parts-correction and double integral, the co-seismic displacements were found from strong motion data only. The results were compared with that from GPS measurements. Finally, there were some near fault records showed the baselines can divided into more than three parts. So in this study, the appropriateness of applying Hilbert-Huang Transform (HHT) method to find each divided time points was also discussed.

1. INTRODUCTION

There were some problems in strong motion records which were using digital instrument during huge earthquake, especially in near-fault region. The baseline of each record was drifted during large shaking from ground tilting (Graizer 2005), instrument impact or seriously permanent displacement occurred. Iwan et al. (1985) mentioned that the processes of baseline drifting could divide into three parts, and the corrected method could base on the slope of these three lines in velocity records.

Boore (2001) then tested and verified the difference corrected results from changing the length of the corrected lines. The results showed the unsuitable divided time choosing would lead great divergence. Wu and Wu (2007) built up a try and error method to choose divided times. In this study, the baseline correction method was modified from Wu and Wu (2007) and reduced some men-made decisions for semi-automatically choosing the most suitable divided times.

After three parts baseline correction, the ground motions of each station in Sichuan from 2008 great Wenchuan earthquake were corrected. And the co-seismic deformation results were corresponding to the GPS measurements including directions and quantity in near fault region.

Anyway, the three part baseline correction model would not appropriate for all the data when the baseline drift was greater than three parts. Huang et al. (1998) mentioned a Hilbert-Huang Transform (HHT) method which can expertly decompose different frequency signal. And commonly the baseline offsets were treated as the very low frequency signal. So in this study, a given waveform with obviously offset were built. The given waveforms were decomposed into several modes by HHT method and try to find out the divided time and offset.

2. METHODS AND DATA PROCESSING

2.1 Semi-Auto Three Parts Baseline Correction Method

Iwan et al. (1985) mentioned the baseline drifting models were associated with starting time of the strong shaking T1 and the end of shaking time T2. Wu and Wu (2007) then added another possible model, which was associated with another important time T3. T3 time means the end of great shaking and the ground started to become stable. (Figure 1, Wu and Wu 2007) In order to verify the suitability of each T1 and T2 time, they determined a parameter f (Eq. 1) :

$$f = \frac{|r|}{|b| \bullet \sigma} \tag{1}$$

This f value was calculated for corrected displacement data of the time history after T3 to the end. Where r: linear correlation coefficient, verified the data was scattered or not. b: the slope of regression line, verified the baseline was flat

or not. σ: variation coefficient, verified the baseline was stable or not .

In this study, the baseline correction method was modified from Wu and Wu (2007, Figures 2 and 3). The variable range for T1 and T2 were applied and semi-auto calculation collocated with try-and-error process was used. After calculated the f-value for different T1, T2 pairs, the time pair with greatest f-value were the final target. The simple linear correction was done from least square fitting with the best time pair in the end.

2.2 Hilbert-Huang Transform

Huang et al. (1998) mentioned a signal analysis method called Hilbert-Huang Transform (HHT) and which was clever at processing non-stationary or non-sinusoidal signal. And the men-made non-sinusoidal signal and real seismic records could finely decompose into several intrinsic mode function (IMF) components with different frequency composition. And the characteristic of each IMF was that the greater the IMF component, the lower the frequency content. (Ray et al. 2003) The HHT method was consisted of two parts: the Empirical Mode Decomposition (EMD) method and the instantaneous frequency in the Hilbert spectral analysis. In this study, the EMD method was used to decompose the given waveform. The procedures can be described as the original signal minus the average envelope lines for several times to get an IMF mode and repeated the process for the residual parts to get the higher IMF mode. Finally, the procedures were ended when the residual parts became a monotone function.

2.3 The Given Waveform

In this study, the given waveform was composed of a 5 Hz sinusoidal wave and a wave package which will attenuate with time. One or two obvious offset were added in this waveform for different situation. (Figure 4) The equation was as followed:

$$y = \frac{600}{0.141} * \sin(\pi t) * \exp(-8t) * \sin(10\pi t) \qquad (2)$$

Where the unit of y was acceleration ground motion (gal.), the obvious offsets were set on 5 seconds in Figure 4 (a) for a two parts baseline drifting model and were set on 5 and 20 seconds in Figure 4 (b) for a three parts baseline drifting model.

3. DISCUSSIONS AND CONCLUSIONS

3.1 Results for the Near-Fault Region During the 2008 Wenchuan Earthquake

The co-seismic deformation values were calculated from the corrected displacement records (Figure 3 (b), the range of double arrow showed) in different components. (NS, EW, Z) And the results were combined into vectors of permanent displacement in near-fault region. The results then compared with the GPS co-seismic deformation from The Project of Crustal Movement Observation Network of China (2008) (Figure 5). They showed a good agreement in vector directions and scales. Figure 6 were the example of corrected waveforms and which were compared the permanent displacement value with nearest GPS station.

The calculated displacement values were greater than 150 cm near the fault (Figure 5). Chang et al. (2008) used the teleseismic records and applied a quick-inversion method to calculate the slip rate on fault plane for Wenchuan earthquake (Figure 7 (a)). In this study, the two regions which had the greatest slip value were showed a good agreement with Chang et al. (2008) on the permanent displacement contour (Blue stars in Figure 7 (b)).

3.2 Results From EMD Process for Given Waveforms

Several IMF components which were decomposed from the given waveform model by EMD process was shown in Figure 8 and Figure 9.

For the two parts baseline drifting models (Figure 4 (a)), IMF components of the greater offset one (Figure 8 (a)), the obviously offset (30 gal.) were appeared at 5 seconds from the given waveform. And it could be found in component IMF2 and IMF3 after EMD decomposition, there were a significant discontinuity occurred at around 5 seconds. It is worthy to mention that the final value of the highest mode (IMF13) will converge toward the original given offset (30 gal). It was considered that whether these characteristics will occur when the offset is small or not. A smaller offset (6 gal) in the same drifting time was decomposed in Figure 8 (b). The discontinuity at 5 seconds in IMF2 and IMF3 and the converged offset in IMF13 still can be found.

For the three parts baseline drifting models (Figure 4 (b)), the IMF components of co-aspect offsets one (Figure 9 (a)), the offsets were occurred at 5 seconds (30 gal) and 20 seconds (10 gal). These drifting times could be found at lower IMF component (IMF2 and IMF3) as the results of two parts baseline drifting models. The final offset in the highest mode (IMF13) was only indicated the second offset (10 gal). Finally, for the IMF components of opposite offsets one (Figure 9 (b)), the offsets were at 5 seconds (30 gal) and 20 seconds (-10 gal). The amplitude of the second drifting time in IMF2 was become much higher than the co-aspect one, and the final offset for IMF13 converged on -10 gal.

3.3 Conclusions

The corrected permanent displacement which was using the semi-auto three part baseline correction method had a good agreement with GPS results for the data of 2008 great Wenchuan earthquake. The permanent displacement contour showed the distribution of correct displacement, which were corresponded with the inversion results of slip model (Chang et al. 2008).

Due to the purpose that there's a problem about the real strong motion might be a multiple drifting model, the suitability of that applying HHT method to identify the drifting time and offset value were tested in this study. For the results of two parts and three parts drifting models, the EMD components showed the drifting time in lower mode

and the final offset will be at the end of the highest mode. If the offsets were opposite with each other for three parts model, the amplitude of the indicated dividing time in second IMF component was much higher than the co-aspect one.

Abstract: The 2010 JiaSian M_L 6.4 earthquake occurred on March 4, 2010 at 00:18:52 UTC. The epicenter was located in southern Taiwan (22.969°N 120.707°E) at the depth 22.6 km. This was the most powerful earthquake in the Kaohsiung area since recent hundred years. The quake did not cause death, but injured 96 people. Several building was collapsed during main shock and aftershock. Six trains of THSR (Taiwan High Speed Rail) were disrupted, and one was de-railed while in an emergency braking. This is the first de-railed accident of THSR caused by earthquake. The strong ground shaking also induced the soil liquefaction near the Xinhua town and close to the THSR bridge pier. Fortunately the soil liquefaction did not cause any building damage. In this study we use 2D finite-difference method to simulating the wave propagation of the JiaSian earthquake. The results of the simulation demonstrate that the long duration surface wave of the west ChiaNan plain resulting from the multi-pathing waves trapped in the top Pleistocene formation. Synthetic PGVs were good fit with the observations. We believe the simulation can be applied to understanding the strong ground motions expected for future earthquake.

1. INTRODUCTION

Taiwan is located on the boundary between the Philippine Sea Plate and the Eurasian Plate. The seismicity in the Taiwan is very high. During the 20th century occurred many large and destructive earthquakes close to the ChiaNan plain. For example M_L=7.1 on 1941 December 17, M_L=7.1 on 1946 December 5 and M_L=6.3 on 1964 January 18. So, southwestern Taiwan has always been considered as probably to occur next big earthquake area. Taiwan is covered with a dense strong motion network array that is operated within the frame of the Taiwan Strong Motion Instrumentation Program (TSMIP) conducted by the Central Weather Bureau (CWB). These recorded events make this study possible to compare with the simulation and the observation. From the results of the microtremor array research (Lin et al. 2009) and seismic tomography (Wu et al. 2007), we can construct a geometry model to estimate the seismic wave propagations for the area of ChiaNan plain. In this study we perform 2D Finite-Difference simulations of the ChiaNan plain for the M_L = 6.4 2010 March 4 JiaSian earthquake. We analyze the synthetic waveform, peak ground velocity (PGVs), 2 dimension wave propagation snapshots for three 2D profiles. This enables us to understand how the surface wave generated and predicting the ground motions. We except the results can provide to the future seismic hazard mitigation for the southwestern Taiwan.

2. METHOD

2.1 2010 March 4 JiaSian Earthquake

On 2010 March 4, a M_L = 6.4 (M_w = 5.97) earthquake occurred near the JiaSian seismic station17 km to the southeast. This was the most powerful earthquake in the Kaohsiung area since recent hundred years. The intensity reach to 6 and the maximum peak ground acceleration recorded over 460 gal at the CHY062. Shaking map and the stations distribution shown in the Figure 1. The quake caused several building collapsed and one high speed rail train was de-railed. We found near the west part of the ChiaNan plain excite significant long period and long duration ground motions at periods of about 2-4 sec. The quake was strong enough to trigger about 390 stations of TSMIP network. Therefore, this event provides us enough observations to study the ground motion characteristic and suitable for comparison of observation and simulation. In this study we simulate 2D wave propagation for three profiles to see how the surface waves generate.

2.2 ChiaNan Plain Velocity Model

The ChiaNan plain located in the southern part of the western coastal plain of Taiwan. It's a low, flat and the largest plain in Taiwan. The plain was filled by alluvium deposits, which resulted in flat-lying Quaternary layers. The detail structure of the plain was study by seismic reflection survey (Pan 1967, 1968) and the shallow velocity structure was estimated from surface to a depth of 3 km by the

microtremor array measurement (Lin et al. 2009). In this study, we combined the shallow layers velocity and the three main interface's depth (Plio-Pleistocene, Pliocene, and Miocene formations) to create the shallow layer 2D velocity model. We give the S velocity 0.3 km/s and P velocity 1.8 km/s between surface to Plio-Pleistocene interface, Plio-Pleistocene to Pliocene is 0.53 and 2 km/s, Pliocene to Miocene is 1.7 and 3.2 km/s, respectively. Then we embedded the shallow 2D model into the Taiwan area subsurface model by Wu et al. (2007) derived from seismic tomography. Figure 2 display the 2D velocity model used in this study.

Density model is also need for the Finite Difference simulation that is calculated from P wave velocities after Glaznev et al. (1996). The convert equation is given as Eq.(1) and Eq.(2) below :

when V_p less than 5500 m/s:

$$density = 2933 - 518 \times \ln(|vp - 7.595|) \quad (1)$$

when V_p large or equal 5500 m/s:

$$density = 1656 + 1068 \times \ln(|vp - 3.18|) \quad (2)$$

Totally we created three 2D profiles velocity model crossed the epicenter and TSMIP station CHY131, CHY021, and CHY023, respectively (Figure 3). Each model has a width 80km and depth 40km.

2.3 Numerical Modeling

We use a 2D Finite-Difference method (Bohlen 2002) for wave propagation simulation. Our simulations are calculated by 4th order standard staggered grid. Damping and one way absorbing boundary (Cerjan et al. 1985) is applied at the left/right, front/back and the bottom to avoid the interference of reflection waves. The calculations are performed on the IBM x3550 supercomputer "Vger" of the center for Computational Geophysics, National Central University. Vger has 108 computing nodes 432 CPUs, calculating performance approach to 3.5TFlops. Our model dimension is 80 × 40 km, grid size is 20 × 20 meters. Therefore, there are 4000 × 2000 = 8,000,000 girds in one model. Estimate *Q* values model are calculated from the S wave velocity model. $Q_p = 0.15 \times V_s$ and $Q_s = 0.1 \times V_s$, where V_s is in meter/sec. We run the code in the supercomputer use two nodes eight processors for each simulation. Total real time of calculating is about 11 hours. Detail modeling parameters are list in Table 1. We set the source as a double coupling point source. The moment tensor calculated respectively depends on the different azimuth of these profiles. The depth of the source was set to 18 km (BATS) and 22.6 km (CWB). After comparing the waveforms simulated by the different depth. We decide to use the result from the source on depth of 18 km because the result has a better fitting between the observation and the simulation than the result from the depth of 22.6 km

3. RESULT

3.1 Observed and Simulated PGVs

We compare observed and simulated waveforms and peak ground velocity. The observed and the simulated data were all filtered (0.05 Hz-1.0Hz) and rotated to radial and transverse component respectively. We also use 2D to 3D conversion (Miksat et al. 2008) to make the amplitude and waveform correction from 2D simulation. The results of the three stations those nearest to the epicenter CHY061, CHY131and CHY089 are good fit with the waveform pattern and the peak ground velocity in horizontal component (Figure 4). In general, the vertical component fit is not so good. However, it's difficult to obtain a very good fit in vertical component from simulating. Figure 5 displays observed and simulated velocity waveforms for the stations that far away the epicenter and located on the soft alluvium layer. The PGVs and durations still had a good fit in the horizontal components. The modeling results also show the velocity waveform has a surface wave generated for the station CHY016 and CHY115. Although the pattern of the waveform is not good fit, the 2D simulating still provide us a good way to study the wave propagation and ground motion prediction.

3.2 Wave Fields

Figure 6 display the snapshots of the 2D wave field for the profile CHY131. The snapshots show the waves into a sub Miocene structure (40-50km) during 12-20 sec did not generated the surface wave and caused short duration. When the waves come into the Pliocene formation the surface wave generated clearly and caused the long duration by the distance increase. Not only the profile CHY131 the other profiles also showed the similar phenomenon. The velocity of the Plio-Pleistocene layer is more slow and soft, but it seems has less influence in our simulation. That is because the Plio-Pleistocene layer is very thin (about 100m) the response of the frequency may be large than 1 Hz. Another reason is our grid size of the model 20 meters is not enough small to analyze such a thin structure. For all this we also found how the surface wave generated very depends on the structure. The surface wave generated almost immediately at the edge of the Pliocene formation for CHY131 and CHY021 model. But this phenomenon did not occur on CHY023 model. The surface wave generated at about 10 kilometers away from the Pliocene formation edge. Figure 7 show the pseudo array radial seismograms of three profiles respectively. The comparing result indicated the shape of the Pliocene interface plays an important role to control the wave propagation and the PGVs value.

4. CONCLUSION

Our simulations for the JiaSian earthquake on ChiaNan plain show a good fit with observed and simulated PGVs on radial component. Indicating our numerical modeling is suitable to predicting the ground motions for the area. Even though the vertical simulated PGVs were always overestimate. These may caused by the *Q* values model are estimated roughly from the V_s. We believe to modulate the attenuate model can solve this and obtain a good fit for

vertical PGVs. The snapshots of the wave propagation show the surface wave generated by the shape change of the top layer's interface. The phenomenon also appears in the observation. Unfortunately the observation is not enough along our profile.

We only discuss the velocity waveforms up to 1 Hz in this study. Because we apply a simple velocity model to the top layers. In the further we expect to combine the borehole drilling data and other detail velocity information to create a high resolution velocity model. This may provide us to obtain a higher frequency (up to 3 Hz) of the synthetic waveforms. The result should be a good solution for investigate the wave propagation behavior and predict the ground motion.

Abstract: Permanent sliding displacement represents a common damage parameter for evaluating the seismic performance of earth slopes. Empirical models for the sliding displacement of shallow (rigid) sliding masses have demonstrated that including both peak ground acceleration and peak ground velocity improves the displacement prediction and reduces its uncertainty. These empirical displacement models have been recently modified for application to flexible sliding masses, where the dynamic response of the sliding mass is important. This unified framework includes predicting the seismic loading for the sliding mass in terms of the maximum seismic coefficient (k_{max}) and the maximum velocity of the seismic coefficient-time history (k-vel_{max}). The predictive models are a function of the peak ground acceleration (PGA), peak ground velocity (PGV), the natural period of the sliding mass (T_s), and the mean period of the earthquake motion (T_m). The empirical predictive models for sliding displacement utilize k_{max} and k-vel_{max} in lieu PGA and PGV, and include a term related to the natural period of the sliding mass. This unified framework provides a consistent approach for predicting the sliding displacement of rigid (T_s=0) and flexible (T_s>0) slopes. This paper summarizes these new developments for predicting permanent sliding displacements of slopes and provides comparisons between the new model and existing models.

1. INTRODUCTION

Permanent sliding displacement represents a common damage parameter for evaluating the seismic stability of slopes. This displacement represents the cumulative, downslope movement of a sliding mass due to earthquake shaking. The magnitude of sliding displacement relates well with observations of seismic performance of slopes (e.g., Jibson et al. 2000), and thus has been a useful parameter in seismic design and hazard assessment.

Figure 1 outlines the process commonly used to compute the earthquake-induced sliding displacement (D) of a slope with yield acceleration, k_y (k_y = seismic coefficient that when multiplied by the weight of the sliding mass and applied to the slope yields a factor of safety of 1.0). If the sliding mass is relatively shallow and stiff, a rigid sliding block analysis is appropriate. In this case, the natural period of the sliding mass (T_s) is essentially zero and the dynamic response of the sliding mass can be ignored. The seismic loading is simply the acceleration-time ($a - t$) history at the base of the sliding mass, with the destabilizing force-time history (F(t))on the slope equal to the $a - t$ history (in units of gravity, g) times the weight of the sliding mass. Seismic loading parameters for the slope can be derived that represent various ground motion characteristics (GM) of an acceleration-time history, such as the peak ground acceleration (PGA), peak ground velocity (PGV), Arias Intensity (I_a), etc. The seismic loading parameters are used, along with the k_y of the slope, to predict D from empirical models (e.g., Jibson 2007, Saygili and Rathje 2008).

Deeper and/or softer sliding masses are flexible and have natural periods greater than zero, such that the rigid sliding block model is not appropriate. In these cases, the dynamic response of the flexible sliding mass must be taken into account (Figure 1). Two-dimensional finite element analysis can be used to model this dynamic response, or alternatively the sliding mass at its maximum thickness can be modeled as a one-dimensional soil column. Previous research (e.g., Rathje and Bray 2001, Vrymoed and Calzascia 1978) has shown that the one-dimensional simplification provides an adequate estimate of the seismic loading for deeper sliding masses. A decoupled sliding block analysis (e.g., Makdisi and Seed 1978, Bray and Rathje 1998) computes the dynamic response of the sliding mass and uses the results of the dynamic response analysis to compute the sliding displacement. The seismic loading time history for the sliding mass is related to the seismic coefficient (k)-time history, in which k represents the average acceleration within the sliding mass. The destabilizing force-time history (F(t)) is then simply equal to the k-time history times the weight of the sliding mass.

It has become common practice to use rigid sliding block analyses for sliding masses with T_s below some threshold, while using a flexible sliding block analysis for T_s greater than some threshold (Jibson 2010). In actuality, the response of slopes does not abruptly change from rigid to

flexible at some value of T_s, but rather there is a transition from rigid to flexible behavior as T_s increases. This paper summarizes a recently developed unified framework that models the full range of dynamic response conditions from rigid through flexible sliding mass behavior (Rathje and Antonakos 2010). This unified approach predicts the seismic loading parameters and permanent displacements of sliding masses as a function of T_s (as defined by the one-dimensional period computed for the maximum thickness of the sliding mass), such that the approach tracks the response from rigid conditions ($T_s = 0$) to very flexible conditions ($T_s >> 0$). The unified model is also built upon recently the developed empirical model for rigid sliding displacement (i.e., Saygili and Rathje 2008) that uses PGA and PGV to predict sliding displacement. The unified approach is described in this paper, and the predicted sliding displacements are compared with those from previously published models.

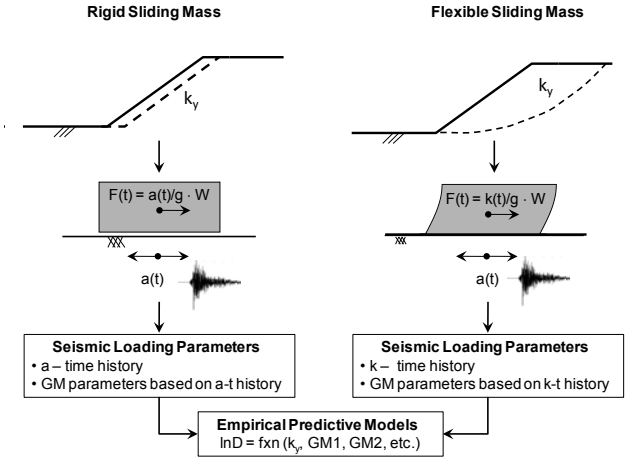

Figure 1 Procedures for computing earthquake-induced sliding displacements for rigid and flexible sliding masses.

2. RIGID SLIDING BLOCK DISPLACEMENTS

Saygili and Rathje (2008) presented a suite of empirical predictive models for the sliding displacement of rigid slopes, and recommended two models: (1) a PGA model that only includes PGA and k_y in the displacement prediction and a (2) PGA, PGV model that includes PGA, PGV, and k_y. Rathje and Saygili (2009) slightly modified the PGA model from Saygili and Rathje (2008) by adding a term related to earthquake magnitude (M). The recommended single (scalar) parameter model is the (PGA, M) model from Rathje and Saygili (2009), and the recommended two (vector) parameter model is the (PGA, PGV) model from Saygili and Rathje (2008). For simplicity, these models are called the SR08/RS09 models.

Figure 2 plots predicted values of D from the SR08/RS09 models as a function of k_y for different earthquake scenarios of M = 6, 7, and 8, each with a site-to source distance (R) equal to 5 km and rock site conditions (i.e., V_{s30} = average shear wave over the top 30 m = 760 m/s) Ground motion parameters for these scenarios were generated using the ground motion prediction equations from the Next Generation Attenuation project for PGA and PGV (the average from 4 different models was used) and using the Rathje et al. (2004) relationship for the Mean Period (T_m). These values are listed in Table 1. Predicted values of D are shown in Figure 2 for both the (PGA, M) and (PGA, PGV) models. Generally, the (PGA, PGV) model predicts smaller displacements than the (PGA, M) model, with the difference as large as 65% for the M=8 scenario. These differences are caused by the fact that the empirical displacement models were developed based on displacements computed from acceleration-time histories recorded on both rock and soil. Because soil motions tend to have larger PGV values than rock motions for the same PGA and the (PGA, M) model does not include the effects of PGV, the (PGA, M) model predicts larger displacements than the (PGA, PGV) model for rock sites. The (PGA, PGV) model does not have the same issue because it uses a PGV as a separate independent variable and thus directly accounts for the differences in PGV for rock and soil motions.

Table 1 Ground motion parameters for each earthquake scenario

M	R (km)	PGA (g)	PGV (cm/s)	T_m (s)
6.0	5.0	0.26	15.1	0.37
7.0	5.0	0.35	30.0	0.45
8.0	5.0	0.42	50.3	0.47

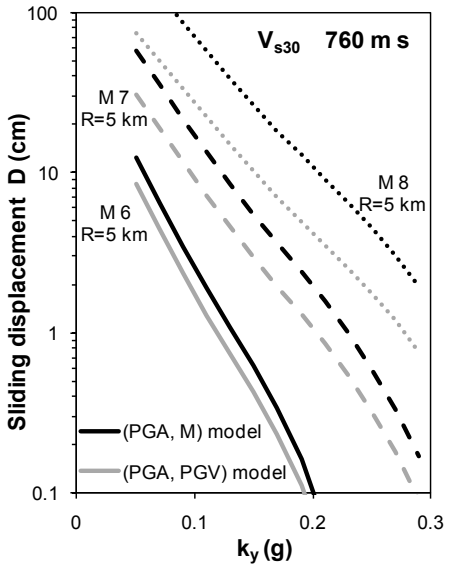

Figure 2 Rigid sliding block displacements calculated from the SR08/RS09 (PGA, M) and (PGA, PGV) models for different earthquake scenarios and site conditions.

In addition to the differences in median displacements from the (PGA, M) and (PGA, PGV) models, there are

significant differences in the standard deviations of the predictions. The standard deviation (σ_{lnD}) for each model increases with increasing k_y/PGA, with values ranging between 0.75 and 1.0 (in natural log units) for the (PGA, M) model (Rathje and Saygili 2009), and values ranging between 0.4 and 0.9 for the (PGA, PGV) model (Saygili and Rathje 2008). Thus, there is significantly less uncertainty in the displacement prediction when PGV is used in the displacement calculation.

One limitation of the SR08/RS09 empirical models is that they only represent rigid sliding block conditions. Rathje and Antonakos (2010) developed a framework similar to SR08/RS09 for flexible sliding conditions and this model is summarized in the next section. Because of the superiority in the (PGA, PGV) model over the (PGA, M) model, only the (PGA, PGV) model will be discussed.

3. MODEL FOR FLEXIBLE SLIDING BLOCK DISPLACEMENTS

3.1 Seismic Loading Parameters for Flexible Sliding Masses

For a rigid sliding mass, the acceleration-time history represents the seismic loading for the sliding mass and this acceleration-time history can be characterized by its PGA and PGV. The recorded acceleration- time history from the GIL067 station during the 1989 Loma Prieta (M=6.9) earthquake is shown in Figure 3(a) (PGA = 0.36 g), and the velocity-time history derived from numerical integration of the acceleration-time history is shown in Figure 3(b) (PGV = 29 cm/s). For a rigid sliding mass subjected to the GIL067 motion, the characteristics of the both the acceleration and velocity time history will influence the level of induced displacement.

The seismic loading for a flexible sliding mass subjected to the GIL067 motion is not the acceleration-time history, because of the dynamic response of the sliding mass. Rather, the seismic loading is the k-time history (e.g., Seed and Martin 1966, Bray and Rathje 1998), which represents the average acceleration within the sliding mass as well as the shear force at the base of the sliding mass. Consider the dynamic response of a 30-m thick sliding mass (H = 30 m) with a shear wave velocity of 250 m/s (V_s = 250 m/s) and associated site period of 0.5 s (T_s= 4H/V_s = 0.5 s). The k-time history for this site, computed using one-dimensional, equivalent-linear site response analysis, is shown in Figure 3(c). Note that the k-time history displays much less high frequency motion than the acceleration-time history due to the averaging of accelerations within the sliding mass. Additionally, its peak value (k_{max}) is smaller than the input PGA (k_{max} = 0.12 g vs. PGA = 0.36 g). k_{max} represents the appropriate seismic loading parameter for this flexible sliding mass.

In the same way that an acceleration-time history is numerically integrated to generate a velocity-time history, the k-time history can be numerically integrated to generate a velocity-time history of the k-time history. This velocity is called k-vel and it provides information regarding the frequency content of the k-time history. The maximum value of the k-vel-time history is called k-vel_{max}. As expected, the k-vel-time history contains less high frequency motion than the velocity-time history. Surprisingly, however, the value of k-vel_{max} (31 cm/s) is similar to the value of PGV (29 cm/s). Because the integrated k-vel-time history is influenced by both the amplitude and frequency content of the k-time history, the increase in long period motion in the k-time history is balanced by the reduction in its peak such that k-vel_{max} is similar in amplitude to PGV.

To use the SR08/RS09 predictive models for flexible sliding blocks, the appropriate seismic loading parameters must be specified. Based on the above descriptions, k_{max} should be used to replace PGA in the SR08/RS09 models and k-vel_{max} should be used to replace PGV. Predictive models for k_{max} and k-vel_{max} are required such that engineers do not need to perform dynamic response analysis to estimate these seismic loading parameters.

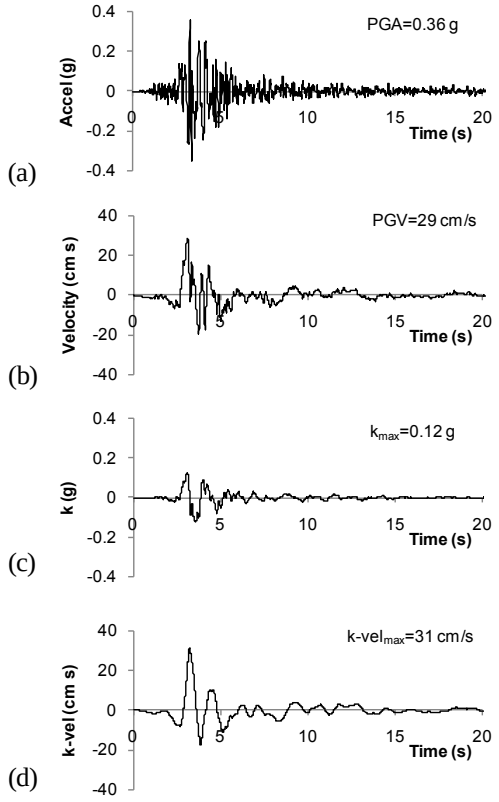

Figure 3 (a) Acceleration and (b) velocity-time histories for a rigid sliding mass, and (c) k-time history and (d) k-vel-time history for a flexible sliding mass with T_s=0.5 s.

3.2 Predictive Models for k_{max} and k-vel_{max}

Predictive models for k_{max} and k-vel_{max} were developed based on one-dimensional site response calculations of five sliding masses subjected to 80 input motions. These calculations were performed using the equivalent-linear site response code Strata (Kottke and Rathje 2008). The sites consisted of one 15-m profile (V_s = 400 m/s), two 30-m profiles (V_s = 400 m/s and 250 m/s) and two 100-m profiles

(V_s = 400 m/s and 265 m/s). The resulting values of site period (T_s) are 0.15 s, 0.30 s, 0.48 s, 1.0 s, and 1.5 s, respectively. The 80 input motions represented motions from earthquakes M = 6 to 7.9 and recorded a distances between 0.1 and 60 km. The input PGA values ranged from 0.02 to 1.0 g, and the input PGV values ranged from 1.2 cm/s to 70 cm/s. k-time histories were computed at the base of each one-dimensional site profile, from which k_{max} and k-vel_{max} values were derived. Further details about the analyses performed can be found in Rathje and Antonakos (2010) and Antonakos (2009).

The computed k_{max} values were normalized by the input PGA and k_{max} / PGA is plotted versus T_s/T_m in Figure 4(a), and several important observations can be made. First, k_{max} / PGA approaches 1.0 as T_s/T_m approaches 0.1. This trend is consistent with k_{max} = PGA for rigid sliding masses, and indicates that T_s/T_m = 0.1 essentially represents rigid sliding conditions. Next, k_{max} is greater than the PGA at moderate period ratios (T_s/T_m = 0.1 to 0.7), while k_{max} is smaller than the PGA at larger period ratios. The data in Figure 4(a) are shown for different ranges of input PGA. These data indicate that the ratio of k_{max} / PGA decreases with increasing input PGA.

A predictive equation for k_{max} / PGA was developed by Rathje and Antonakos (2010) to model these trends. This model predicts $\ln(k_{max}/PGA)$ as a function of $\ln[T_s/T_m]$ and PGA.

For $T_s/T_m \geq 0.1$:

$$\ln(k_{max}/PGA) = (0.459 - 0.702 \cdot PGA) \cdot \{ \ln([T_s/T_m]/0.1) \} + (-0.228 + 0.076 \cdot PGA) \cdot \{ \ln([T_s/T_m]/0.1) \}^2 \quad (1)$$

For $T_s/T_m < 0.1$:

$$\ln(k_{max}/PGA) = 0$$

The standard deviation for this model in natural log units is 0.25. The model predications from equation (1) are shown in Figure 4(a) for PGA = 0.1, 0.3, and 0.7 g. These predictions fit the computed data well. Given the predicted value of k_{max} / PGA and the input motion PGA, k_{max} is estimated.

The additional information required predictive models is for k-vel_{max}. Figure 4(b) shows the computed values of k-vel_{max} normalized by the input PGV and plotted versus T_s/T_m. The k-vel_{max} / PGV data display similar trends to the k_{max} / PGA data. The data indicate k-vel_{max} equal to PGV at very small period ratios ($T_s/T_m \leq$ 0.2 in this case), k-vel_{max} greater than PGV at smaller period ratios (T_s/T_m = 0.2 to 1.5), and k-vel_{max} less than PGV at larger period ratios. The range of period ratios where k-vel_{max} / PGV > 1.0 is larger than the range of period ratios where k_{max} / PGA > 1.0. Again, there is an input amplitude effect, with smaller values of k-vel_{max} / PGV observed at larger values of input PGA. However, this input amplitude effect is not pronounced at smaller period ratios.

A predictive model for k-vel_{max} / PGV was developed by Rathje and Antonakos (2010) with a similar functional form to equation (1). The predictive model for k-vel_{max} / PGV is given by:

For $T_s/T_m \geq 0.2$:

$$\ln(\text{k-vel}_{max}/PGV) = (0.240) \cdot \{ \ln([T_s/T_m]/0.2) \} + (-0.091 - 0.171 \cdot PGA) \cdot \{ \ln([T_s/T_m]/0.2) \}^2 \quad (2)$$

For $T_s/T_m < 0.2$:

$$\ln(\text{k-vel}_{max}/PGV) = 0$$

The standard deviation for this model in natural log units is 0.25. The model predications from equation (2) are shown in Figure 4(b) for input PGA = 0.1, 0.3, and 0.7 g. Again, the predictions fit the computed data well.

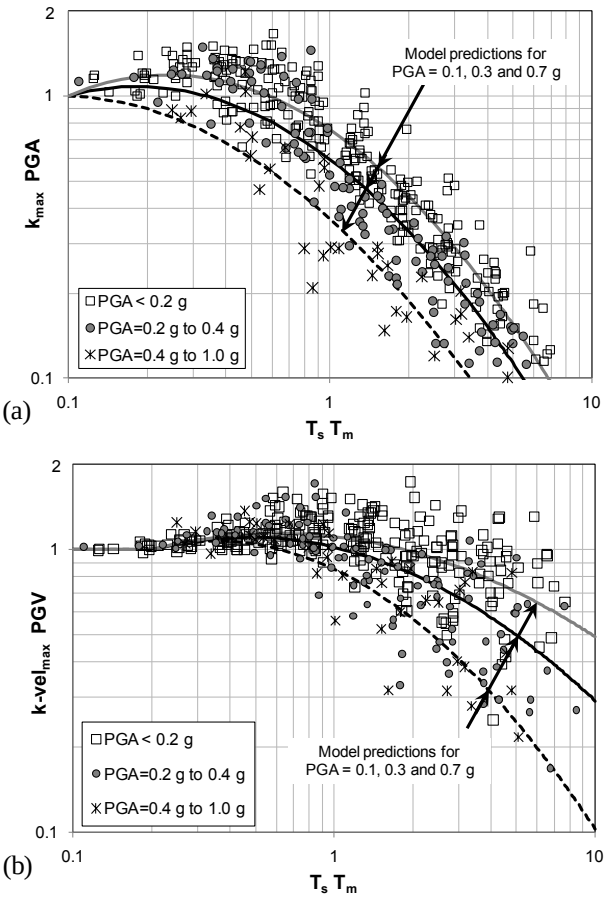

Figure 4 (a) Computed values of k_{max}/PGA vs. T_s/T_m along with model predictions and (b) computed values of k-vel_{max}/PGV vs. T_s/T_m along with model predictions.

Bray and Rathje (1998) developed a predictive model for k_{max} that uses a power law relationship to predict a normalized k_{max} (k_{max} / [NRF·PGA]) as a function of T_s/T_m. The power law relationship results in a log-linear relationship between k_{max} and T_s/T_m for a constant value of PGA. The PGA normalization effectively scales k_{max} linearly with PGA, although the nonlinear response factor (NRF) recommended by Bray and Rathje (1998) takes into account some nonlinear scaling. Bray and Rathje (1998) state that their model is appropriate for T_s/T_m greater than 0.5. Predicted values of k_{max} from equation (1) (Rathje and

Antonakos 2010) are compared to the predictions from Bray and Rathje (1998) in Figure 5 for input PGA values of 0.2 and 0.8 g. For PGA=0.2 g, the Bray and Rathje (1998) predictions agree favorably with Rathje and Antonakos (2010) in the period range of 0.5 to 2.0 where the log-linear shape is most valid. At larger period ratios the Bray and Rathje (1998) model predicts larger values of k_{max}. The second-order polynomial used in Rathje and Antonakos (2010) more accurately models the variation of k_{max} / PGA over a wide range of period ratios. For PGA=0.8 g, the Bray and Rathje (1998) model is consistently larger than Rathje and Antonakos (2010), although the difference is most pronounced at large period ratios. This difference indicates that the NRF factor incorporated in Bray and Rathje (1998) does not model as much soil nonlinearity as Rathje and Antonakos (2010).

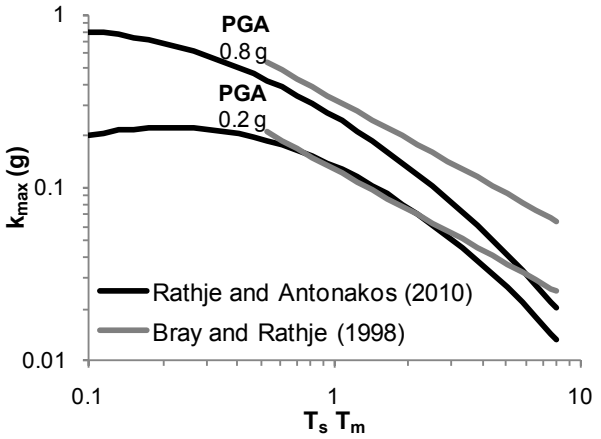

Figure 5 Comparison of k_{max} predictions from Rathje and Antonakos (2010) and Bray and Rathje (1998)

3.3 Predictive Model for Flexible Displacements

Rathje and Antonakos (2010) computed decoupled sliding displacements using the calculated k-time histories for the five sites and 80 input motions (400 time histories). Displacements were calculated for k_y = 0.04, 0.08, 0.12, and 0.16. The resulting dataset included 569 non-zero values of displacement (i.e., instances where $k_y < k_{max}$). Additionally, rigid sliding block displacements were computed for the 80 input time histories and the four values of k_y for comparison with the median values predicted by the SR08/RS09 empirical models.

The Rathje and Antonakos (2010) approach for computing the displacement of a flexible sliding mass is based on first computing the sliding displacement using the SR08/RS09 empirical models with k_{max} used in lieu of PGA and k-vel_{max} used in lieu of PGV. This value of displacement is then further modified based on the period of the sliding mass (T_s). The modifications developed by Rathje and Antonakos (2010) are based on comparisons of the computed displacements from the calculated k-time histories and the predicted displacements from the SR08/RS09 empirical models using the values of k_{max} and k-vel_{max} of the calculated k-time histories. These comparisons showed that the SR08/RS09 empirical models underestimated the sliding displacement of flexible sliding masses such that the displacement must be increased. Rathje and Antonakos (2010) developed modifications for both the (PGA, M) and (PGA, PGV) models, but only the (PGA, PGV) modification is given here. The resulting modification to the SR08/RS09 (PGA, PGV) model to account for flexible sliding is:

For $T_s \leq 0.5$:

$$\ln(D_{flexible}) = \ln(D_{PGA,PGV}) + 1.42 \cdot T_s \quad (3)$$

For $T_s > 0.5$:

$$\ln(D_{flexible}) = \ln(D_{PGA,PGV}) + 0.71$$

where $D_{PGA,PGV}$ represents the median displacement predicted by the (PGA, PGV) SR08/RS09 rigid sliding block model and T_s is the natural period of the sliding mass. For the calculation of $D_{PGA,PGV}$, k_{max} is used in lieu of PGA and k-vel_{max} is used in lieu of PGV. These values can be estimated from equations (1) and (2).

After modification of the displacement predictions, the standard deviation of lnD (σ_{lnD}) was estimated. A linear relationship is used to predict σ_{lnD} for flexible sliding masses for the (PGA, PGV) model:

$$\sigma_{lnD} = 0.40 + 0.284 \cdot k_y/k_{max} \quad (4)$$

4. PREDICTIONS OF SLIDING BLOCK DISPLACEMENT

4.1 Example Application

To illustrate the application of the Rathje and Antonakos (2010) model for predicting the dynamic response and sliding displacement of slopes, consider the following example. The critical sliding mass for a slope is 20-m thick with an average V_s = 400 m/s and resulting T_s = 0.2 s. The k_y is equal to 0.1. The design event is M = 8 and R = 5 km, with the input rock motions described in Table 1. Based on the site and ground motion characterizations, T_s/T_m = 0.43.

Equations 1 and 2 are used to predict k_{max} and k-vel_{max} based on the PGA (=0.42 g), PGV (=50 cm/s), and T_s/T_m (=0.43). Using these values, equation (1) predicts k_{max}/PGA = 0.84, while equation (2) predicts k-vel_{max}/PGV = 1.09. Thus, the seismic loading parameters for this sliding mass are predicted as:

$$k_{max} = 0.84 \cdot 0.42 \text{ g} = 0.35 \text{ g} \quad (5)$$

$$\text{k-vel}_{max} = 1.09 \cdot 50 \text{ cm/s} = 55 \text{ cm/s} \quad (6)$$

Using the seismic loading parameters of k_{max} = 0.35 g and k-vel_{max} = 55 cm/s along with k_y = 0.1, the SR08/RS09 (PGA, PGV) model predicts 23.7 cm. This value then is adjusted using the modification for flexible sliding given in

equation (3). For T_s = 0.2 s, the modification from equation (3) is:

$$\ln(D_{flexible}) = \ln(23.7\text{ cm}) + 1.42 \cdot 0.2 \quad (7)$$

This expression predicts a median displacement value of 31.5 cm for flexible sliding conditions. In all cases, the modification in equation (3) increases the displacement.

To estimate the + 1 standard deviation displacement, the standard deviation (σ_{lnD}) is estimated from equation (4). For this example k_y = 0.1 and k_{max} = 0.35 g, which results in k_y/k_{max} = 0.28. Using equation (4), σ_{lnD} =0.48 and the resulting +1 σ_{lnD} displacement is:

$$\ln(D_{flexible,\,+1\sigma lnD}) = \ln(D_{flexible,median}) + \sigma_{lnD} \quad (8)$$

$$\ln(D_{flexible,\,+1\sigma lnD}) = \ln(31.5) + 0.48 \quad (9)$$

$$D_{flexible,\,+1\sigma lnD} = 50.9\text{ cm} \quad (10)$$

4.2 Comparison with Previous Models

Bray and Travasarou (2007) also developed a model to predict the sliding displacement of rigid and flexible slopes. This model uses only a single ground motion parameter to characterize the seismic loading, $S_a(1.5T_s)$, which is defined as the input rock response spectral acceleration at a period equal to 1.5 times the natural period of the sliding mass. The seismic loading parameter for the sliding mass (i.e., k_{max}) is not computed directly in this approach, such that the condition of $k_y \geq k_{max}$ (i.e., no sliding and D = 0 cm) is not explicitly checked. To circumvent this issue, Bray and Travasarou (2007) include a statistical model for the probability that the displacement is equal to zero (i.e., $k_y \geq k_{max}$) that is a function of k_y and $S_a(1.5T_s)$.

Median sliding displacements were computed using both the Rathje and Antokankos (2010) and Bray and Travasarou (2007) models for comparison. These displacements were computed for two ground motion scenarios (M=7, R=5km and M=8, R=5 km) and two values of k_y (0.05 and 0.1) over a range of T_s equal to 0.0 to 1.0 s. For the Rathje and Antonakos (2010) calculations, the required input ground motion parameters are PGA and PGV, and they are given in Table 1 for the earthquake scenarios. The Bray and Travasarou (2007) model requires $S_a(1.5T_s)$, such that the full input acceleration response spectrum was computed using the Next Generation Attenuation project ground motion prediction equations. $S_a(1.5T_s)$ was computed for each value of T_s by linear interpolation of the acceleration response spectrum around the period of $1.5T_s$.

Figure 6 shows plots of the displacements predicted by the two models as a function of T_s. These displacement spectra show how the flexible sliding block displacements vary with T_s for a given ground motion scenario and k_y. For both models the displacement spectra show that the maximum displacement occurs at T_s around 0.1 s to 0.2 s. In this period range the dynamic response of the sliding mass increases the seismic loading, which results in more displacement. As T_s increases beyond 0.2 s, the seismic loading starts to decrease and the resulting displacements also decrease.

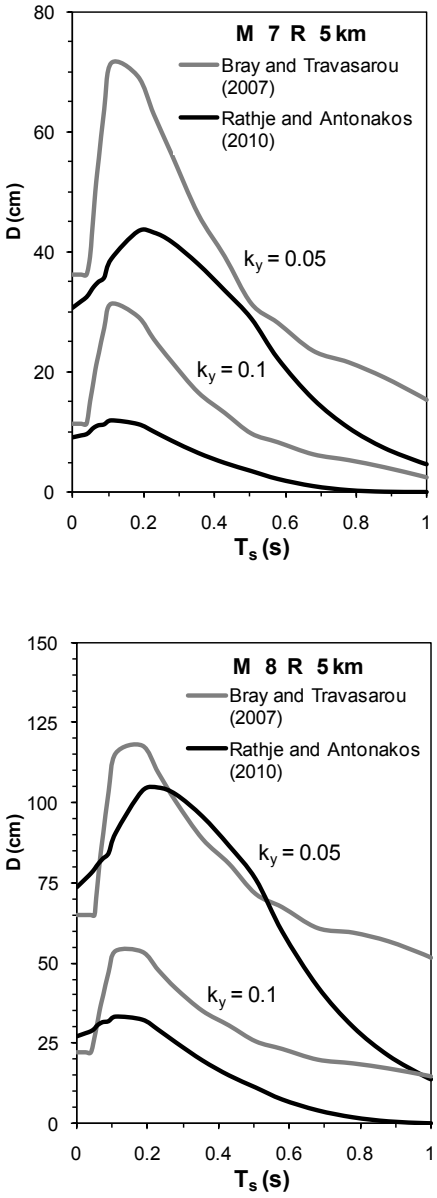

Figure 6 Comparison of displacements from Rathje and Antonakos (2010) and Bray and Travasarou (2007) models

Figure 6 generally shows that Bray and Travazarou (2007) model predicts larger displacements than Rathje and Antonakos (2010) model. At the period of peak displacement, the Bray and Travasarou (2007) model predicts between 1.3 times larger displacement (M=8, R=5 km, and k_y = 0.05) and 2.6 times larger displacement (M=7, R=5 km, and k_y = 0.1) than the Rathje and Antonakos (2010) model. This large difference at the peak is controlled by the very steep increase in displacement that occurs between Ts = 0.0 and 0.2 s for the Bray and Travasarou (2007) model. The maximum difference between the two models occurs at longer periods, where the Rathje and Antonakos (2010) model tends towards zero displacement and the Bray and

Travasarou (2007) maintains relatively large values (Figure 6). The predictions of k_{max} from Rathje and Antonakos (2010) indicate that the displacements should tend towards zero here because k_{max} becomes close to, or less than, k_y. While Bray and Travasarou (2007) attempt to account for this issue by predicting the probability that the displacement is equal to 0.0, this probability never exceeded 0.3 for the cases considered here. For the median displacement to be equal to zero, this probability would need to be equal to or greater than 0.5.

The differences in the displacements predicted by the Rathje and Antonakos (2010) and Bray and Travasarou (2007) models are a function of various features of the two models. The more distinct peak produced by the Bray and Travasarou (2007) model is caused by the use of the spectral acceleration as the input ground motion parameter. The maximum spectral acceleration is typically about 2.0 to 2.5 times larger than the PGA, such that the seismic loading at $T_s \sim 0.1$ to 0.2 s is significantly larger than it is at $T_s = 0.0$ s and leads to a rapid increase in displacement with increasing T_s. The increase in seismic loading with T_s for the Rathje and Antonakos (2010) model is more gradual, as shown by the k_{max}/PGA data in Figure 4, and thus the model predicts a more gradual increase in displacement with increasing T_s. The larger displacements predicted by the Bray and Travasarou (2007) model may be a result of using only one ground motion parameter (i.e., $S_a(1.5T_s)$) in the predictive equations and using rock and soil motions to compute the sliding displacements upon which the model is based. Rathje and Antonakos (2010) observed that the Saygili and Rathje (2009) model that uses (PGA, M) predicted larger displacements than the (PGA, PGV) model, and ascribed this difference to the fact that the (PGA, M) model did not adequately account for frequency content differences between rock and soil motions. While $S_a(1.5T_s)$ certainly provides more frequency content information than PGA, it appears that it does not provide as much information as PGV.

5. CONCLUSIONS

This paper summarizes recent work by Rathje and Antonakos (2010) to develop a unified empirical model to predict the sliding displacements of rigid and flexible sliding masses. The unified model is an extension of the empirical models for rigid sliding masses developed by Saygili and Rathje (2008) and Rathje and Saygili (2009). The main advancements contributed by the SR08/RS09 models include: (1) the addition of a frequency content parameter (PGV) to better predict displacements and (2) a better description of the standard deviation associated with the prediction of sliding displacements. This paper focused on summarizing and comparing the Rathje and Antonakos (2010) based that is based on (PGA, PGV).

The unified approach involves first predicting the seismic loading parameters for a potential sliding mass, and then using these seismic loading parameters to predict sliding displacement. The seismic loading parameters are given by k_{max} and k-vel_{max}, defined as the maximum value of the k-time history and the maximum velocity of the k-time history, respectively. The predictive model for k_{max} is a function of PGA and T_s/T_m and the predictive model for k-vel_{max} is a function of PGV, PGA, and T_s/T_m. To predict sliding displacement, k_{max} is used in lieu of PGA and k-vel_{max} is used in lieu of PGV in the SR08/RS09 (PGA, PGV) model.

In addition to the change in seismic loading parameters, the SR08/RS09 (PGA, PGV) model must be further modified to account for the differences in frequency characteristics between acceleration-time histories and k-time histories. This modification is a function of T_s and increases the predicted displacement.

Comparisons between the Rathje and Antonakos (2010) model and a previously published model of Bray and Travasarou (2007) show that the Rathje and Antonakos (2010) model predicts smaller displacements, in general. These smaller displacements result from the important frequency content information provided by PGV.

APPLICATION OF DISCRETE ELEMENT METHOD IN GEOGRID AND AGGREGATE INTERACTION IN A REINFORCED UNPAVED ROADWAY

Wen-Chao Huang

Assistant Professor, Department of Civil Engineering, National Central University, Jhongli City, Taiwan
wenchaoh@ncu.edu.tw

Abstract: For wet or soft subgrades in an unpaved roadway system, it is usually difficult for the roadway to meet design expectation due to high potential of excessive rut depth. One way to treat the wet or soft subgrade condition is to employ geogrid reinforcement in the unpaved roadway system. In this study the interaction between geogrid and aggregate material was investigated through discrete element method. The aggregate material in the discrete element model is assumed to be consisted of cylinders, while due to the reinforcing characteristic of geogrid reinforcement, it is assumed to be consisted of unmovable grids.
Results showed that the inclusion of geogrid reinforcement at the interface of aggregate layer and the subgrade layer limits the lateral movement of the aggregate material, while when no geogrid reinforcement was included in the roadway system, the deformation of the aggregate layer shows pattern of lateral and upward movement. Due to the patterns and amounts of movement observed in the models, the deformation expressed at the surface of the aggregate layer has shown improvement comparing to unreinforced model.

1. INTRODUCTION

The presence of wet or soft subgrade soils in roadway construction has been a major issue of concern in the geotechnical area for a long time. What is generally meant by wet or soft subgrade in this study is a soft soil deposit that constitutes a poor foundation for roadways, because of its fine grain size and high water content associated with low density. Such characteristics result in high deformability, low permeability, and low shear strength. In consequence, the bearing capacity of these subgrades is very low. For pavements built on such poor foundation conditions, this lead prematurely to excessive permanent deformation, rutting, and cracking. Currently, the methods to address wet and soft subgrade conditions include excavation-substitution, soil improvement with chemical additives, and mechanical reinforcement with geosynthetics. In particular, the use of geosynthetics, such as geotextiles and geogrids, is a practice that has been used since the 1970s. The study presented in this paper is devoted to the use of geogrids in unpaved roads.

Geogrids are large aperture meshes made of plastic polymers. They are placed horizontally on the subgrade and backfilled with compacted aggregate. As a tensile-resistant reinforcement, geogrids can provide mechanical support and added stiffness to the aggregate layer. Geogrid reinforcement spreads the load more broadly to the subgrade, thus improved performance in terms of bearing capacity and deformation is achieved.

In this study, application of discrete element method (DEM) to examine the mechanisms of geogrid reinforcement is proposed. From the microscopic view of the aggregate particles in the sense of discrete element method, the reinforcing mechanisms such as lateral restraint, and the enhanced stiffness of the aggregate layer is easily to be observed with the installation of geogrid reinforcement. The main reinforcing mechanisms of the geosynthetic reinforcement are discussed in the following section.

2. REINFORCING MECHANISMS

2.1 Tensile Membrane

The tensile membrane effect (Figure 1) is a major mechanism in weak subgrade reinforcement. Application of concentrated vertical load to the aggregate layer surface produces compression of the subgrade. As a result, the geosynthetic deflects and tensile forces are developed. This provides additional vertical support to the aggregate and lightens pressure on the subgrade. Tensile membrane effect can also contribute to spreading vertical load over a wider area of subgrade and, consequently, increasing the bearing capacity.

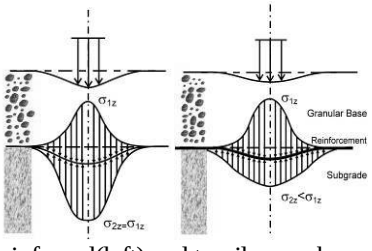

Figure 1 Unreinforced(left) and tensile membrane effect in reinforced case(right)

A number of analytical or numerical models have been proposed to quantify this mechanism in two dimensional plane strain conditions. Analyses suggest the tensile membrane effect would be maximized when high modulus geosynthetics are used and the subgrade is very soft (Bourdeau, 1989). Miura et al. (1990) performed laboratory tests to investigate the influence of geogrid tensile modulus. According to their experimental results, improved performance was related to the magnitude of strain measured in the geogrid during loading. Field test results also showed that the improvement was obtained in terms of rut depth reduction when using higher modulus geogrids, although not to the same level as would be obtained from the laboratory tests.

2.2 Lateral Restraint

Lateral restraint (Figure 2) is a reinforcement mechanism that does not require geosynthetic deflection. Under the vertical compressive pressure, particles in the aggregate layer and the soft subgrade tend to spread away from the loaded area. If the geosynthetic has sufficient interface shear resistance and tensile stiffness, friction or tangential interaction between soil and geosynthetic counteract this movement of the particles. This induces tension in the geosynthetic and enhances lateral confining stresses in the aggregate layer and the subgrade. Because confining stresses are increased, compressive stiffness and resistance of both the aggregate layer and the subgrade are improved by the lateral restraint mechanism. It was shown using X-ray radiography of reinforced soil experiments that the tensile membrane and lateral restraint actions are not independent from each other but they can develop simultaneously in two-layer systems reinforced at the interface. (Bourdeau et al. 1990) Lateral restraint was also recognized as a major function of reinforcement in multilayered reinforced soil. (Bourdeau and Ashmawy, 2002) In a recent case study of reconstructed road where geosynthetic composites were installed, it was observed that the enhanced confinement of aggregate contributed to reduction of the rut depth (Al-Qadi et al., 2000).

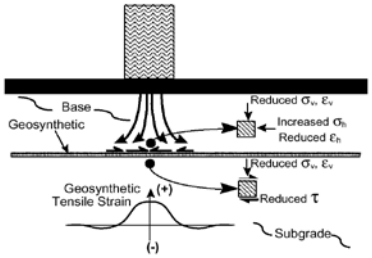

Figure 2 Principle of lateral restraint action (modified from Perkins, 1997)

2.3 Passive Anchorage

Passive anchorage is a necessary condition for tensile membrane effect as well as lateral restraint to develop effectively. Tensile forces in the geosynthetics need to be balanced by mobilized anchorage resistance. Interface shear resistance is a combination of surface friction and grain/geosynthetic interlock. Pullout tests are used for simulating and quantifying in the laboratory soil-geosynthetic interaction in the passive anchorage zone. Laboratory test suggests that the tensile strain in a geogrid decreases, due to anchorage effect, with increasing radial distance from the loading plate to approximately twice the radius of the plate, i.e. 10 to 15 in (Haas et al. 1988). Thus, relatively short anchorage length is sufficient to allow tensile forces be mobilized in a geogrid. However, this is not the case with geotextile reinforcement where longer anchorage length may be needed because interface shear strength between geotextile and soil is typically lesser than that of a geogrid with interlocking aggregates.

2.4 Interlocking of Aggregate and Geogrids

Interlocking of aggregate and geogrid as shown in Figure 3 can be effective under cyclic loading due to traffic. With repetitive loadings from the surface, the aggregate particles are rearranged and moved to a denser state. The relative size of aggregate material and geogrid openings are needed to be properly chosen such that the interlocking can be developed effectively.

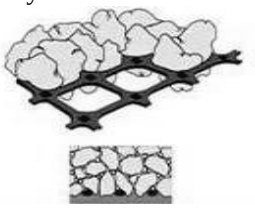

Figure 3 Interlocking of aggregate and geogrid

Additional compaction effort can also be achieved when the interlocking between aggregate and geogrid is formed. As aggregate particles are stuck inside the apertures of geogrid, the tensile membrane effect provides lateral restraint as mentioned previously; hence the resultant stress acted on the subgrade clay layer is reduced. The consequence of this condition is that the excessive pore water pressure induced by the stress increment after each cycle of loading on subgrade clay layer can be dissipated in a more effective way; therefore the subgrade clay layer can become stronger with effective compaction behavior.

3. MODEL FORMULATION

Because of the enhancement effect from geogrid reinforcements to the aggregate layer which consisted of mostly individual particles, it is of interest to investigate the effects through the application of discrete element method (DEM). The advantage of employing DEM in the unpaved roadway system is that the aggregate material behaves like a number of individual cylinders. The reinforcing mechanisms as mentioned in section 2 are therefore to be investigated through the observation of aggregate cylinder movements both qualitatively and quantitatively under either unreinforced or reinforced cases. The commercial software - Particle Flow Code 2D (PFC 2D) developed by Itasca, Inc. is employed for analysis in this study. Due to the nature of two dimensional analysis of PFC 2D, we have assumed that the particles and walls are cylinders and plates, which may

not be a perfect modeling of the real case. However, the 2D analysis result can provide an insight toward the behavior of the aggregate material with geogrid reinforcement installed.

To simplify the unreinforced/reinforced condition in the discrete element model, the following models are established for analyses:

(a) aggregate particles rest on a frictional surface.
(b) aggregate particles rest on a series of continuous small particles.
(c) aggregate particles rest on pairs of smaller particles which is not subject to move in both the horizontal and vertical directions. This case is used to simulate the geogrid reinforced case.

The particles as mentioned above are simulated as cylinders in the models and generated randomly in a predetermined space (formed by boundaries – or walls), and then gravity force is applied to the system in order to simulate the effect of geostatic stress, another wall with limiting width simulating the foundation footing is moving downward at a certain velocity within a period of time until a given distance is achieved.

The geometry of the discrete element model is illustrated in Figure 4. The aggregate layer consisted of 300 cylinders with radius ranging from 0.14 m to 0.28 m. The grids are assumed to be consisted of a series of two smaller cylinders with radius 0.1 m. The spacing of the grid is 1.2 m (center to center).

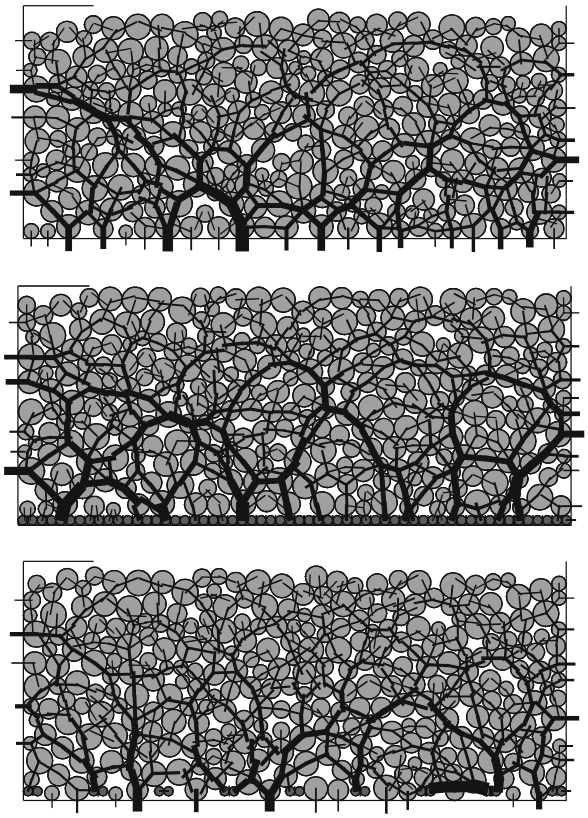

Figure 4 Discrete element model with gravity force applied (top: control model, unreinforced; middle: unreinforced case; bottom: reinforced case)

The velocity of the loading plate is 0.5 mm/sec downward. Due to the requirement of stabilization of the discrete element modes, a total number of 1500 time steps for the unreinforced case and 8000 time steps for the reinforced case are applied to whole system. The contact forces generated during the "loading" period are then recorded and discussed, as well as the moving direction of each particle especially those below the foundation footing.

4. RESULTS AND DISCUSSION

4.1 Contact forces

After the gravity force is applied to the system, it is found that the contact forces (shown in the figure as black lines) are increasing with depth, as shown in Figure 4 under different cases. Out of the three cases shown in Figure 4, the reinforced case showed stress concentration above some geogrid locations. Due to this condition, the induced gravity force was also reduced in the locations adjacent to stress concentration areas, and thus the stress transferred to the subgrade layer is also reduced.

After force equilibrium is achieved in the gravity-applied system, the loading plate is then lowered at a constant speed and the development of contact forces between cylinders is recorded as shown in Figure 5. In the unreinforced case, the stress is distributed within a wider range and concentrated at the corner of the loading plate. In the reinforced case, the contact forces are more concentrated, especially under the loading plate. Most of the contact forces are balanced by the geogrid reinforcement in the reinforced cases, while in the unreinforced case, the forces are balanced by the cylinder-wall friction which is not as effective as in the reinforced case.

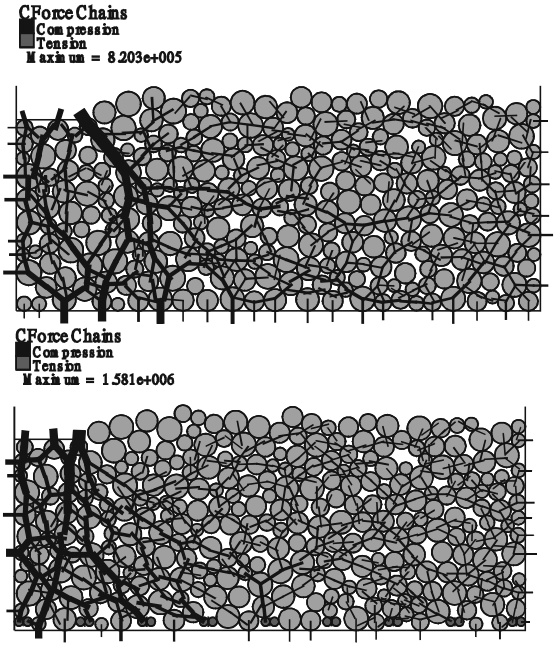

Figure 5 Contact forces in unreinforced (top) and reinforced cases (bottom)

The forces are recorded when similar plate displacements are achieved. In the unreinforced case, the

maximum contact force is about 820 kN at the edge of the loading plate. In the reinforced case, the maximum contact force is 1483 kN, which is evenly distributed below the loading plate. From the examination of contact forces developed in the above cases, it is therefore understood that the induced stiffness (equivalent of force divided by displacement) in the reinforced case is much larger than that in the unreinforced case. In the reinforced case, due to the limitation of lateral movement of the geogrid cylinders, the forces are balanced by the reaction provided by the geogrid reinforcement.

From the above results, we have expected that the reinforcing mechanisms from geogrid reinforcements are therefore developed gradually. First of all, with gravity force before the external loading is applied to the system, some of the contact forces are already balanced by the geogrid reinforcement (Figure 4 bottom one, the arching effect on the right). The location might be random; however, this condition can reduce the potential stress increment onto the subgrade clay layer. Secondly, as the loading plate is moving downward onto the aggregate layer, the contact forces are balanced by the geogrid with the particles directly above it. Since the local stiffness of the aggregate material is enhanced due to geogrid reinforcement, the propagation of enhanced stiffness of the aggregate material is moving upward to the area below the loading plate as the loading plate is pushed down further. This procedure creates a limited force-concentrated area compared to the unreinforced case. In this area, the local stiffness is enhanced significantly due to the geogrid reinforcement.

As mentioned above, the requirement for interlocking of aggregate particle and the geogrid reinforcement is needed to ensure the effectiveness of geogrid reinforcement. Without effective interlocking of aggregate particles and geogrid aperture, lateral restraint and tensile membrane effect cannot be activated sufficiently. In order for the geogrid reinforcement to have the most beneficial effect, proper aperture opening size and aggregate size needs to be chosen accordingly, a common suggestion is to make sure that the aggregate size is about 1/2 to 1/3 of aperture opening size. (AASHTO)

4.2 Particle movements

In the previous section, the contact forces for unreinforced and reinforced cases are discussed. When taking a look at the displacement vector in the cases shown in Figure 6, it is found that for all the cases, the cylinders that are right outside the loading plate have a tendency to move counterclockwise, the only different phenomenon that has been observed is the range of the heaving of the particles close to the surface. In the unreinforced control case, the overall heaving of the particles extends to a greater depth and extends more horizontally to the right (this can be observed from the vector at the bottom of the unreinforced case). In the unreinforced case with fine particles below, the aggregate particles that are moving outward extend to almost the boundary of the model while in the reinforced case, the moving particles extend to only half of the space and the remaining particles almost remain immobilized.

The most important effect of the geogrid reinforcement can be observed in this analysis as well. From the vectors of the unreinforced case, it is found that at the bottom of the model, a noticeable horizontal displacement can be observed, in the controlled unreinforced case, it even extends more to the right. In the reinforced case, it is found that the "lateral restraint effect" of the reinforcement has most significant effect below and right outside of the loading plate. Although the assumption of the "geogrid reinforcement" which is consisted of several "unmovable cylinders" may not be realistic in the actual practice, it provides us an insight from this extreme case.

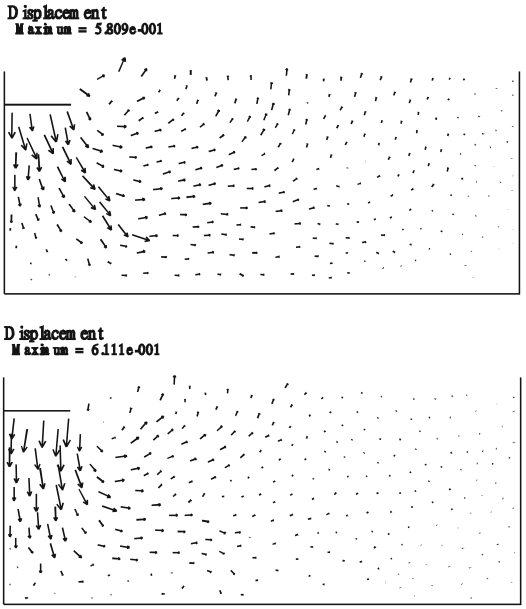

Figure 6 Displacement vector of aggregate cylinders (top: unreinforced; bottom: reinforced case)

When observing from the particle moving directions, it is shown that in the reinforced case, especially the rectangular area under the loading plate, most of the particles are confined horizontally, i.e. only vertical movements are permitted during loading. This condition explains the effect of lateral restraint and its consequences of enhanced confinement. As mentioned previously, the particles that are stuck in the geogrid apertures are confined laterally and vertically. As loading plate is moving downward, the lateral and vertical movement of the particles is less-limited such that particles below the loading plate started to express some degree of vertical and horizontal displacement. This condition can be observed apparently when comparing unreinforced and reinforced cases.

4.3 Contamination of particles

One condition that can deteriorate the performance of the unpaved roadway system is the contamination of subgrade clay layer and aggregate base layers. When finer particles penetrate into the voids of coarse particles, the original friction angle of the aggregate layer can be reduced significantly. Moreover, the drainage function of the aggregate layer can be hindered when clogging condition initiates. However, with the geogrid reinforcement installed at the interface of aggregate and subgrade clay layer, the

interlocking of the aggregate particle and the geogrid aperture may prevent the fine particles from moving upward, and thus the friction angle of the aggregate particles could be retained.

A DEM model is assumed to consist of a finer subgrade layer with 600 cylinders and an aggregate base layer with 100 cylinders. In order to simulate the pumping of fine particles, we have assumed that the fine particles are moving upward, that is, by moving the bottom of the boundary upward, as shown in Figure 7. The openings of the geogrid reinforcement are assumed to consist of a series of two small cylinders with radius 0.1 m. The spacing of the openings is 1.2 m (center to center). Unreinforced and reinforced cases are analyzed in order to compare the results qualitatively. The unreinforced case is achieved by just eliminating the cylinders that represent the geogrids, as shown in the top one of Figure 7. The amount of movement of the wall is kept constant so that the illustrations are comparable.

It is found both in the unreinforced and reinforced cases that the finer cylinders cannot move any further upward since they are blocked by coarser cylinders which represent the aggregate material, only a small amount of the finer cylinders squeezed into the voids that are at the interface, no other finer cylinders moved upward beyond this boundary. In terms of the "contaminated" zones in these two cases, in the reinforced case it is found that the contaminated zone is wide-spread all over the interface while in the reinforced case, the "contaminated" zones are somehow confined by the grids as can be seen in the bottom one of Figure 7 that some of the aggregate particles get stuck between the grids and this provides a barrier to prevent any other aggregate particles around that zone from moving down.

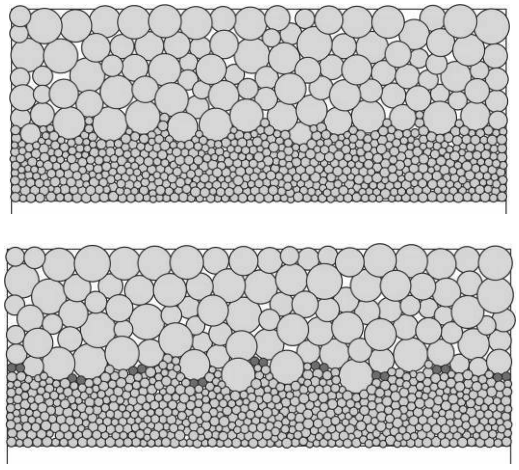

Figure 7 Fine particle movements in unreinforced (top) and reinforced (bottom) cases

This simulation of pumping of fine particles may not be too realistic since the ratio of void size in the coarser layer to the size of the finer layer is chosen due to the analysis limitation of the software in this study. Meanwhile, the loading is a load-unload mono cycle procedure that the contamination behavior of the soils may be more significant when more cycles of loading are applied. However, this simulation gives an idea about how the grids play a role to maintain the aggregate particles (by forming an arched zone) and prevent the particles above it from moving down into the subgrade layer, and vice versa. Although in Figure 7 not all the aggregate particles are retained by the geogrids in the reinforced case, the contaminated zone is somehow confined due to the presence of the geogrids.

5. CONCLUSIONS

A common approach to improve the performance of the unpaved roadway system with soft subgrade is to install geogrid reinforcement. Typically the incompetent soft subgrade clay material can be excavated partially, and a certain amount of aggregate material is backfilled with geogrid reinforcement positioned on top of the aggregate material. After this step is completed, another layer of aggregate material is placed and compacted.

As mentioned previously, the reinforcement effect provided by geogrid in the unpaved roadway system comes from several mechanisms: (1) tensile membrane effect; (2) lateral restraint; (3) passive anchorage and (4) interlocking of aggregate material and geogrid openings. In this study, the discrete element method (DEM) is used to analyze the mechanisms of geogrid reinforcement in an unpaved roadway from the viewpoints of individual particles of both the aggregate and geogrid material.

First of all, from the resultant contact forces recorded below the loading plate when comparing the unreinforced and reinforced cases, an approximate 50% increase of contact force to reach similar plate settlement is required for the reinforced case. Therefore, the local stiffness of the reinforced case was increased significantly when geogrid reinforcement is added. What was meant by local stiffness is that for reinforced case, most of the increased contact forces between cylinders were located right below the loading plate, only in the area below the loading plate and close to the geogrid reinforcement can we find the enhanced area extended slightly outward.

When checking from the movements of the cylinders, it is found that in the reinforced case, the aggregate cylinders tend to move within a limited range in the area under the loading plate both horizontally and vertically. Due to the assumption that the geogrid (which is consisted of unmovable cylinders) has very high stiffness, the aggregate cylinders are stuck (interlocked) in the apertures of the geogrid with very minor lateral deformation. When interlocking of aggregate material and geogrid aperture is formed at the interface, progressive interlocking between aggregate cylinders is initiated such that an enhanced confinement effect of the aggregate layer is appeared. The above condition explains that a higher resultant contact force may be required to reach similar plate settlement in the reinforced case.

Another effect of geogrid reinforcement in the system is to prevent the contamination of the coarse and fine particles. With the interlocking effect of the geogrid reinforcement, the aggregate material forms a barrier such that the finer clay particles have fewer tendencies to penetrate into the aggregate layer above. Meanwhile, the aggregate material was also retained on the geogrid apertures to prevent the clay

layer from being contaminated.

To ensure the best effect of the geogrid reinforcement, relative sizes of aggregate material and geogrid apertures need to be properly chosen such that interlocking can be initiated at the interface. With the propagation of enhanced areas that contain confined aggregate material, the local stiffness of the aggregate material is increased below the loading plate, and therefore the resulting settlement can be reduced.

Abstract: In order to verify the applicability of strain space multiple mechanism model based on finite strain (both total Lagrangian (TL) and updated Lagrangian (UL)) formulations, seismic response analyses are performed on Breakwater No.7 in Kobe Port during 1995 Hyogoken-Nanbu earthquake. Both infinitesimal and finite deformation analyses are performed to examine the effect of geometrical nonlinearity. As an input dilatancy parameter in the model, two types of undrained shear strength (20 kPa and 40 kPa) are adopted according to the results of undrained triaxial compression tests. The settlements at the top of the caisson in the infinitesimal deformation analyses are 3.62 m and 2.89 m for the undrained shear strength of 20 kPa and 40 kPa, both of which exceed the upper limit of measurements (2.6 m). In contrast, the computed settlements in the TL/UL formulations with the undrained shear strength of 20 kPa and 40 kPa are 2.46/2.46 m and 1.93/1.88 m, respectively, both of which fall inside the measured range (between 1.4 and 2.6 m). The results confirm that the TL and UL formulations are numerically equivalent and the effect of geometrical nonlinearity has to be accurately considered in predicting the seismic response of port structures such as breakwaters.

1. INTRODUCTION

During the Hyogoken-Nanbu earthquake of 1995, Kobe Port was shaken by a strong ground motion having peak ground accelerations of 0.54 and 0.45 g in the horizontal and vertical directions, respectively (Inagaki et al., 1996). Many port structures in Kobe Port, most of which were classified into a rigid block type made of concrete caissons, were damaged. Caisson type quay walls moved up to 5 m toward the sea. Composite breakwaters settled down about 2 m without significant horizontal movement.

Japan has been repeatedly hit by major earthquakes such as Tokachi-Oki (2003) and Niigata Chuetsu (2004) earthquakes after the Hyogoken-Nanbu earthquake. In the next 30 years, it is predicted that Japan will be hit by some major earthquakes (e.g., Tokai and Tonankai earthquakes), which are likely to cause serious damage to port structures. In order to propose effective measures against such major earthquakes, it is very important to predict the damage of port structures due to major earthquakes accurately and verify their seismic performance appropriately.

In order to estimate the seismic damage, various simplified methods have been proposed. However, most of such simplified methods, in which the action of soil is idealized through earth pressure, subgrade reaction force and bearing capacity, can't directly take into account the characteristics of earthquake motion and the variation in soil behavior due to liquefaction. Actual seismic response of port structures, in particular, is a result of dynamic soil-structure interaction, which is much more complicated than considered in such simplified methods. The soil behavior should be interpreted through the dynamic soil-structure interaction process due to earthquake shaking.

Effective stress analysis by finite element method is one of effective means for taking into account the complex behavior of soil. In particular, a strain space multiple mechanism model can take into account the effect of rotation of principal stress axis directions, the effect of which is known to play an important role in the cyclic behavior of sand (Iai et al., 1992). However, the formulation of this model has been carried out based on the infinitesimal strain theory, and thereby the model has difficulty in analyzing large deformation and rotation. This is why the strain space multiple mechanism model has been extended based on two types of finite strain formulations (total and updated Lagrangian) to take into account the effect of geometrical nonlinearity for large deformation analyses (Ueda, 2009; Iai et al., 2010c).

The objective of this study is to examine how well the model, which has capability to take into account the effect of geometrical nonlinearity, can simulate the induced damage to Breakwater No. 7 in Kobe Port during 1995 Hyogoken -Nanbu earthquake and to verify the applicability of the model to seismic response of port structures.

2. SUMMARY OF DAMAGED BREAKWATER

Breakwater No. 7, which is the target of numerical simulation in this study, is located south of Rokko Island in Kobe Port as shown in Fig. 1. A typical cross section and deformed configuration of the breakwater are shown in Fig. 2. The breakwater is a composite type, which consists of a concrete caisson installed on foundation rubble without backfill and embedment, and was constructed on decomposed granite soils, which were backfilled into the area excavated from the original alluvial clay layer. The clay layer reaches a thickness of up to 25 m at the southern front, in which Breakwater No.7 is located, in Kobe Port. During 1995 Hyogoken-Nanbu earthquake, the breakwater induced the settlement of about 1.4 m to 2.6 m. However, the horizontal displacements of the breakwater were less than tens of centimeters. The deformation configuration suggests that the caisson was settled down into the foundation rubble due to the liquefaction or degradation of the loose deposit and the gravity force of the caisson itself, and the settlement also dragged down the rubble and pushed it into the loose deposit below it.

3. CONSTITUTIVE MODEL OF SOILS

3.1 Generalized Multiple Mechanism Model Based on Infinitesimal Deformation Theory

An effective stress model proposed by Iai et al. (1992), which is called "Multiple mechanism model", has been extended as a generalized form, which is called "Cocktail glass model", by introducing a new stress-dilatancy relationship (Iai et al., 2010a and b).

With the effective stress and strain vectors in plane strain condition expressed as

$$\boldsymbol{\sigma}' = \left\{ \sigma'_x \quad \sigma'_y \quad \tau_{xy} \right\}^{\mathrm{T}} \tag{1}$$

$$\boldsymbol{\varepsilon} = \left\{ \varepsilon_x \quad \varepsilon_y \quad \gamma_{xy} \right\}^{\mathrm{T}} \tag{2}$$

the integrated form of the constitutive relation is given by

$$\boldsymbol{\sigma}' = -p\mathbf{I} + \sum_{i=1}^{I} q^{(i)} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \Delta\omega \tag{3}$$

$$\left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle = \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} + \mathbf{n}^{(i)} \otimes \mathbf{t}^{(i)} \tag{4}$$

where p denotes effective confining pressure (isotropic stress), $\mathbf{I}$ denotes second order identity tensor, q denotes virtual simple shear stress, $\mathbf{n}$ denotes a unit vector along the direction of the branch between the particles in contact with each other, $\mathbf{t}$ denotes a unit vector normal to $\mathbf{n}$.

The volumetric strain ε and the virtual simple shear strain γ are defined as follows:

$$\varepsilon = \mathbf{I} : \boldsymbol{\varepsilon} \tag{5}$$

$$\gamma^{(i)} = \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle : \boldsymbol{\varepsilon} \tag{6}$$

where the double dot symbol defines double contraction. In order to take into account the effect of volumetric strain due to dilatancy ε_{d}, effective volumetric strain ε' is introduced by

$$\varepsilon' = \varepsilon - \varepsilon_{\mathrm{d}} \tag{7}$$

Dilatancy in Equation (7) is decomposed into contractive component $\varepsilon_{\mathrm{d}}^{\mathrm{c}}$ and dilative component $\varepsilon_{\mathrm{d}}^{\mathrm{d}}$ as

$$\varepsilon_{\mathrm{d}} = \varepsilon_{\mathrm{d}}^{\mathrm{c}} + \varepsilon_{\mathrm{d}}^{\mathrm{d}} \tag{8}$$

The time derivative of both sides of Equation (3) yields the incremental constitutive equation as follows:

$$\dot{\boldsymbol{\sigma}}' = \mathbb{C} : \dot{\boldsymbol{\varepsilon}} \tag{9}$$

where

$$\begin{aligned} \mathbb{C} = {} & K_{\mathrm{L/U}} \mathbf{I} \otimes \mathbf{I} + \sum_{i=1}^{I} G_{\mathrm{L/U}}^{(i)} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \otimes \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \Delta\omega \\ & - K_{\mathrm{L/U}} \mathbf{I} \otimes \mathbf{I}_{\mathrm{d}} + \sum_{i=1}^{I} \left(H_{\mathrm{L/U}}^{(i)} + L_{\mathrm{L/U}}^{(i)} \right) \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \otimes \mathbf{I} \Delta\omega \\ & - \sum_{i=1}^{I} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \otimes \left(H_{\mathrm{L/U}}^{(i)} \mathbf{I}_{\mathrm{d}} + L_{\mathrm{L/U}}^{(i)} \mathbf{I}_{\mathrm{d}}^{\mathrm{c}} \right) \Delta\omega \end{aligned} \tag{10}$$

The increments of the dilative and contractive components of dilatancy are given as follows:

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{d}} = \mathbf{I}_{\mathrm{d}}^{\mathrm{d}} : \dot{\boldsymbol{\varepsilon}} \tag{11}$$

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{c}} = \mathbf{I}_{\mathrm{d}}^{\mathrm{c}} : \dot{\boldsymbol{\varepsilon}} \tag{12}$$

where

$$\mathbf{I}_{\mathrm{d}}^{\mathrm{d}} = \sum_{i=1}^{I} \frac{\gamma^{(i)} / \gamma_{\mathrm{v}}}{1 + \left| \gamma^{(i)} / \gamma_{\mathrm{v}} \right|} \mathrm{M}_{\mathrm{fv}} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \Delta\omega \tag{13}$$

$$\mathbf{I}_{\mathrm{d}}^{\mathrm{c}} = -\sum_{i=1}^{I} \mathrm{M}_{\mathrm{v}} \left(1 - \left(\frac{G_{\mathrm{L/U}}^{(i)}}{G_{\mathrm{L0}}} \right) \right) \left| \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \right|^{*} \Delta\omega \tag{14}$$

For more details, refer to Iai et al. (2010b).

3.2 Finite Strain Formulation of Generalized Multiple Mechanism Model in Reference Configuration

The generalized multiple mechanism model described in the previous section has been extended based on finite strain formulation (Ueda, 2009; Iai et al., 2010c). In the finite strain formulation of the model, the unit vector $\mathbf{N}$ along the direction of the branch and the unit vector $\mathbf{T}$ normal to $\mathbf{N}$ are defined in the reference configuration of the material. These vectors are assumed to change their direction and magnitude into $\mathbf{n}$ and $\mathbf{t}$ in the current configuration through the deformation gradient $\mathbf{F}$ as follows:

$$\mathbf{n} = \mathbf{F}\mathbf{N} \tag{15}$$

$$\mathbf{t} = \mathbf{F}\mathbf{T} \tag{16}$$

$$\mathbf{F} = \frac{\partial \mathbf{x}}{\partial \mathbf{X}} \tag{17}$$

where the motion of the material transforms the initial position vector $\mathbf{X}$ defined in the reference configuration to the current position vector $\mathbf{x}$ defined in the current configuration.

The material description of integrated form of the strain space multiple mechanism model in the reference configuration is given by using the second Piola-Kirchhoff effective stress $\mathbf{S}'$ as follows:

$$\mathbf{S}' = \mathbf{S}'_{p} + \mathbf{S}'_{q} = -Jp\mathbf{C}^{-1} + J^{-1}\mathbb{Q} : \overline{\mathbf{S}} \tag{18}$$

where $\mathbf{C}$ and J denote the right Cauchy-Green tensor and Jacobian determinant ($= \det \mathbf{F}$). The fourth-order tensor $\mathbb{Q}$ and the second-order tensor $\overline{\mathbf{S}}$ in Equation (18) are respectively defined by

$$\mathbb{Q} = \mathbb{N} - \frac{1}{2}\mathbf{C}^{-1} \otimes \mathbf{C} \tag{19}$$

$$\overline{\mathbf{S}} = \sum_{i=1}^{I} Jq^{(i)} \left\langle \mathbf{T}^{(i)} \otimes \mathbf{N}^{(i)} \right\rangle \Delta\omega \tag{20}$$

Incremental form of the constitutive equation in the reference configuration is derived by taking the material time derivative of both sides of Equation (18) as

$$\dot{\mathbf{S}}' = \mathbb{C} : \dot{\mathbf{E}} = \left(\mathbb{C}_{p} + \mathbb{C}_{q} \right) : \dot{\mathbf{E}} \tag{21}$$

where

$$\begin{aligned} \mathbb{C}_{p} = {} & J\left(K_{\mathrm{L/U}} - p\right)\mathbf{C}^{-1} \otimes \mathbf{C}^{-1} \\ & + 2Jp\mathbf{C}^{-1} \odot \mathbf{C}^{-1} - JK_{\mathrm{L/U}}\mathbf{C}^{-1} \otimes \mathbf{C}_{\mathbf{d}}^{-1} \end{aligned} \tag{22}$$

$$\begin{aligned} \mathbb{C}_{q} = {} & J^{-1}\left[\mathbb{Q} : \overline{\mathbb{C}}_{q} + \left(\mathbf{C} : \overline{\mathbf{S}} \right) \tilde{\mathbb{Q}} \right] \\ & - \left(\mathbf{C}^{-1} \otimes \mathbf{S}'_{q} + \mathbf{S}'_{q} \otimes \mathbf{C}^{-1} \right) \end{aligned} \tag{23}$$

$$\overline{\mathbb{C}}_{q} = \sum_{i=1}^{I} J \left\langle \mathbf{T}^{(i)} \otimes \mathbf{N}^{(i)} \right\rangle \otimes \mathbf{C}_{q}^{(i)-1} \Delta\omega \tag{24}$$

$$\begin{aligned} \mathbf{C}_{q}^{(i)-1} = {} & q^{(i)}\mathbf{C}^{-1} + G_{\mathrm{L/U}}^{(i)} \left\langle \mathbf{T}^{(i)} \otimes \mathbf{N}^{(i)} \right\rangle \\ & + H_{\mathrm{L/U}}^{(i)} \left(\mathbf{C}^{-1} - \mathbf{C}_{\mathbf{d}}^{-1} \right) + L_{\mathrm{L/U}}^{(i)} \left(\mathbf{C}^{-1} - \mathbf{C}_{\mathbf{dc}}^{-1} \right) \end{aligned} \tag{25}$$

$$\tilde{\mathbb{Q}} = \mathbf{C}^{-1} \odot \mathbf{C}^{-1} - \frac{1}{2}\mathbf{C}^{-1} \otimes \mathbf{C}^{-1} \tag{26}$$

The dilative and contractive components of dilatancy in the reference configuration are given through a derivation analogous to that in the infinitesimal strain formulation as follows:

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{d}} = \mathbf{C}_{\mathrm{dd}}^{-1} : \dot{\mathbf{E}} \tag{27}$$

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{c}} = \mathbf{C}_{\mathrm{dc}}^{-1} : \dot{\mathbf{E}} \tag{28}$$

where

$$\begin{aligned} \mathbf{C}_{\mathrm{dd}}^{-1} = {} & J^{-1} \sum_{i=1}^{I} \left(\frac{\gamma^{(i)} / \gamma_{\mathrm{v}}}{1 + \left| \gamma^{(i)} / \gamma_{\mathrm{v}} \right|} \right) \mathrm{M}_{\mathrm{fv}} \\ & \times \left(\left\langle \mathbf{T}^{(i)} \otimes \mathbf{N}^{(i)} \right\rangle - \frac{1}{2}\gamma^{(i)}\mathbf{C}^{-1} \right) \Delta\omega \end{aligned} \tag{29}$$

$$\mathbf{C}_{\mathrm{dc}}^{-1} = -\sum_{i=1}^{I} \mathrm{M}_{\mathrm{v}} \left(1 - c_{1} \left(\frac{G_{\mathrm{L/U}}^{(i)}}{G_{\mathrm{L0}}} \right) \right) \left| \left\langle \mathbf{T}^{(i)} \otimes \mathbf{N}^{(i)} \right\rangle \right|^{*} \Delta\omega \tag{30}$$

3.3 Finite Strain Formulation of Generalized Multiple Mechanism Model in Current Configuration

The spatial description of integrated form in the current configuration is obtained through the push-forward operation (Holzapfel, 2001) of the material description in Equation (18) as follows:

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma}'_p + \boldsymbol{\sigma}'_q = -p\mathbf{I} + J^{-1}\mathbb{Z} : \overline{\boldsymbol{\sigma}} \tag{31}$$

where $\boldsymbol{\sigma}'$ denotes the Cauchy effective stress and

$$\mathbb{Z} = \mathbb{N} - \frac{1}{2}\mathbf{I} \otimes \mathbf{I} \tag{32}$$

$$\overline{\boldsymbol{\sigma}} = \sum_{i=1}^{I} q^{(i)} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \Delta\omega \tag{33}$$

With the Oldroyd stress rate of the Kirchhoff effective stress (Holzapfel, 2001), incremental form of the strain space multiple mechanism model in the current configuration is given as follows:

$$\mathrm{Oldr}\left(J\boldsymbol{\sigma}'\right) = J\mathbb{C} : \mathbf{d} = J\left(\mathbb{C}_p + \mathbb{C}_q\right) : \mathbf{d} \tag{34}$$

where $\mathbf{d}$ denotes the rate of deformation tensor and

$$\mathbb{C}_p = \left(K_{\mathrm{L/U}} - p\right)\mathbf{I} \otimes \mathbf{I} + 2p\mathbb{N} - K_{\mathrm{L/U}}\mathbf{I} \otimes \mathbf{I}_{\mathrm{d}} \tag{35}$$

$$\mathbb{C}_q = J^{-1}\left[\mathbb{Z} : \overline{\mathbb{C}}_q + \mathrm{tr}\overline{\boldsymbol{\sigma}}\mathbb{Z}\right] - \left(\mathbf{I} \otimes \boldsymbol{\sigma}'_q + \boldsymbol{\sigma}'_q \otimes \mathbf{I}\right) \tag{36}$$

$$\overline{\mathbb{C}}_q = \sum_{i=1}^{I} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \otimes \mathbf{I}_q^{(i)} \Delta\omega \tag{37}$$

$$\begin{aligned} \mathbf{I}_q^{(i)} &= q^{(i)}\mathbf{I} + G_{\mathrm{L/U}}^{(i)} \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \\ &\quad + H_{\mathrm{L/U}}^{(i)} \left(\mathbf{I} - \mathbf{I}_{\mathrm{d}}\right) + L_{\mathrm{L/U}}^{(i)} \left(\mathbf{I} - \mathbf{I}_{\mathrm{d}}^{\mathrm{c}}\right) \end{aligned} \tag{38}$$

The dilative and contractive components of dilatancy in the current configuration are defined as follows:

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{d}} = \mathbf{I}_{\mathrm{d}}^{\mathrm{d}} : \mathbf{d} \tag{39}$$

$$\dot{\varepsilon}_{\mathrm{d}}^{\mathrm{c}} = \mathbf{I}_{\mathrm{d}}^{\mathrm{c}} : \mathbf{d} \tag{40}$$

where

$$\begin{aligned} \mathbf{I}_{\mathrm{d}}^{\mathrm{d}} &= J^{-1} \sum_{i=1}^{I} \left(\frac{\gamma^{(i)} / \gamma_{\mathrm{v}}}{1 + \left|\gamma^{(i)} / \gamma_{\mathrm{v}}\right|} \right) \mathrm{M}_{\mathrm{fv}} \\ &\quad \times \left(\left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle - \frac{1}{2}\gamma^{(i)}\mathbf{I} \right) \Delta\omega \end{aligned} \tag{41}$$

$$\mathbf{I}_{\mathrm{d}}^{\mathrm{c}} = -\sum_{i=1}^{I} \mathrm{M}_{\mathrm{v}} \left(1 - c_1 \left(\frac{G_{\mathrm{L/U}}^{(i)}}{G_{\mathrm{L0}}} \right) \right) \left| \left\langle \mathbf{t}^{(i)} \otimes \mathbf{n}^{(i)} \right\rangle \right|^{*} \Delta\omega \tag{42}$$

For more details, refer to Ueda (2009) or Iai et al. (2010c).

4. OUTLINE OF FINITE ELEMENT ANALYSIS

4.1 Determination of Model Parameters

The strain space multiple mechanism model described in the previous chapter has 15 parameters for the analysis of liquefaction; three specify volumetric mechanism, three specify shear mechanism, and the rest control liquefaction and dilatancy.

The parameters for defining the characteristics of volumetric and shear deformation are shown in Table 1. They were determined as following the past analytical study (Fujii et al., 2008). The parameters r_K and l_K in Table 1, which are defined only for the backfill soil (viz. decomposed granite soil), control the bulk modulus for liquefaction analysis and were determined according to the volumetric strain of the undisturbed soil samples after undrained cyclic triaxial tests (The Third District Port Construction Bureau, 1997).

Table 1 Model parameters for deformation characteristics

Soil Type				Parameters for deformation characteristics						
				volumetric mechanism			shear mechanism			
	ρ (t/m^3)	n	σ_{ma}' (kPa)	K_{ma} (kPa)	r_K	l_K	G_{ma} (kPa)	φ_f (°)	c (kPa)	h_{max}
Alluvial Clay	1.70	0.45	143.0	195500	-	-	74970	30.00	0.0	0.30
Foundation Rubble	2.00	0.45	98.0	469000	-	-	180000	40.00	0.0	0.30
Backfill Soil	1.80	0.45	98.0	220872	0.11	2.0	84695	39.67	0.0	0.24

The rest of 15 parameters, which specify the characteristics of liquefaction and dilatancy, are defined only for the backfill soil as shown in Table 2. They were determined by referring to the liquefaction resistance curves, which were obtained from undrained cyclic triaxial tests of decomposed granite soil taken from the reclaimed ground in Rokko Island (see Fig.1), as shown in Fig. 3. The relative density of the decomposed granite soil was 67 % to 77 %. An example on the simulated cyclic behavior of the backfill soil is given in Fig. 4. The parameter q_{us} in Table 2, which is undrained shear strength for describing the steady state of sand (e.g., Yoshimine and Ishihara (1998)), was determined from undrained monotonic triaxial compression tests. According to Hyodo et al. (1997), the undrained shear strength of decomposed granite soil with relative density of 80 % in Rokko Island is about 20 kPa and 40 kPa ($=q/2$) depending on initial confining pressure as shown in Fig. 5. In the following analysis, without considering the effect of initial confining pressure on undrained shear strength, both 20 kPa and 40 kPa were simply adopted as the undrained shear strength of the backfill soil.

Table 2 Model Parameters for Dilatancy

Soil Type	Parameters for dilatancy								
	φ_p (°)	ε_d^{cm}	r_{ε_d}	r_{ε_d}	q_1	q_2	S_1	c_1	q_{us} (kPa)
Backfill Soil	28.0	0.45	1.20	0.90	1.00	1.00	0.005	1.65	20.0 40.0

4.2 Modeling of Structures and Sea Water

The concrete caisson was idealized by linear plane elements, which have been extended for large deformation analysis based on the concept of multiple shear mechanism (Ueda et al, 2009). The parameters of the plane elements are shown in Table 3. The relative sliding and separation between the foundation rubble and the concrete caisson was taken into account by introducing joint elements.

The sea water was modeled as incompressible fluid and formulated as an added mass matrix considering the equilibrium and continuity of the fluid at the solid-fluid interface (Zienkiewicz, 2000).

Table 3 Model Parameters for structures

Structure Type	Density	Young's modulus	Poisson ratio
	ρ (t/m^3)	E (kPa)	ν
Caisson	2.1	2.23×10^7	0.17
Upper Concrete	2.3	2.94×10^7	0.17
Footing	2.1	2.94×10^7	0.17

4.3 Initial and boundary conditions and input motion

The finite element mesh for numerical analysis is shown in Fig. 6. Before the seismic response analysis, a static (self-weight) analysis was performed with gravity force under drained condition to simulate the initial stress acting in-situ before the earthquake.

During the seismic response analysis, the seismic wave should be appropriately simulated to transmit from the analysis domain with the finite elements to the outside field. In order to take into account this effect, the side boundaries were idealized by viscous dampers.

With these boundary conditions, seismic response analyses were performed on Breakwater No.7. As an input motion, both of the horizontal (NS) and vertical (UD) components of the earthquake motion recorded at Port Island during 1995 Hyogoken-Nanbu earthquake, shown in Fig. 7, were adopted through the deconvolution by the equivalent linear method for obtaining the incident waves. In this research, EW component of the horizontal waves, the direction of which is parallel to the longitudinal direction of Breakwater No.7, was not considered.

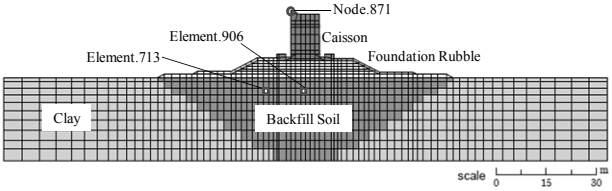

Figure 6 Finite element mesh for numerical analysis

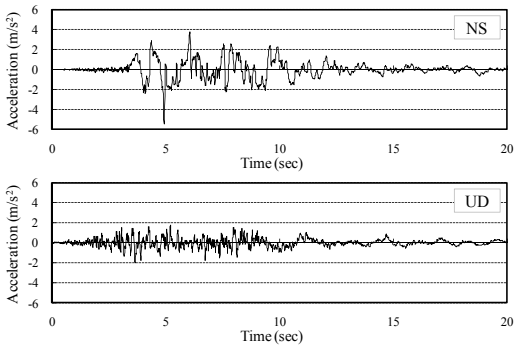

Figure 7 Input acceleration

The seismic response analyses were performed under undrained conditions. The numerical time integration was done by the Wilson-θ method (θ=1.4) using a time step of 0.01 seconds. Rayleigh damping (α =0.0 and β =0.002), which is proportionally decreasing with the degree

of cyclic mobility, was used to ensure stability of the numerical solution process. Selective reduced integration was adopted for Gauss integration using four nodes isoparametric elements.

In computation, both an infinitesimal deformation analysis and finite deformation analyses were performed to compare the effect of geometrical nonlinearity. In the finite deformation analyses, we employed both total Lagrangian (TL) formulation with material description based on reference configuration (see Section 3.2) and updated Lagrangian (UL) formulation with spatial description based on current configuration (see Section 3.3).

5. RESULTS OF THE ANALYSIS

5.1 Seismic response and deformation

The computed settlements at the top (Node.871, see Fig. 6) of the breakwater in the infinitesimal and finite deformation analyses are compared in Fig. 8. For both the infinitesimal and finite deformation analyses, the settlements are negatively correlated with the undrained shear strength. In other words, the settlement decreases as the undrained shear strength becomes larger. The figure shows that the results in the infinitesimal deformation analyses for the case of q_{us} =20 kPa and 40 kPa are 3.62 m and 2.89 m, respectively, both of which exceed the upper limit of measurements (2.6 m). In contrast, the settlements in the finite deformation analysis based on TL formulation are 2.46 m and 1.93 m for the case of q_{us} =20 kPa and 40 kPa, respectively, both of which fall within the measured range from 1.4 m to 2.6 m. The results in the UL formulation show the same tendency and no significant difference from those in the TL formulation for each undrained shear strength, which suggests that both formulations are not only theoretically but also numerically equivalent to each other. The figure also indicates that the difference between the settlements in the infinitesimal and finite deformation analyses, which is due to the effect of geometrical nonlinearity, increases as the undrained shear strength becomes smaller. The difference in the case of q_{us} =20 kPa is about 1.2 times as large as that in the case of q_{us} =100 kPa, which suggests that it is preferable to carry out the finite deformation analysis by taking into account geometrical nonlinearity, in particular, when the undrained shear strength used as an input parameter is small.

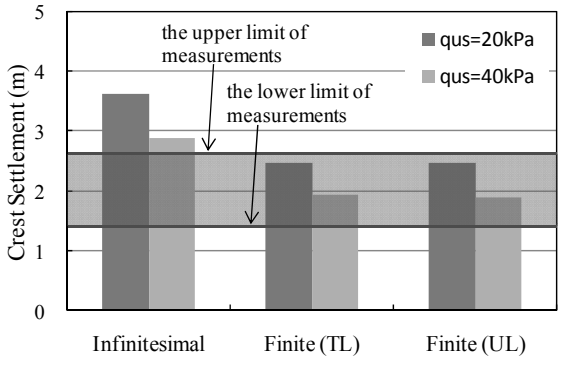

Figure 8 Comparison between computed settlements at the top of Breakwater No. 7

The computed horizontal displacements at the top of the breakwater are shown in Fig. 9. All of the results exceed the average of measurements. However, the differences are less than 0.6 m and of little consequence compared to the dimension of the breakwater. Unlike the settlements shown in Fig. 8, the horizontal displacements increase as the undrained shear strength becomes larger. This is because the deformation mode, in particular, about the inclination of the caisson during shaking in the case of q_{us} =40 kPa is slightly different from that in the case of q_{us} =20 kPa as described hereinafter.

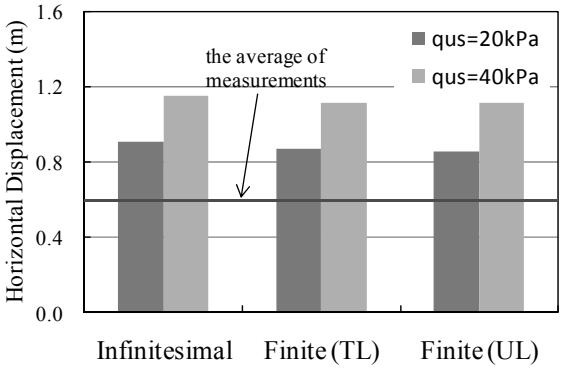

Figure 9 Comparison between computed horizontal displacements at the top of Breakwater No. 7

The computed deformations of the breakwater after shaking in the case of q_{us} =20 kPa are shown in Fig. 10, in which solid lines illustrate the deformed meshes with reference to the original configuration in broken lines. In both the infinitesimal and finite deformation analyses, the deformation mechanism is similar to that mentioned earlier in Chapter 2. However, it seems that the extent of deformed region in the infinitesimal deformation analysis becomes more widespread than the observation, in particular, in the vicinity of the foundation rubble around the caisson, while the deformation mode in the finite deformation analyses is consistent with the observation. By comparison, the results in the case of q_{us} =40 kPa are shown in Fig. 11. The deformation mechanism is considered to be the same as that in the case of q_{us} =20 kPa although the extent of deformation is slightly different from that in Fig. 10. Compared to the results in the case of q_{us} =20 kPa, the caisson sinks down with a slightly larger inclination in the case of q_{us} =40 kPa, which may be affected by the difference of stress states in the backfill soil just below the caisson. As mentioned earlier about the settlements, the TL and UL formulations are also equivalent to each other about the deformed configuration in both Fig. 10 and Fig. 11.

The computed accelerations and displacements at the top of the breakwater in the case of q_{us} =20 kPa are shown in Fig. 12. The first and second rows in the figure show that both the horizontal and vertical accelerations are hardly affected by the difference of analytical methods (e.g., infini-

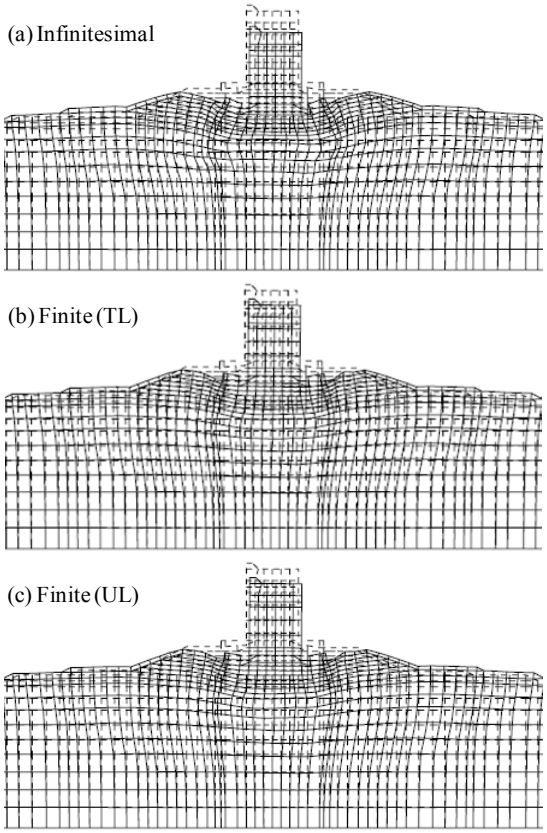

Figure 10 Computed deformation after shaking (q_{us} =20 kPa)

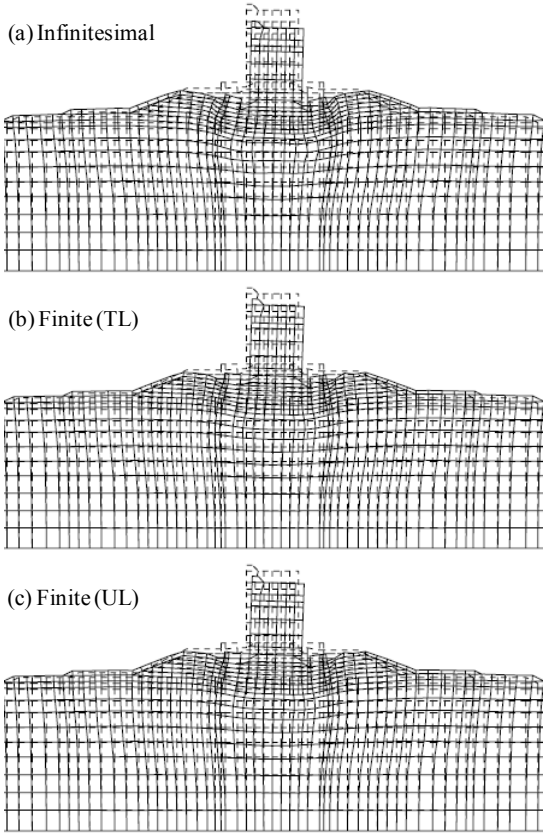

Figure 11 Computed deformation after shaking (q_{us} =40 kPa)

tesimal or finite deformation analysis). The vertical displacements shown in the fourth row gradually accumulate and reach the residual values shown in Fig .8 while the horizontal displacements shown in the third row are oscillating due to shaking. As shown in Fig. 13, the same tendencies about accelerations and displacements are recognized in the case of q_{us} =40 kPa. Comparison between the first rows in Fig. 12 and Fig. 13 indicates that the horizontal acceleration at the top of the caisson is more attenuated after about 6 seconds as the undrained shear strength in the backfill soil becomes smaller, which causes the difference of the horizontal displacements shown in the third rows and Fig. 9. The attenuation is attributed to the decrease of effective stress, which is equivalent to the build-up of excess pore water pressure under the condition that total stress is constant, in the backfill soil just below the caisson.

5.2 Excess pore water pressure

The computed excess pore water pressure ratios (= $1-\sigma'_{m}/\sigma'_{m0}$) at the end of shaking in the case of q_{us} =20 kPa and 40 kPa are shown in Fig. 14 and Fig. 15, respectively. In the both figures, the excess pore water pressure ratios in the infinitesimal deformation analysis are a little lower than those in the finite deformation analyses, in particular, in the area just below the foundation rubble far away from the caisson. The settlements of the caisson in the

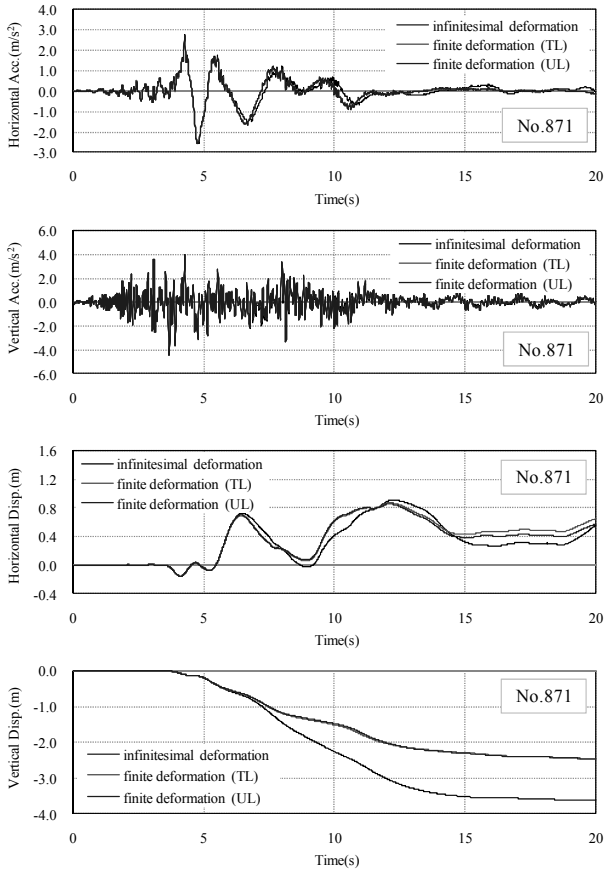

Figure 12 Time history of computed accelerations and displacements (q_{us} =20 kPa)

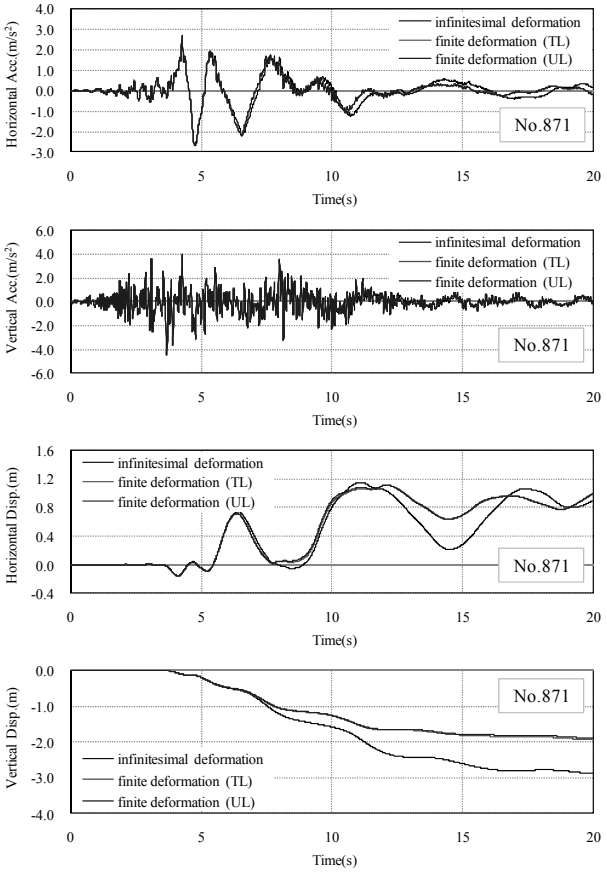

Figure 13 Time history of computed accelerations and displacements (q_{us} =40 kPa)

infinitesimal deformation analysis, however, are larger than those in the finite deformation analyses for each undrained shear strength as mentioned earlier in Fig. 8, which suggests that the difference of the settlements is more directly affected by the effect of geometrical nonlinearity (e.g., difference of the relationship between displacements and strains in simple terms) rather than by the difference of the excess pore water pressure ratios. In major parts of the backfill soil below and in the vicinity of the caisson, which affects the behavior of the caisson most susceptibly, the excess pore water pressure ratios in Fig. 14 are slightly higher than those in Fig. 15. This is why the settlement of the caisson in the case of q_{us} =20 kPa is larger than that in the case of q_{us} =100 kPa as shown in Fig. 8. As mentioned earlier about the settlements, Fig. 14 and Fig. 15 confirm that the TL and UL formulations are equivalent to each other about the excess pore water pressure ratios.

5.3 Effective stress path and stress-strain relationship

The computed effective stress paths and stress-strain relations are shown in Fig. 16 and Fig. 17 for the elements in the backfill soil below the caisson (see Fig. 6). The filled circles and triangles represent the initial stress state before shaking and the finial stress state after shaking, respectively. The maximum shear stress τ and mean effective stress σ'_{m} in the effective stress paths for the finite deformation

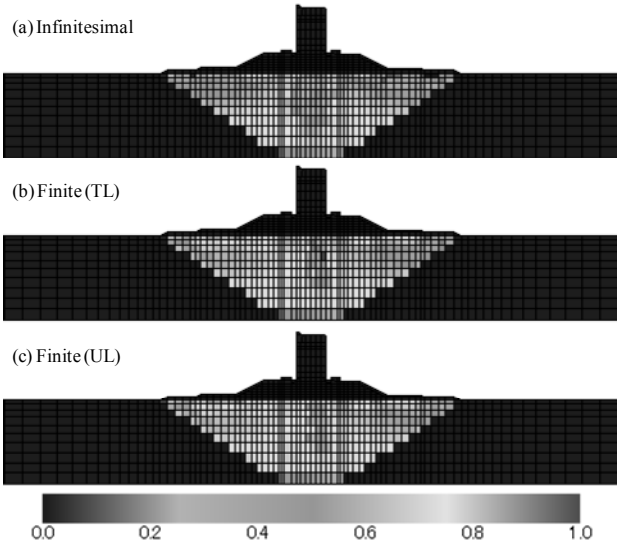

Figure 14 Computed distribution of excess pore water pressure ratio (q_{us} =20 kPa)

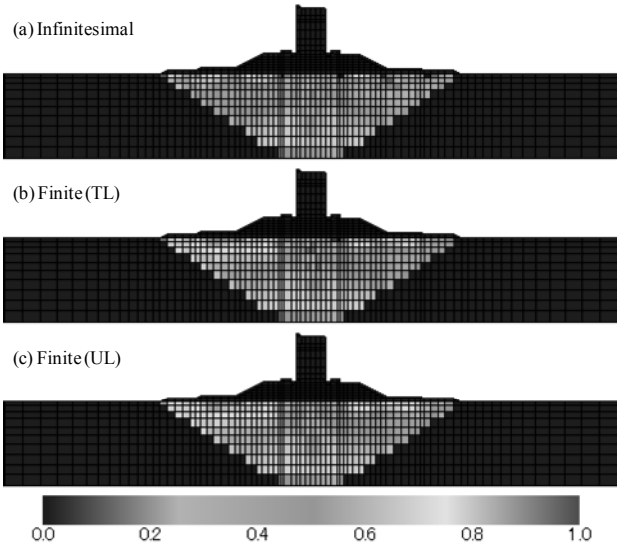

Figure 15 Computed distribution of excess pore water pressure ratio (q_{us} =40 kPa)

analyses (both the TL and UL formulations) are given as follows:

$$\tau = \sqrt{\left(\left(\sigma'_{11} - \sigma'_{22}\right)/2\right)^2 + \left(\sigma'_{12}\right)^2} \tag{43}$$

$$\sigma'_{\mathrm{m}} = \left(\sigma'_{11} + \sigma'_{22}\right)/2 \tag{44}$$

where $\sigma'_{11}, \sigma'_{12}, \sigma'_{22}$ are the components of Cauchy effective stress. The computed second Piola-Kirchhoff effective stress and Green-Lagrange strain in the TL formulation are converted into Cauchy effective stress and Euler-Almansi strain. Both of Fig. 16 and Fig. 17 confirm that the stress paths and stress-strain relations obtained in the

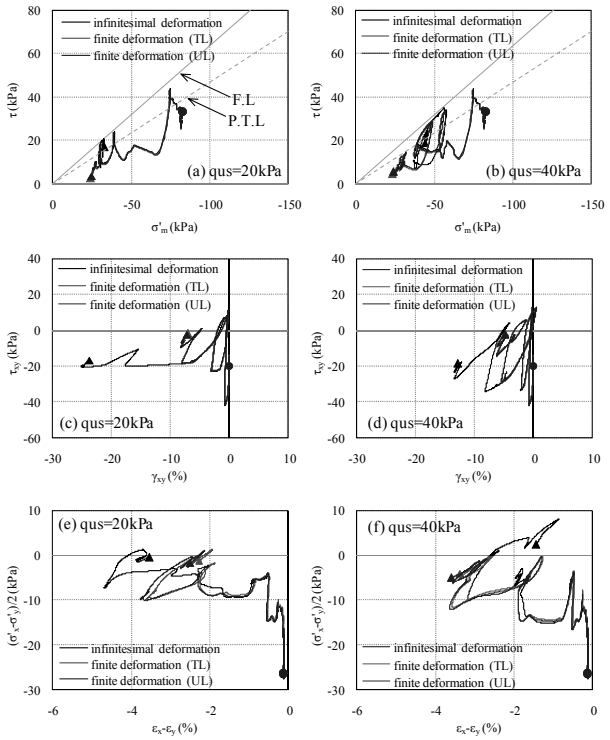

Figure 16 Computed effective stress path and stress-strain relations (for element No. 713)

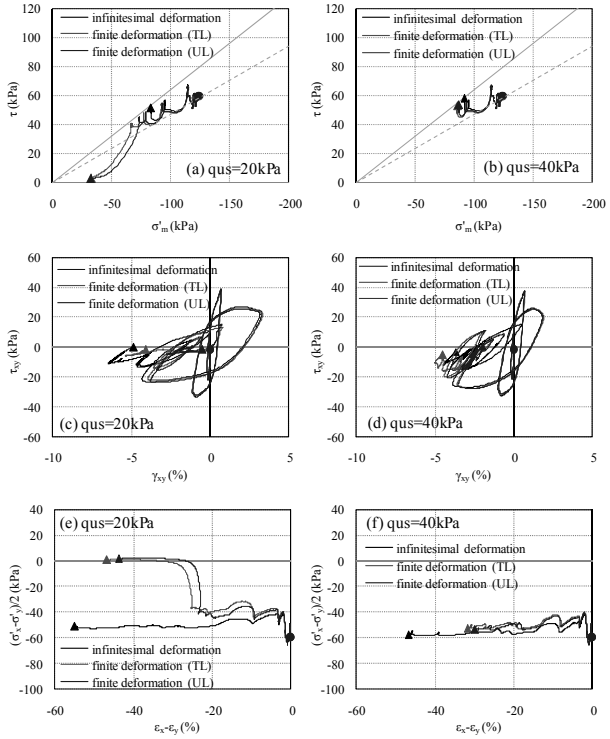

Figure 17 Computed effective stress path and stress-strain relations (for element No. 906)

TL formulation are nearly identical to those in the UL formulation. Thus, we can say for sure that the TL and UL formulations are not only theoretically but also numerically equivalent to each other. In what follows, we discuss in detail.

The initial stress states in Fig. 16(a) are the same as those in Fig. 16(b) because the undrained shear strength doesn't affect the results of the self-weight analysis performed under drained condition. In addition, the initial stress states are equivalent regardless of the analytical method, which suggests that the effect of geometrical nonlinearity is hardly induced in the self-weight analysis, and are relatively close to the failure line (F.L) even before shaking due to the overburden pressure of the caisson by gravity. We obtain the same consequence in Fig. 17(a) and (b). As shown in Fig. 16(a) and (b), the difference of undrained shear strength significantly affects the effective stress paths except for the initial point in both the infinitesimal and finite deformation analyses. In the area beyond the phase transformation line (P.T.L) and below the maximum shear stress of 40 kPa, the results for the case of q_{us} =40 kPa exhibit dilative behavior under cyclic shear loading while those for the case of q_{us} =20 kPa show contractive behavior. In both Fig. 16 and Fig. 17, the effective stress paths of the infinitesimal deformation analysis are consistent with those of the finite deformation analyses except for the last portion, in which the effective stress paths in the finite deformation analyses generally show a tendency to get closer to the origin (viz., fully liquefied condition) than those in the infinitesimal deformation analysis do.

Comparison between the stress-strain relations for the case of q_{us} =20 kPa in Fig. 16 and Fig. 17 suggests that the deformation mechanism of the backfill soil directly below the caisson (e.g., element No. 906) differs from that at the same depth away from the caisson (e.g., element No. 713) regardless of the analytical method. The former is dominated by deviatoric strain as shown in Fig. 16(c) and (e), and the latter depends mainly on shear strain as shown in Fig. 17(c) and (e). We can recognize the same tendency in the case of q_{us} =40 kPa. However, the absolute maximum values of shear and deviatoric strain in the case of q_{us} =40 kPa are generally less than their counterparts in the case of q_{us} =20 kPa for both the infinitesimal and finite deformation analyses.

The stress-strain relations in Fig. 16 and Fig. 17 confirm that the infinitesimal deformation analysis is virtually the same as the finite deformation analyses for small strain range. However, as shown in Fig. 16(c) and (d), the results of the infinitesimal deformation analysis become different from those of the finite deformation analyses beyond the absolute value of the shear strain of about 10 % due to the effect of geometrical nonlinearity. The threshold value is similar to the results obtained in simulation for soil behavior during monotonic and cyclic simple shear (Ueda, 2009; Iai et al., 2010c). However, we can recognize some discrepancy between the infinitesimal and finite deformation analyses even in the area below the threshold value in Fig. 17(c) and (d). This may be because the relations are affected by stress and strain conditions of the surrounding soils. Figures 17(e) and (f) confirm that the effect of geometrical

nonlinearity becomes obvious beyond the deviatoric strain level of about 20 % and 30 %. The discrepancy in Fig. 16(e) and (f), which is visible beyond the deviatoric strain level of about 3 %, is considered to depend on stress and strain conditions of the surrounding soils as well as in the shear stress-strain relations.

6. CONCLUSIONS

In this study, infinitesimal and finite deformation analyses were performed on the seismic response of Breakwater No.7 in Kobe Port during 1995 Hyogoken-Nanbu earthquake in order to verify the applicability of an effective stress model. The model used in the analyses was a strain space multiple mechanism model, which has been extended based on finite strain (both total and updated Lagrangian) formulations to take into account the effect of geometrical nonlinearity. As an input dilatancy parameter in the model, two types of undrained shear strength (q_{us} =20 kPa and 40 kPa) were adopted according to the results of undrained triaxial compression tests. Primary conclusions of this study are summarized as follows:

For the both cases of q_{us} =20 kPa and 40 kPa, the settlements at the top of the breakwater exceeded the upper limit of measurements in the infinitesimal deformation analyses while those in the finite deformation analysis (both the total and updated Lagrangian formulations) fell inside the measured range. In both the infinitesimal and finite deformation analyses, the computed settlements increased as the undrained shear strength became smaller. In addition, the difference of the settlements between the infinitesimal and finite deformation analyses also increased with the decrease in the undrained shear strength. Thus, it is preferable to perform the finite deformation analysis by considering geometrical nonlinearity, in particular, when the undrained shear strength is small.

All of the computed results (e.g., deformation, stress path, and stress-strain relationship) indicated that the total and updated Lagrangian formulations are not only theoretically but also numerically equivalent to each other, which demonstrated the validity of the computer programming for finite deformation analysis. We conclude that in order to predict accurately the seismic response of port structures such as breakwaters by finite element method, it is necessary to carry out the analysis by considering the effects of not only material nonlinearity but also geometrical nonlinearity with total or updated Lagrangian formulations.

Abstract: Recently strong earthquakes around the world caused serious disasters for port structures. It shows the shortcoming of current design and construction procedures and the needs to develop the performance based guidelines for seismic design. The performance-based seismic design method has taken in the seismic design standards of buildings and bridges. However, port structures still use working stress design method. There are lots of improvements needed to be done to upgrade the current design codes. This research discusses the performance-based seismic design process of port structures, including the performance objective, design method, and seismic estimation. The seismic capability of gravity quay walls at different cases histories are studied by using performance-based seismic design method. Afterwards, seismic performance of gravity quay walls is studied through effective stress analysis by varying structural and geotechnical parameters of quay walls under various levels of shaking. This research will be useful for future seismic design of gravity quay walls.

1. INTRODUCTION

Experience at ports has demonstrated that waterfront retaining structures are highly susceptible to earthquake-induced damage. A significant percentage of the damage is due to the liquefaction of adjacent soils. In the case of caisson-type quay walls subjected to earthquake excitation, typical damage modes are found out to be seaward displacement, settlement and tilting as shown in Figure 1. In several cases, ground deformations associated with liquefaction-induced failure of caissons have extended as much as 150 m into backland areas damaging waterfront components and suspending port operations (Inagaki et al., 1996; PHRI, 1997; Werner; 1998; PIANC, 2001; Iai, 2005).

In order to develop a simplified technique for estimating seismically-induced deformations of gravity quay walls "caisson-type" this research focused on field performance data, as well as numerical analyses. The authors have utilized a numerical model, validated with well-documented case histories, for parametric studies of seismic performance of gravity quay walls. The results of this study have been synthesized into practice oriented design charts for estimating the lateral deformations of gravity quay walls.

2. NUMERICAL MODEL

The computer program FLAC (Itasca, 2005) was used in this study. The FLAC program employs an explicit finite difference method for modeling nonlinear static and dynamic problems in two dimensions.

The numerical modeling has been analyzed under plane strain and fluid–mechanical interaction conditions. The soil modeling was performed using an effective stress based Mohr-Coulomb constitutive model. The elastic behavior of the soil was defined by the bulk and shear modulus, and the shear strength is defined by the friction angle and the cohesion. For the quay wall, the concrete caisson has been modeled by linear elastic elements, with soil–structure interfaces modeled by joint interfaces. The lateral boundaries of the model were modeled as free field boundaries and set a distance of seven times the caisson height to eliminate boundary effects on the computed pattern of soil deformations.

In this analysis, the Finn and Byrne model of FLAC 2D has been used to carry out coupled dynamic groundwater flow calculations (Itasca, 2005). This analysis which takes into account the effects of seismically induced pore water pressures was used to investigate the degree and extent of liquefaction

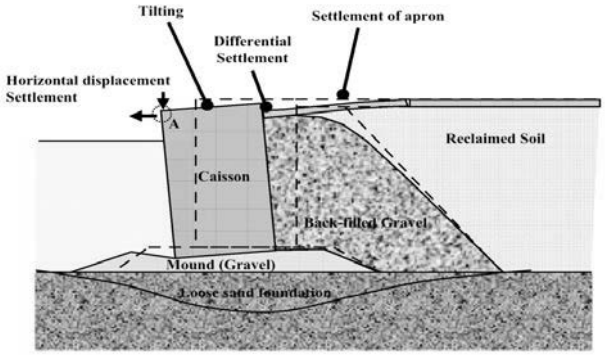

Figure 1 Parameters of damage criteria for gravity quay walls

3. VALIDATION OF THE NUMERICAL MODEL

An early stage of the research involved the validation of the numerical analysis procedure for modeling the seismic performance of concrete caissons. Requisite data for the case studies included: the geometry of the caisson, foundation

pad and backfill, acceleration time histories recorded near the site, site specific geotechnical data, and pre- and post-earthquake wall geometry. After an extensive review of the literature six case studies were selected, including: a wharf at Akita Port during the MJMA 7.7 1983 Nihonkai Chubu Earthquake Japan (Hamada, 1992), two wharves at Kushiro Port during the MJMA 7.8 1993 Kushiro Oki Earthquake Japan (Iai et al., 1994), two wharves at Kobe Port during the Mw 6.9 1995 Hyogoken-Nanbu Earthquake Japan (Inagaki et al., 1996), and one wharf at Taichung port during the Mw 7.6 1999 Chi-Chi Earthquake Taiwan (Chen and Hwang, 2000).

As an example of the seismic performance of a concrete caisson, typical damage at Rokko Island, Kobe Port is shown in Figure 2. This lateral and vertical deformation was common at the port in the aftermath of the 1995 Hyogoken Nanbu earthquake. The portion of the berth illustrated in Figure 2 was modeled using FLAC and the results of this study are shown in Figure 3.

The results of the numerical analyses were consistent with the measured displacements as shown in Table 1. The case studies have been particularly useful for calibrating the numerical model, evaluating the uncertainty associated with the model, and assessing the applicability of the model for computing the dynamic behavior of gravity quay walls.

4. SEISMIC PERFORMANCE EVALUATION CHARTS

4.1 Limitation of the Advanced and Empirical Methods

Although the applicability of the effective stress analysis method for seismic performance evaluation of caisson type quay walls was verified with case histories, it is difficult to conduct effective stress analyses for all varieties of quay walls considered during the design procedure due to the limitation of costs and time. Furthermore, the effective stress method needs many input parameters and the calibration of which is not easy. It is necessary to become accustomed with the program in Advance if one wants to use, and practicing the parameter calibration and executing the numerical simulation is time consuming. Therefore, it is desirable to establish a simple but robust estimation technique for deformation of gravity quay walls and to confirm the numerical results in some cases.

For gravity quay walls, a conservative relation between seismic coefficients and the level of input motion needed to cause damage to quay walls was proposed based on the case histories (Noda et al., 1975). Furthermore, a simplified damage evaluation technique using seismic coefficients was developed (Uwabe et al., 1983). However, these studies are only applicable in the cases without liquefaction and it is difficult to take into account the effect of subsoil conditions below and behind quay walls. The applicability of the sliding block concept for this purpose was examined (Mohajeri et al., 2004); however, experimental results revealed the complexity of the behavior of caisson walls, and the sliding block concept does not work well for such a complex behavior.

To overcome this problem, simplified seismic performance evaluation charts based on parametric studies using effective stress analyses are proposed.

4.2 Parametric Study Using a Structurally Simplified Model

4.2.1 Parameters characterizing gravity quay walls

The factors governing the seismic performance of a caisson-type quay wall include wall dimensions, the thickness of the soil deposit below the wall and liquefaction resistances of subsoil below and behind wall, as well as the levels of seismic shaking at the base layer. In this study, the soil deposit below the wall was represented by a sand backfill used to replace the original soft clay deposit in order to attain the required bearing capacity. The effects of this soil deposit on the deformation of a caisson-type quay wall may be approximately the same as those of a natural sand deposit below the wall; thus, the results of the parametric study may be applicable not only for the quay wall with sand replacement studied here but also for a quay wall constructed on a natural sandy deposit.

Note: * seaward lateral displacements at the top of the caisson
** settlements at the top of the caisson

The standard cross section of the caisson used for the parametric study is shown in Figure 4. Major cross-sectional dimensions were specified by the width (W) and the height (H) of the caisson wall and by the thickness of subsoil (D1) and thickness of the backfill (D2). A width-to-height ratio of the caisson wall (aspect ratio; W/H) is one of the most important

parameters in conventional seismic design and correlates with the seismic coefficients used in the pseudo-static method as shown in Figure 5, which is based on Japanese case histories. The width-to-height ratio (W/H) was thus considered a major parameter in this study. The

parameters used in this study were W/H = 0.50, 0.65, 0.90, 1.05, 1.20, which correspond to the seismic coefficients of Kh range from 0.05 to 0.30, which is the range of interest for port engineers (PIANC, 2001).

In this study, the peak acceleration of the input seismic excitation assigned at the base layer is the north-south direction of Kobe vertical seismic array. This motion is scaled to six different acceleration values ranging from 0.1g to 0.6g. Figure 6 shows the time history of north south direction of Kobe Earthquake applied at the base of the model at -32m.

The thickness of the liquefied soil deposit below the wall (D1) was specified by a ratio with respect to the wall height (H), ranging from D1/H = 0.0 (i.e. a rigid base layer located immediately below the wall) to D1/H = 1.0 (i.e. thick soil deposit below the wall). The thickness of the liquefied soil deposit behind the wall (D2) was specified by a ratio with respect to the wall height (H), ranging from D2/H = 0.0 (i.e. a non liquefied soil layer) to D2/H = 1.0 (i.e. a liquefied soil layer with depth equal to the height of the wall).

Other geometrical conditions assumed for the effective stress analyses include: wall height H= 13m water level = 2 m lower than the top of the wall, thickness of the rubble mound = 4m.

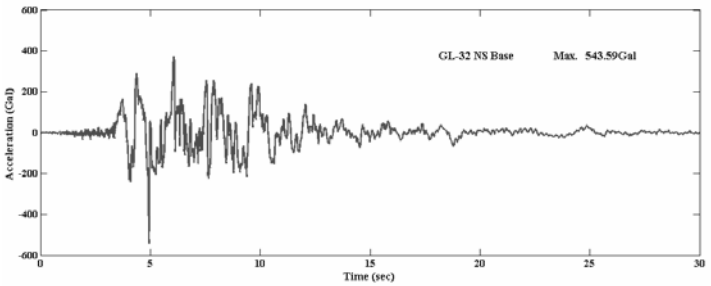

Figure 6 Time history of input ground acceleration (Inagaki et al.,1996)

4.2.2 Geotechnical conditions and parameters

The geotechnical conditions of the soil deposits below and behind the wall were assumed to be the same, represented by the equivalent SPT-N value (the corrected SPT-N value for the effective vertical stress of 65 kPa of an equivalent relative density). The equivalent SPT-N value has been widely used for the assessment of liquefaction potential (PHRI, 1997). The geotechnical model parameters determined by the equivalent SPT-N value are summarized in Table 2. The assumed relative density (Dr) for each equivalent SPT-N value, which was given in the process of the simplified procedure, is also shown in Table 2 as a reference. The range of densities used can be correlated with the corrected standard penetration resistances of 5 to 25 in soil.

4.3 Parameter Sensitivity and Charts

The results of the parametric study were summarized in terms of the residual horizontal displacement (d) at the top of the wall. The residual horizontal displacement was normalized with respect to the wall height (H). The effects of the major parameters on the normalized residual horizontal displacement (d/H) are discussed as follows.

4.3.1 Width-to-height ratio (W/H)

As seen from Figure 7 at SPT N = 5 increasing the width to height ratio (W/H) leads to significant decrease in the normalized lateral displacement (d/H), especially for W/ H = 1.05 and 1.02 and at higher input excitation level 0.4g, 0.5g and 0.6g. Similar trends are shown in Figure 8 and Figure 9 for SPT N = 10 and 15 respectively. However, in Figure 10 at SPT N =20 and Figure 11 at SPT N= 25 increasing the width to height ratio (W/H) leads to negligible effect n the o normalized lateral displacement (d/H) at any excitation level for different soil conditions (i.e W/H = 1.05 is considered as the optimum).

4.3.2 Input excitation Level (g)

Increasing the input excitation level lead to significant increase of the lateral normalized displacements (d/H) and normalized vertical displacements especially for the SPT N values of 5 and 10.In case of width to height ratio (W/H) (from 0.50, 0.65, 0.90) the normalized horizontal displacement (d/H) for moderate earthquakes (i.e g = 0.2 to 0.3) and high earthquakes (i.e g = 0.4 to 0.6) is within the range 0.05 to 0.13 and 0.13 to 0.30 respectively. These ranges of normalized horizontal displacements (d/H) are consistent with the normalized horizontal displacement, which proposed by PIANC 2001 whatever the value of SPT.

In case of width to height ratio (W/H) >1.00 the normalized horizontal displacement (d/H) for moderate earthquakes (i.e g = 0.2 to 0.3) and high earthquakes (i.e g = 0.4 to 0.6) is within the range 0.02 to 0.04 and 0.04 to 0.13 respectively.

4.3.3 SPT-N value

The effects of the equivalent SPT N value are shown in Figure 7 to Figure 11 for width-to-height ratio (W/H) 0.50, 0.65, 0.90, 1.05 and 1.20. For W/H=0.50 and W/H=0.65 increasing the SPT N value leads to decrease the normalized lateral displacement and it can be shown clearly for higher input excitation level 0.4g , 0.5g and 0.6g. This trend is the same for W/H = 1.05 and 1.20.

SPT N values	ρ_d (kg/m^3)	ϕ (deg)	G (Pa)	K (Pa)	Dr (%)	C1	C2
5	1500	35	3.50E7	7.59E7	41	1.164	0.344
10	1500	38	5.82E7	1.26E8	55	0.49	0.82
15	1600	40	8.18E7	1.77E8	66	0.29	1.38
20	1700	41	1.06E8	3.17E8	77	0.21	1.90
25	1800	42	1.30E8	3.91E8	85	0.16	2.50

Note: ρd=dry density; φ =friction angle; G= shear modulus; K=bulk modulus; C1 and C2 = Finn model constant

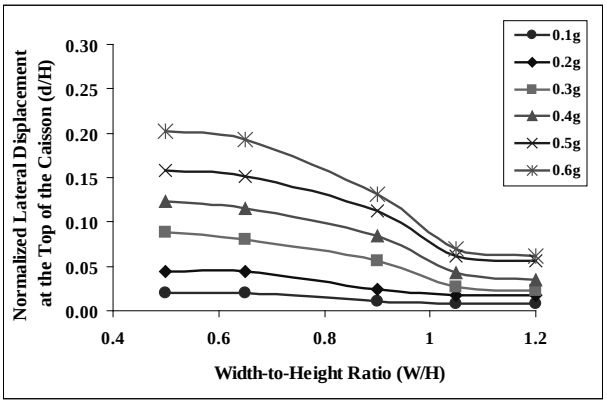

Figure 9 Effects of the width-to-height ratio W/H on normalized lateral displacement (d/H) (for SPT N value of 15) at D1/H=1.0

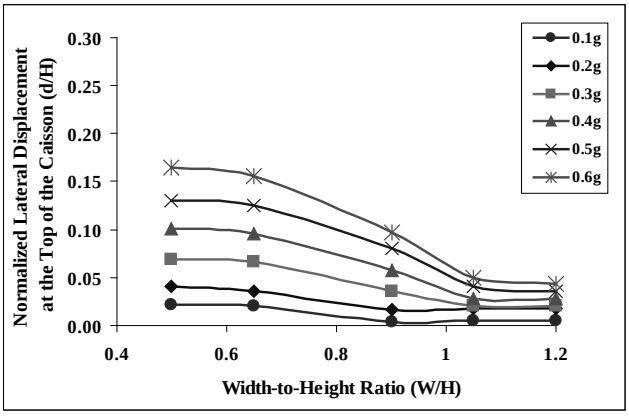

Figure 10 Effects of the width-to-height ratio W/H on normalized lateral displacement (d/H) (for SPT N value of 20) at D1/H=1.0

4.3.4 Thickness of soil deposit below wall (D1/H)

The effects of the thickness of the soil deposit below the wall is shown in Figure 12 for W/H=0.90. There is a linear relation between D1/H and d/H as D1/H reaches 0.5 the rate of change greatly increases particularly for g above 0.4. This comment is the same for different N values up to 25 which clarify that the thickness of a soil deposit below the wall and its SPT N values are two important factors that affect the displacement.

The thickness of the soil deposit below the wall significantly affects the displacement. For a wall built on a thick soil deposit (D1/H> 0.50), the effects of the equivalent SPT N values of the soil below and behind the wall are significant.

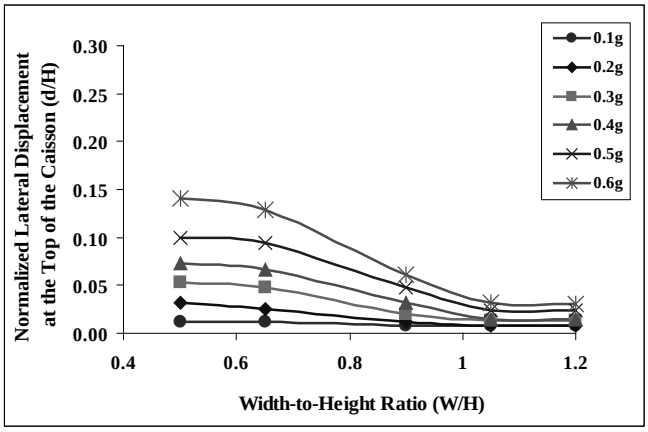

Figure 11 Effects of the width-to-height ratio W/H on normalized lateral displacement (d/H) (for SPT N value of 25) at D1/H=1.0

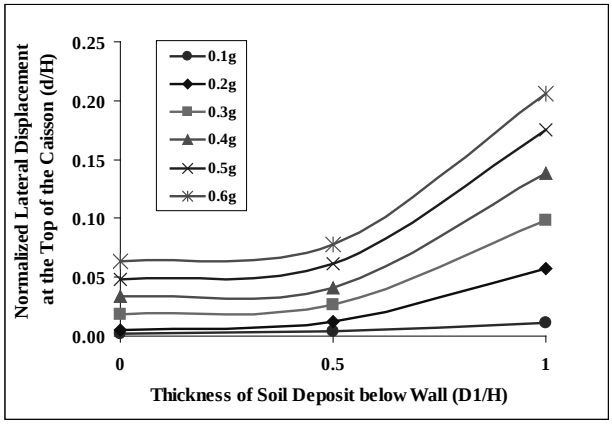

Figure 12 Effects of thickness of soil deposit below the wall (D1) on normalized lateral displacement (d/H) (for SPT N value of 5) at W/H=0.90

4.3.5 Thickness of backfill soil (D2/H)

The effects of the thickness of backfill soil behind the wall is shown in Figure 13 W/H=0.90 and at D1/H=1.0. When the level of excitation is high, significant increase in the displacement is recognized for D2/H> 0.50 and for smaller SPT N values, this clarify that the existence of a soil deposit behind the wall and its SPT N values are two important factors that affect the displacement.

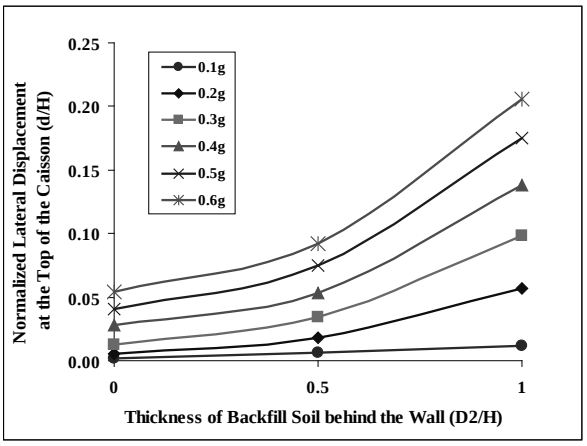

Figure 13 Effects of thickness of backfill (D2) on normalized lateral displacement (d/H) (for SPT N value of 5) at W/H=0.90 and D1/H=1.0

4.4 Procedures for Evaluating Wall Displacement

Based on the results of the parametric study shown in the previous section, a simple procedure is easily developed for evaluating the displacement of gravity quay walls. The flow chart for the simplified procedure is shown in Figure 14. In this procedure, the displacement is evaluated with respect to the parameters in the order of their sensitivity to the displacement.

5. CONCLUSIONS

This investigation had highlighted the following pertinent aspects of the seismic design and performance of gravity quay walls.

1. The proposed nonlinear, effective stress analysis has been proved that it is a more appropriate method to simulate the seismic performance of the caisson as compared to conventional design approaches. It is more efficient especially when excess pore pressure generation and liquefaction have occurred in the backfill.
2. Among the parameters considered in this study, the most sensitive parameter affecting the quay wall displacement under a prescribed level of shaking was the range of SPT-N values of subsoil below and behind the wall. Second was the thickness of backfill soil (D2/H). Thirdly was the thickness of the soil deposit below the wall (D1/H). Fourthly was the width to height ratio (W/H).
3. The factors of safety computed with standard pseudo-static design methods are not adequately correlated with the wall deformations to facilitate estimates of seismically-induced lateral deformations. Therefore, deformation based analyses which account for the generation of excess pore pressures in the backfill are recommended.
4. Simplified design charts have been developed to aid in the performance based seismic design of gravity quay walls.

Abstract: In order to maintain the depth of waterways and sea basins, huge amounts of soft clayey soil are dredged at many ports every year in Japan. In recent years, it has become more difficult to secure disposal areas for dredged soil due to environmental and economical restrictions. The effective use of the dredged soils is therefore required. Granular treated soil, which is dredged clay mixed with cement and polymer, has been developed as a countermeasure against this background and expected to be practical uses for reclamation, backfill or subsoil materials. In this study, a series of dynamic centrifuge tests on applicability of granular treated soil to quay-wall backfill was conducted. The test results indicated that backfill of granular treated soil can reduce lateral displacement of caisson and that such backfill is resistant to liquefaction because of its high permeability.

1. INTRODUCTION

In order to maintain waterways and sea basins, huge amounts of soft clayey soil are dredged at many ports every year in Japan. The dredged soil is dumped at disposal sites in coastal areas as reclamation material. In recent years, however, it has become more difficult to secure disposal areas for dredged soil and subsoil due to environmental restrictions and economic factors. The effective use of these dredged soils is therefore required.

Dredged clay usually has relatively low strength and requires long period for consolidation. Therefore, dredged soil cannot be used without improvement such as solidification. The granulation technique was proposed as a method of improving dredged soil (Kiyota et al. 2000; Kawai et al. 2002). In this technique, dredged soil is mixed with cement and polymer and converted into high-strength particles. Dredged soil improved by granulation technique (hereinafter referred to as "granular treated soil") is a light weight material comparing with sand or gravel because of trapped air inside its particles. The granular treated soil is therefore expected to be used for load embankment, backfill of quay wall and retaining wall, and subsoil material of artificial tidal flat (Amano et al. 2002; Takahashi et al. 2008). Furthermore, granular treated soil is resistant to liquefaction, because it has high permeability because of its relatively large particle size of 1 to 10 mm. Against this background, the authors initiated a project to promote effective use of granular treated soil.

This paper reports the applicability of the granular treated soil for backfill with caisson-type quay walls. A series of centrifuge model tests was performed to investigate the dynamic vibration characteristics of backfill reclaimed with granular treated soil. In these tests, sand was also used for backfill in order to compare with granular treated soil. The results of these tests indicated that backfill consisting of granular treated soil can reduce earth pressure behind caisson and lateral displacement of caisson due to its low unit weight, and that such backfill is resistant to liquefaction because of its high permeability. Furthermore, the effects of phase lag and wave reduction were observed in backfill of granular treated soil. These results show that an isolation effect in ground reclaimed with granular treated soil can be expected.

2. MODEL GROUND PREPARATION

2.1 Granular Treated Soil

The material of the granular treated soil used was marine clay (called Kawasaki clay) dredged at Kawasaki Port. The materials for treatment of the clay were water-soluble chelating polymer (partially neutralized polyacrylate), which was used to reduce the water content of the clay, and ordinary Portland cement used as a solidification agent. The mix ratios of the polymer and the cement were 0.1% and 5%, respectively, of the dry weight of the clay. The Kawasaki clay was stirred into a homogeneous slurry while its water content was adjusted to be 60%, which

was slightly higher than its liquid limit (w_L = 48.6%). The slurry was then mixed with the polymer for two minutes followed by five minutes of mixing with the cement using a small blade mixing machine. This length of mixing time was needed to ensure a homogeneous condition for the mixture, which was further re-mixed for a minute one hour after the first mixing to prevent re-bonding between its particles. After being mixed thoroughly, the materials were then cured in trays covered with plastic sheeting to maintain a constant water content in a steady-temperature room at 20°C.

Table 1 and Figure 1 show the physical properties and photos of backfill materials, respectively. Soma sand was excavated in the Fukushima Prefecture area of Japan and used for comparison with granular treated soil. Figure 2 shows grain size distribution curves for Kawasaki clay and backfill materials. It can be seen that the D_{50} and D_{10} values of granular treated soil are larger than those of Kawasaki clay and Soma sand. Accordingly, granular treated soil can be expected to have high permeability.

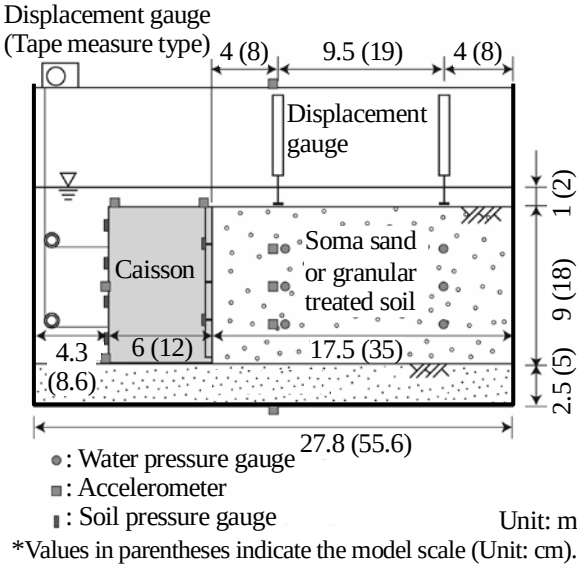
2.2 Model Test Apparatus and Model Ground Preparation



The geotechnical centrifuge used was the PARI centrifuge, which has a radius of 3.8 m, a maximum payload of 2.7 metric tons and a maximum acceleration of 113 G. The details of the centrifuge were described by Kitazume & Miyajima (1995). In this study, shaking table tests were carried out in a centrifugal acceleration field of 50 G.

A schematic representation of the model ground is illustrated in Figure 3, which shows the prototype scale corresponding to the centrifugal acceleration. The specimen container used had rigid sidewalls and a width of 20 cm, a height of 40 cm and a length of 55.6 cm. Membranes coated with grease were placed on inside surfaces of the specimen container to reduce friction between the container and the model ground.

Before preparing the model ground in the specimen container, accelerometers and water pressure gauges were placed precisely at designated depths from the ground surface with the help of fine fishing lines, rubber bands and acrylic plates. After the container had been filled with sand, the fishing lines were cut.

The foundation layer was made of Soma sand poured using a sand hopper, which was placed high enough that the ground density was not influenced by the reduction in the falling height of sand as the specimen container filled up. The relative density of the foundation layer was 90 - 93%.

A caisson model was placed on the foundation layer. This caisson model had a width of 19.5 cm, a height of 18 cm, a length of 12 cm and a unit weight of 18.8 kN/m^3. The centre of mass of the caisson model coincided with its centroid. The caisson model also had four pressure plates on backfill side as shown in Figure 4. The vertical and horizontal force behind the caisson model can be measured by load cells attached inside the pressure plates (Vertical force was not measured because the membrane was also put on the backfill side of the caisson model.)

*Values in parentheses indicate the model scale (Unit: cm).

Figure 3 Schematic View of Model Ground

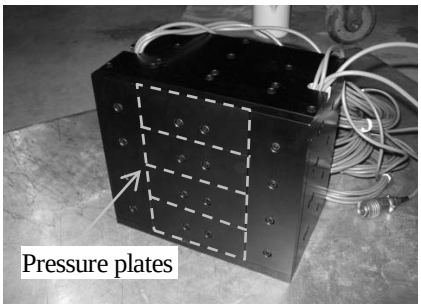


Figure 4 Pressure Plates of the Caisson Model

Table 2 Test Cases

	Backfill material	Initial relative density (%)	Void ratio *e*
Case 1	Granular treated soil	-	3.08
Case 2	Soma sand (Cat. 5)	95	0.73
Case 3		53	0.90

The conditions of the backfill are shown in Table 2. In Case 1, backfill was reclaimed with loose granular treated soil, which was poured from a height of 0 cm. The height of the backfill of granular treated soil was made so that its surface corresponded to the height of the caisson after self-weight consolidation and compaction as outlined below. In Cases 2 and 3, Soma sand was used as a backfill material. It was poured in the same manner as the foundation layer, and the relative density was controlled.

Then, the ground was saturated by difference of water head levels in a centrifugal acceleration field of 20 G. It was confirmed that saturated ground can be obtained by this method (Takahashi et al. 2006). A viscous fluid, which is an aqueous solution of cellulose ethers (Brand name: METOLOSE), was used for saturation. The kinematic viscosity of the solution was controlled to 50 cSt in consideration of similitude of the phenomena of the dynamic deformation of ground and the dissipation of excess pore water pressure in a centrifugal acceleration field of 50 G.

The model ground prepared was set up in the centrifuge facility and subjected to a centrifugal acceleration field of 50 G. After the target acceleration was reached, self-weight consolidation was conducted before the shaking table test to stabilize the backfill against stress induced by such acceleration.

After self-consolidation, several vibrations of 20 sinusoidal waves with a frequency of 100 Hz (corresponding to 2 Hz on the prototype scale) were applied. The amplitude of the input waves was increased in a stepwise manner. During each step, the displacement of the caisson and settlement of the backfill were measured using displacement gauges, and the response acceleration and pore water pressure were measured using embedded accelerometers and water pressure gauges, respectively. Furthermore, the horizontal force behind the caisson was also measured by load cells attached inside the pressure plates.

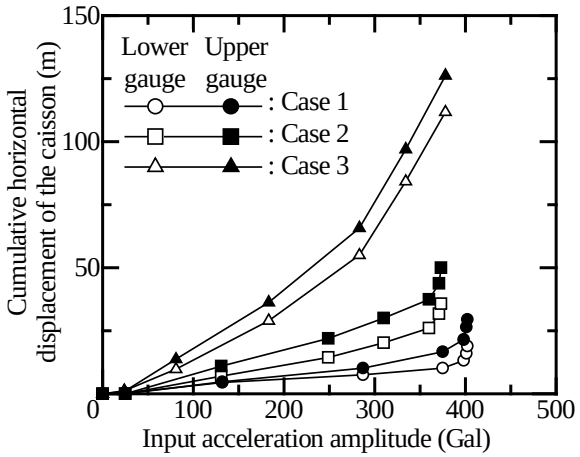

Figure 5 Relationship between Cumulative Horizontal Displacement of the Caisson Top and Input Acceleration Amplitude

3. RESULTS OF MODEL TESTS

3.1 Cumulative Displacement

Figure 5 compares the amounts of displacement on the prototype scale to highlight the relationships between the cumulative horizontal displacement of the caisson and the input acceleration amplitude. The cumulative displacement was evaluated from the position of the caisson before the first step of the shaking table test, although small displacement was observed until the target acceleration was reached.

In all cases, cumulative displacement increased with higher inputs of acceleration amplitude. Displacement in Case 3 was considerably larger than that in the other cases. It can be thought that the large displacement seen in this case was caused by liquefaction in the backfill of loose Soma sand and high earth pressure, as discussed later. The displacement in Case 1 was reduced to half that seen in Case 2 when the input acceleration was large. It can be considered that the earth pressure from the backfill of granular treated soil during vibration was lower than that from dense sand because of its low unit weight and small response acceleration, as outlined in the next section.

The relationships between cumulative settlement of the backfill behind the caisson and input acceleration amplitude are shown in Figure 6 on the prototype scale. Settlement was obtained at 4 m and 13.5 m (8 cm and 27 cm on the model scale) behind the caisson. The settlement of the backfill shown in Figure 6 contains deformation component caused by displacement of the caisson as well as densification component. In all cases, settlement of the backfill increased with higher values of input acceleration amplitude. In particular, the settlement in Case 3 was larger than that seen in the other cases; this was considered to be a result of liquefaction of backfill. The settlement seen in Case 1 was greater than that in Case 2. Furthermore, in Case 1, the difference between settlement at 4m and 13.5 m behind the caisson was smaller than that in Case 2. These facts indicate

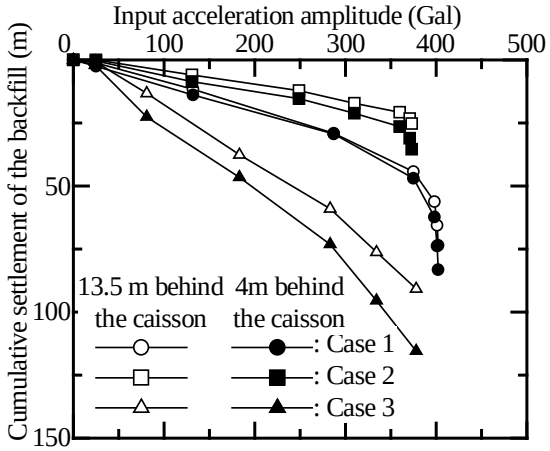

Figure 6 Relationship between Cumulative Settlement of the Backfill and Input Acceleration Amplitude

the high compressibility of granular treated soil, because the displacement of the caisson in Case 1 was smaller than that in Case 2. The high compressibility of granular treated soil is a pending issue to be resolved.

3.2 Response Acceleration

Time histories of response acceleration during the shaking table tests are shown in Figures 7 and 8 on the prototype scale, except for Case 3, in which the response acceleration was unreliable due to liquefaction of the backfill. A limited span (2 sec. on the prototype scale) of the time histories is plotted to facilitate understanding of phase lag and the amplitude of response acceleration.

In Figure 7 (a), a phase lag and amplification were observed in the response acceleration of the backfill and the caisson. It can be thought that the phase lag was caused by low stiffness of the backfill, because the submerged unit weight of the granular treated soil was low (γ' = 4.4 kN/m^3) in comparison with that of dense Soma sand (γ' = 9.2 kN/m^3). When the input acceleration amplitude was large, the response acceleration of the upper part of the backfill and the caisson fell out of step with the input acceleration (Figure 7 (b)). The phase lag increased and acceleration amplitude was reduced, which indicates that stiffness of the backfill of granular treated soil was significantly degraded during vibration because of large strain.

In Figure 8 (a), the response acceleration of the backfill was amplified, but no phase lag was observed. When the input acceleration amplitude was large, the response acceleration of the upper part of the backfill and the caisson included a phase lag. However, the acceleration was amplified in contrast to Case 1 (Figure 7 (b)).

The reduction of acceleration amplitude in the backfill of granular treated soil can be regarded as a kind of isolation effect. The backfill of granular treated soil can be expected to reduce acceleration at the surface.

3.3 Excess Pore Water Pressure

Figure 9 shows time histories of the excess pore water pressure ratio during the shaking table tests. The excess pore

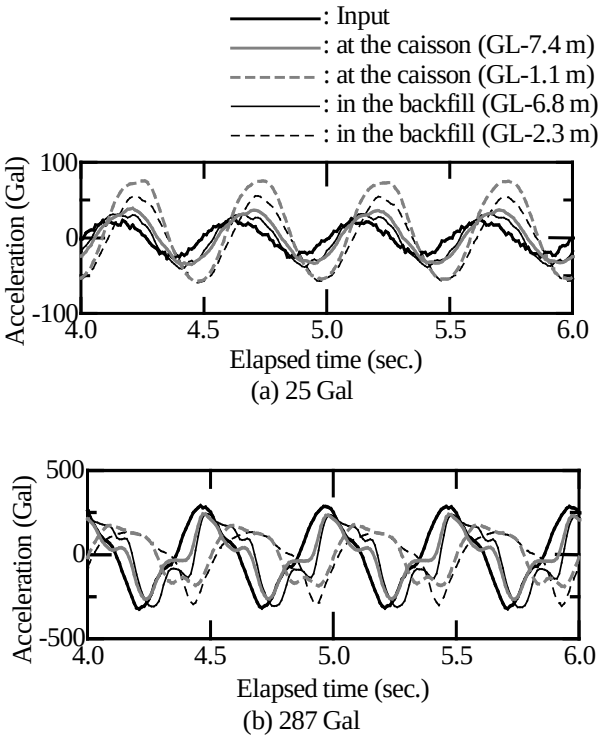

Figure 7 Time Histories of Response Acceleration (Case1)

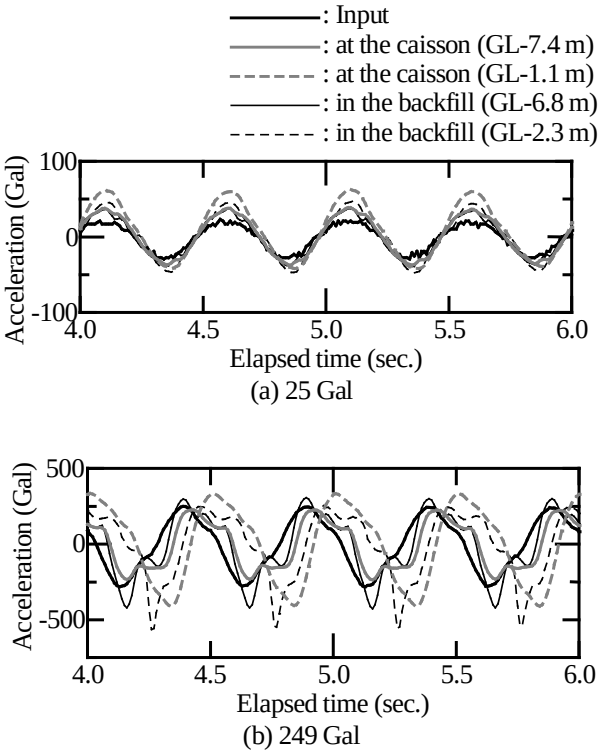

Figure 8 Time Histories of Response Acceleration (Case2)

water pressure shown in the figure was measured at GL-2.3 m and 4 m behind the caisson. The ratio is the excess pore water pressure normalized by the effective overburden pressure. These time histories show simple moving averages of data within the wave length because the ratio shows sharp

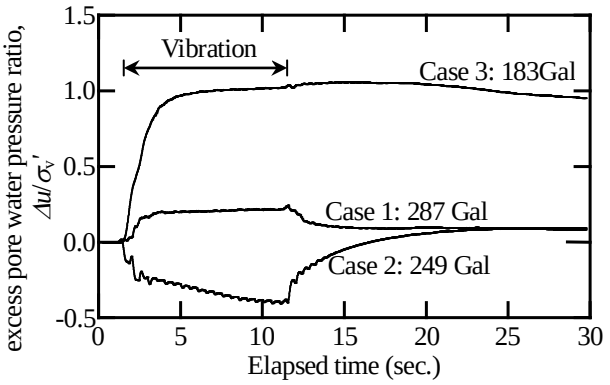

Figure 9 Time Histories of Pore Water Pressure Ratio

fluctuations.

In Case 2, the excess pore water pressure ratio shows a negative value. This can be considered as suction induced by outward displacement of the caisson and dilatancy of dense sand. On the other hand, in Case 3, the backfill of loose Soma sand was found to be liquefied, as the excess pore water pressure ratios reached about 1.0. In Case 1, liquefaction was not observed and the excess pore water pressure ratio increased slightly to 0.24. Furthermore, no suction was observed. This behaviour of the excess pore water pressure in Cases 1 resulted from the high permeability of the granular treated soil, which can be considered highly applicable for quay-wall backfill as a countermeasure against liquefaction.

3.4 Earth pressure behind the caisson

Figure 10 shows distributions of the earth pressure behind the caisson before the first and third vibration. Fluctuation range of the earth pressure during the third vibration is also shown in the figure. The dynamic water pressure is contained in the fluctuation range, but the hydrostatic pressure is not included. The earth pressure before vibration and its maximum value during vibration in Case 1 are smaller than that in Case 2. It can be noted that the backfill reclaimed by granular treated soil instead of dense sand can reduce the earth pressure behind the caisson, because it depends on the response acceleration of the backfill as well as unit weight. The maximum value of the earth pressure during vibration in Case 3 was larger than that in other cases, which was caused by liquefaction.

Figure 11 shows relationships among the total earth pressure, inertia force and dynamic water pressure, which induces the outward displacement of the caisson. (Inertia force, of which positive direction is outward, was evaluated from the acceleration measured at the middle height of the caisson.) The resultant force of these three components to slide the caisson is also shown in the figure as broken line. Resultant forces to slide the caisson of Cases 1, 2, and 3 were 380, 460, and 560 kN/m^2, respectively. It can be thought that the horizontal displacement of the caisson shown in Figure 5 depends on the resultant force. The total earth pressure and inertia force shows positive correlation in Case 3. This correlation is in accord with the results of

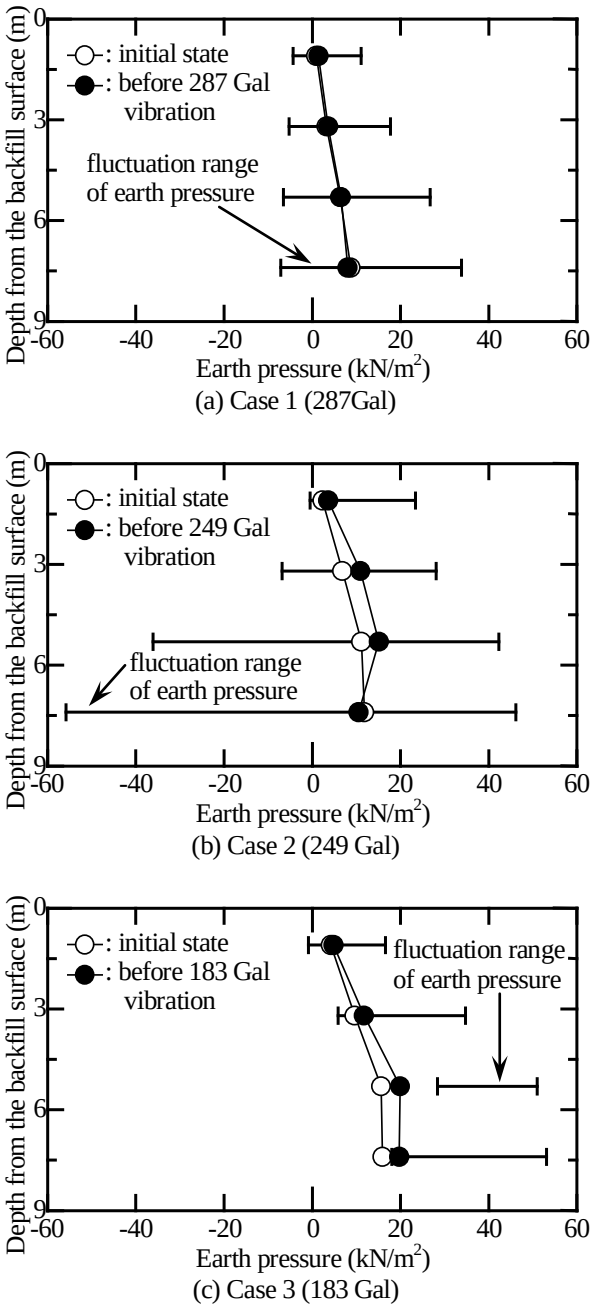

Figure 10 Distribution of Earth Pressure

Kohama et al. (1998), which is the earth pressure and inertia force cooperate together to slide the caisson when liquefaction occurs. In Case 1, the positive correlation between the total earth pressure and inertia force is also observed. It can be thought that this behaviour was caused by stiffness degradation of the backfill. The resultant force in Case 1 was smaller than that in other cases. Therefore, the horizontal displacement of the caisson in Case 1 was reduced in spite of synchronization of the total earth pressure and inertia force. On the other hand, in Case 2, it is because the maximum values of total earth pressure and inertia force were not simultaneous that the horizontal displacement of the caisson was small despite relatively large resultant force to slide the caisson.

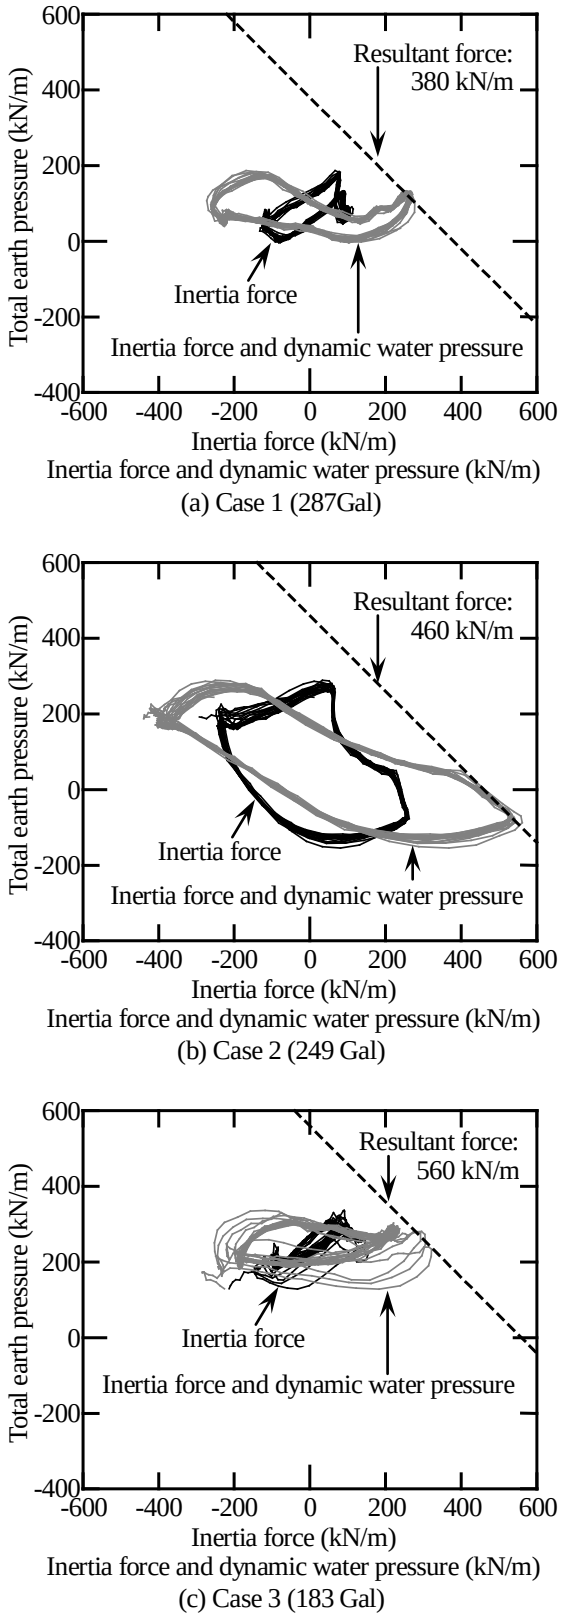

Figure 11 Relationship between Inertia Force and Earth Pressure during Vibration

4. CONCLUSIONS

In this study, dynamic centrifuge tests on the applicability of granular treated soil for quay-wall backfill were conducted. As results of the tests, the response acceleration amplitude and the earth pressure behind the caisson was reduced. This leads to reduction of the horizontal displacement of the caisson. Furthermore, Liquefaction was not observed in the backfill of the granular treated soil, which resulted from its high permeability. The granular treated soil can be considered to have high applicability to the quay-wall backfill in terms of a countermeasure against liquefaction.

Acknowledgements:

The authors wish to express their sincere gratitude to Dr. S. Nishimura (Hokkaido University) who developed the model of the caisson used here. They also thank Mr. K. Takehana (Geo-design Co. Ltd) for providing technical support in conducting a major part of the model test.

Abstract: A fault simulator was newly designed and manufactured for centrifuge study on the structure in or on the soils over dip-slip fault. The design specifications are (1) the simulator can function under 50 G with the surcharge pressure of 500kPa, (2) maximum offset of 30 mm with the dip angle of 60^o can be achieved at the bottom of model soil, (3) both normal and reverse faulting can be generated and adequate force is available for generating reverse faulting, (4) the front face is transparent to observe the model ground during centrifuge tests. This paper describes the newly developed fault simulator and its functions and performance. Some results obtained from an initial test series are also presented. In the initial tests, the effects of overburden stress, type of faults, namely, reverse and normal faulting, and contact conditions between the base rock and the soil, on the rupture propagation and associated ground deformation were studied.

1. INTRODUCTION

The behaviour of alluvial deposits subjected to fault displacement of the base rock is one of the major concerns for almost all structures within fault zone. An understanding the fault rupture propagation through soils would assist engineers in siting and designing the critical structures, such as, building, bridges, tunnels and buried pipes, in the regions where soils overlie active or potentially active fault.

Well and Coppersmith (1994) complied 421 historical earthquakes and selected 244 earthquakes with reliable source parameters. They produced empirical relationships among magnitude, rupture length, rupture width, rupture area, and surface displacement. From indicative fault rupture field studies, Bray et al. (1994) suggested that the characteristics of subsoil overlying the bedrock fault strongly influence the observed fault rupture propagation in the soil.

To compensate the shortcoming of the field study, that is, the lack of well documented field data on the behaviour of subsoil due to the bedrock fault, and to study the mechanisms involved in the fault rupture propagation, both 1G and centrifuge model tests have been performed for several decades. Roth et al. (1981) conducted centrifuge model tests to observe the pattern of shear ruptures in a 6-m alluvial deposit caused by a bedrock fault movement. Cole and Lade (1984), and Lade et al. (1984) performed an extensive 1G experimental study on the shapes and locations of failure surfaces propagating through dense and loose sand caused by a fault movement. They observed that larger vertical displacements are required to form a complete failure surface throughout the sand layer under reverse fault conditions, compared to those under normal fault conditions. El Nahas et al. (2006) developed a centrifuge model setup which can simulate normal and reverse faults, using a triangle shape base block supported by two hydraulic cylinders. Using the centrifuge test results obtained from this simulator and finite element analyses, Anastasopoulos et al. (2007) discussed fault rupture propagation through sand. Ha et al. (2006) developed a two-section split-container for centrifuge modeling of ground deformation by faulting. They reported the results of centrifuge model tests using this container on the effect of permanent ground deformation caused by strike-slip faults on buried pipes.

Numbers of physical model tests have contributed for understanding the mechanisms of fault rupture propagation, behavior of geotechnical structures subjected to the ground deformation by the fault, and the effects of various factors on them. However, there are still remaining factors which have not been well investigated by physical model, for example, the effect of depth of the alluvium overlying the bedrock fault, especially on behavior of the soils at the large depth under a large overburden pressure and the conditions of interface between the base rock and overlying alluvium.

This paper describes a newly developed dip-fault simulator in a centrifuge, by which a large overburden pressure can be applied to the model soil. Some results obtained from an initial test series are also presented. In the initial tests, studied were the effects of overburden stress and type of faults, namely, reverse and normal faulting, and contact conditions between the base rock and the soil, on the rupture propagation and associated ground deformation.

2. FAULT SIMULATOR AND CENTRIFUGE MODEL TEST

2.1 Fault Simulator

A fault simulator was newly designed and manufactured for Mark III Centrifuge at the Tokyo Institute of Technology (Takemura et al., 1999) for centrifuge study of underground structures in soils over dip-slip faults. Specific conditions considered in the design of simulator and soil container are (1) the simulator can function under 50 G with the surcharge pressure of 500kPa, (2) maximum offset of 30 mm with the dip angle of 60^o can be imposed, (3) both normal and reverse faulting can be generated and adequate force is available for generating reverse faulting under the maximum surcharge pressure, (4) the front face is

Thrust rate of jack	0 - 2.18mm/min
Dip angle	60 degree
Max surcharge pressure	500kPa

transparent to observe the model ground during centrifuge tests, (5) inner dimensions of the container should be large as much as possible, but the whole test system can be housed in a space available in the swing platform.

Specification of the fault simulator is given in Table 1. Details of fault simulator are shown in Figure 1. The simulator accommodates a container for model ground, which has internal dimensions of 500mm long, 400mm wide

Table 2 Specification of Toyoura sand used in the test

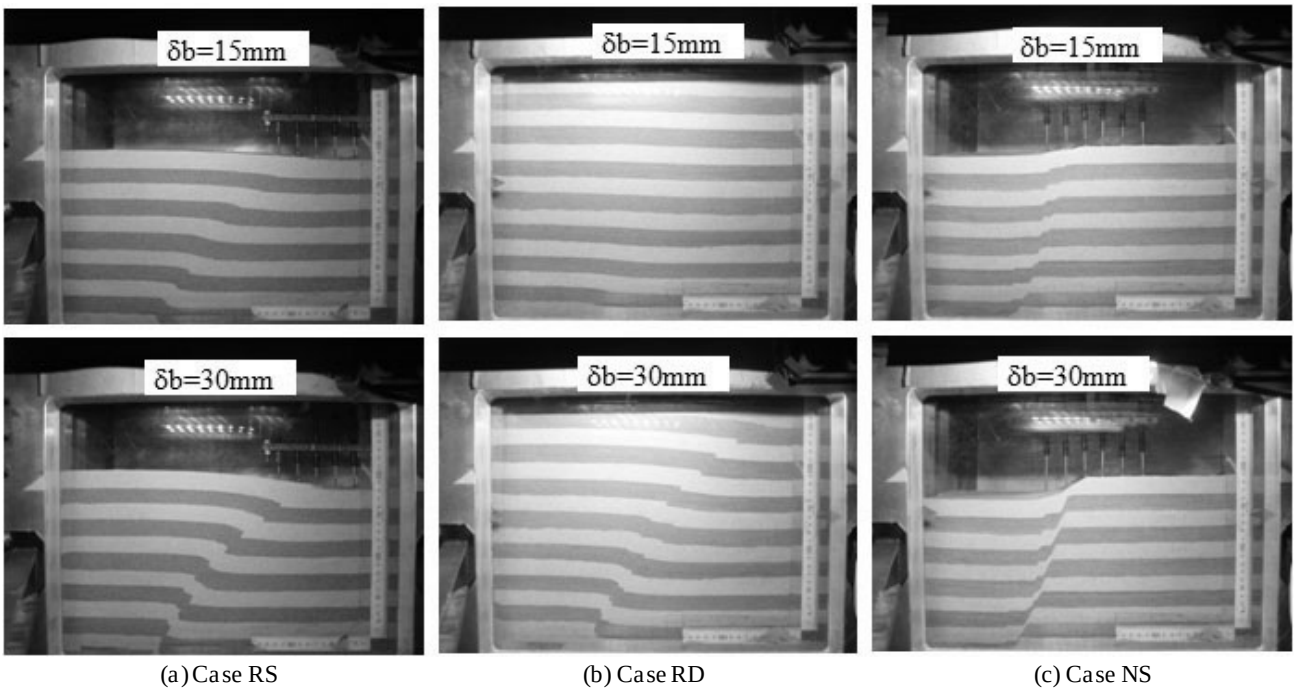
and 300mm deep, made of aluminum alloy. Left side wall and base is movable, which is made from an ingot of the alloy to have an accuracy of the shape. Displacement of the movable wall and base is restricted in the direction of the horizontal angle of 60^o by the inclined guide and the brackets (Figure 1(c)). Fault actuating system consisting of an AC servo-motor with 1/50 reduction gear, a 1/50 reduction worm gear, and a screw jack can create the maximum thrust force of 230kN in a relatively small space beneath the container. The screw jack consists of a rod with normal and reverse screws at the rear and front parts respectively, two trapezoidal prisms, and a pentagon steel block as shown in Figure 1 (e). The trapezoidal blocks are

connected to the rear and front screws of the rod through nuts. With this combination the two trapezoidal prisms move back and forth in the opposite direction, which actuates the pentagon block and the movable side wall & base upward and downward with a dip angle of 60°, simulating reverse and normal faulting, respectively.



A cubic shape rubber bag can be placed on the top of the model ground to apply the maximum surcharge pressure of 500 kPa. To support the pressure of the rubber bag, a rid made of aluminum is fixed to the top of simulator (Figure 1(c)). The front plate of the model container has a rectangular glass window of 400mm wide, 300mm high and 40mm thick, through which the propagation of fault rupture and ground deformation can be viewed (Figure 1(b)).

2.2 Model Preparation and Test Procedures

Using the fault simulator, an initial test series was performed on sand with a buried steel pipe. Figure 2 shows a setup for the test without surcharge and the test cases. Three test cases with pipe are presented in this paper as shown in Figure 2, namely Case RS (reverse faulting and shallow pipe), Case RD (reverse faulting and deep pipe) and Case NS (normal faulting and shallow pipe). In 50G centrifugal acceleration adopted in the tests, the thickness of model ground and pipe cover depth for RS and NS are 11.2m and 2m respectively. Although the model thickness of RD is 15.7m, the overburden stress is equivalent to those of about 40m for the dry sand used in the test. In addition to the three tests, two reverse faulting tests, Cases RDS and RDR were conducted for the sand model with the same dimensions and surcharge as Case RD, but without pipe. Different roughness was made at the container base, namely, frictional condition for Case RDR, which was created by an abrasive paper and less frictional condition with aluminum surface for Case RDS.

Typical test procedures are as follows: (i) fix a model buried pipe to the right side wall; (ii) pour dry Toyoura sand (Table 2) into the container by air pluviation method with a target relative density of 80% to the predetermined height. Every 20mm thickness, colored Toyoura sand is poured adjacent to the front window to create alternate layers with 20 mm thick each for clear identification of the failure surface in the front view (Figure 2); (iii) for Cases RD, RDS and RDR, place the rubber bag on the surface of the model sand layer; (iv) After bolted the top rid onto the container, feed the air pressure to the rubber bag; (v) mount the completed model on the swing platform ready for centrifugal acceleration; (vi) having reached 50G acceleration, activate the fault simulator by the speed of 2.18mm/min to the maximum offset of δb =30mm; (vii) during the faulting period, capture the front view by a digital camera located in front of the front face.

The digital image taken by the camera is used for Particle Image Velocimetry (PIV) processing (White et al., 2003). The model pipe (Figure 2) used in the test is made of stainless steel with outer diameter of 15mm and thickness of 0.5mm, which is equivalent to 750mm diameter and 25mm thick pipe in a prototype. Ten pairs of strain gages are attached to the inner top and bottom surfaces of the pipe with 40mm interval to measure the bending strain of the pipe. The model pipe has a circular flange at the right end, with which the pipe is rigidly fixed to the side wall. On the other a solid circular bar with a flange is inserted to the left end of the pipe. This left flange was attached to the left wall to create a slider. With this slider no extra axial force is induced to the pipe due to the faulting.

3. TEST RESULTS AND DISCUSSIONS

3.1 Fault Rupture Propagation in Sand

During the faulting period, digital image of the front view of the model ground was captured every 1mm displacement of the movable wall and base (δb), which corresponds to the base rock movement along the dip. The in-flight photos of Cases RS, RD and NS at δb=15mm and 30mm are shown in Figure 3. Shape of the rupture surface could be approximated by log-spiral as suggested by Cole and Lade (1984). However, the number and propagation rate of the rupture surface depend on the type of fault and vertical stress of the ground.

From the captured image, propagations of rupture surfaces were traced as shown in Figure 4. In the figure the rupture surfaces observed at the end of the faulting (δb=30mm) are compared for three test cases. The locations of the rupture end at every 5mm of δb are also indicated for each rupture surface. From the figure the followings are confirmed.

1) Rupture propagation rate to the base movement (δb) was greater in the order of Cases NS, RS and RD. 2) The rupture surfaces caused by reverse faulting at the same distance from the container base sloped lower for the shallow case (NS) than the deeper case (RD). 3) Only one rupture surface reached to the ground surface for the reverse faulting, while for the normal faulting two surfaces reached to the ground surface. 4) For the normal faulting, a vertical rupture (NS1) initiated at small base movement but its propagation terminated at δb=5mm. Second one (NS2) appeared and reached to the surface in a small increment of δb from 5 to 10mm at the foot wall side, which was followed by the third one (NS3) at the further foot wall side.

The possible reasons for 1) and 2) is the difference of stress-strain relation which is affected by the stress condition and the confining stress. For the normal faulting, the soil is horizontally expanded, while for the reverse faulting the soil is compressed. Although the stress increment on the failure surface depended on the degree of dilation and the dip angle, the stress of the soil for the normal fault is relatively small and close to active condition compared to those for the reverse fault which have a large stress increase in passive condition. As a result, soils for the normal fault have smaller failure stain than those for the reverse fault, requiring small relative movement for creating shear band for the former than the latter. Difference of dilation of soil between high and low confining stress could explain the difference between Case RS and Case RD. In the previous studies (El Nahas, et al.,2006; Lee and Hamada, 2005), similar results to 3)and 4) were reported. Some previous 1 g model experiments (Cole and Lade,1984; Lee and Hamada, 2005) showed the secondary rupture surface for the normal fault in the hanging wall side for the relatively low dip angles. In Case NS with relatively steep dip angel of 60°, the secondary rupture and the resultant graben were not observed.

3.2 Vertical Deformation of the Ground due to Faulting

The propagation of fault rupture causes deformation in the alluvium over the bedrock. For the case of dip-slip fault with a relatively steep dip angle, like the condition of the test (60°), the vertical differential movement is one of the most critical concerns for the structures constructed in or on the ground. The displacement of the ground induced by the model fault offset was measured from the photos taken by the digital camera using PIV technique with Geo PIV (White and Take, 2003). It should be noted that patch size adopted in the PIV analysis was 64 pixels, equivalent to about 9mm, to have a reliable measurement. However, due to this relatively large patch size, discontinuous deformation might be underestimated. Vertical displacement, δv, profiles at various vertical distances from the base measured at δb=20mm are compared in Figure 5. The displacement is normalized by the vertical component of fault movement, δb_v. The horizontal variation of vertical displacement was more continuous for the reverse faults than the normal fault, and also for Case RD than Case RS. The maximum vertical displacements are almost the same as δb_v for Case RS and Case NS, while for Case RD the vertical displacements were smaller than δb_v. Clear discontinuities can be seen in the profile at the hanging wall side for all depths for the normal fault. In the reverse fault cases, discontinuities were also observed at the hanging wall side

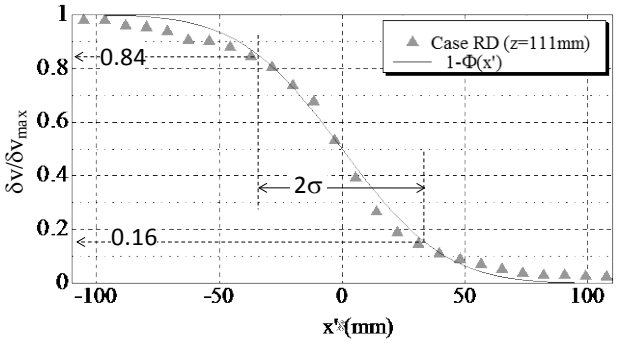

Figure 6 Approximation of vertical displacement profile by cumulative distribution function Φ.

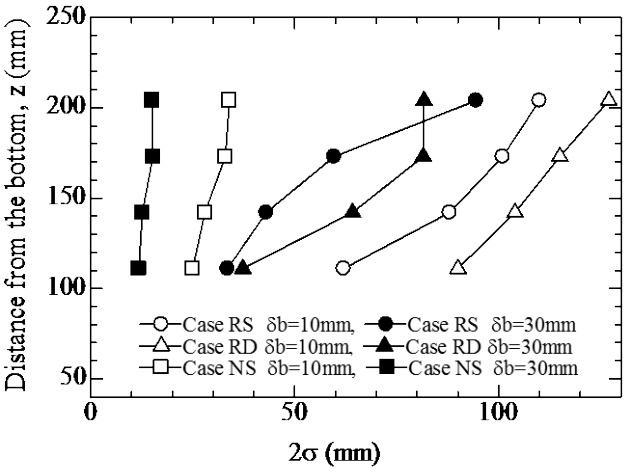

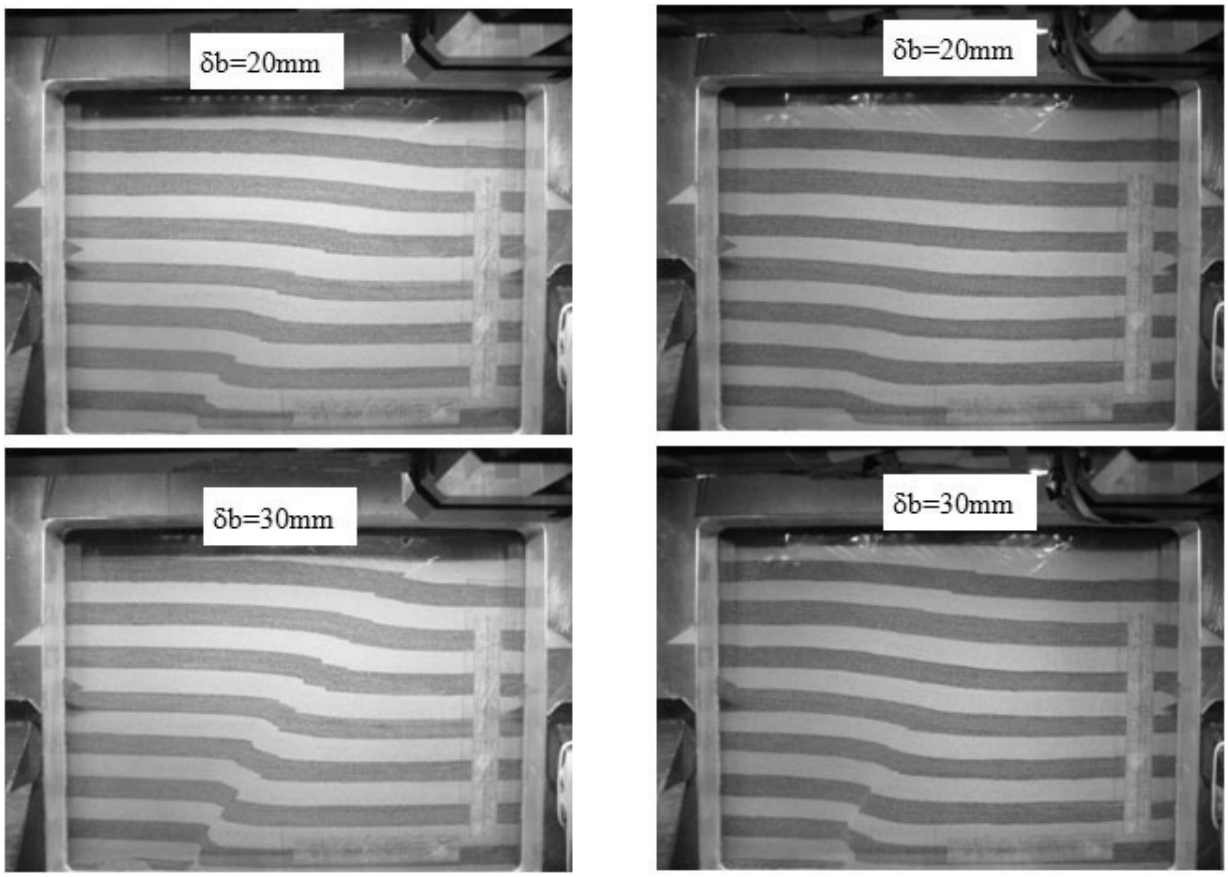

Figure 7 Variation of differential settlement width in terms of 2σ

(a) Case RDR (b) Case RDS

Figure 8 In flight photos of deformation and rupture propagation in sand by to reverse faulting with different base rock-sand interface.

especially for the shallower depth.

Figure 6 shows a typical vertical displacement profile for the case of continuous variation. In the ordinate the δv, is normalized by the maximum value, δv_{max}, and in the abscissa the horizontal coordinate, x', at $\delta v / \delta v_{max}=0.5$ is taken as zero. As can be seen in the figure, the normalized profile can be approximated by cumulative distribution function *Φ*. 2σ (where σ is standard deviation), which is obtained by the method shown in the figure, can be considered as one of the indices representing the width of steep differential vertical displacement. The variations of 2σs obtained from the normalized profile with the distance from the bottom of the container are compared for the three tests at δb=10 and 30mm in Figure 7. The width of differential settlement was larger in the order of Cases RD, RS and NS. The width became larger as the distance from

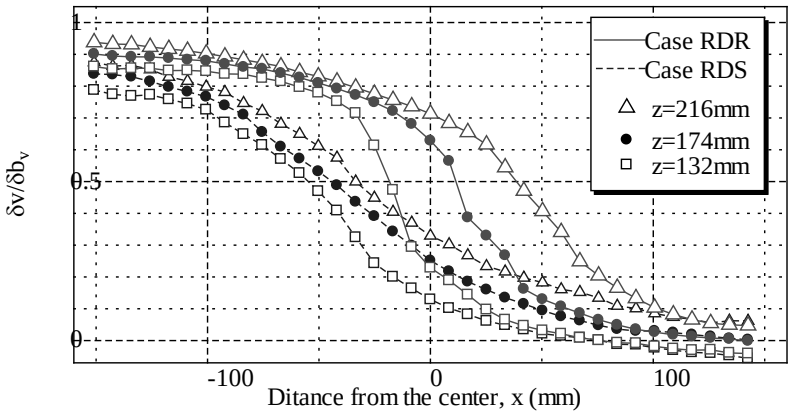

Figure 9 Profiles of normalized vertical displacement in sand by reverse faulting with different base rock-sand interface.

the bottom increased especially for the reverse fault, and it became narrower as the fault offset increased, which is attributed to the concentration of deformation due to the rupture propagation.

3.3 Effect of Interface between Base Rock and Sand.

The movement of bed rock by a dip fault has a horizontal component, which causes shear stresses on the rock surface against horizontal compression and extension for the reverse and normal faulting respectively. In order to the effect of the shear forces mobilized at the interface between the base and sand for the relatively deep depth, the reverse faulting tests were conducted with two different interface conditions, namely high frictional (Case RDR) and less frictional (Case RDS) as explained in 2.2.

The in-flight photos taken at δb=20mm and 30mm are shown in Figure 8. For the case with rough base, clear rupture or discontinuous deformation was propagated from the edge of the fault offset to the upper portion of the sand at δb=20mm. At δb=30mm, new rupture surfaces emerged in hanging wall side above the old one and finally reached to the sand surface. On the other hand for the case with relatively smooth base surface, although vertical movement was extended to the upper portion, no clear rupture surface was observed at δb=20mm. Even at δb=30mm, ground rupture took place at limited depth. It is noted that the rupture surface was not emerged from the edge of the fault offset but at hanging wall side slightly from the edge.

Figure 9 depicts the profiles of the normalized vertical displacement, $\delta v/\delta b_v$, measured for δb=30mm at various vertical distances from the base for the cases with rough base and relatively smooth base conditions. From the figure, the effect of interface condition between the base and sand on the deformation of sand due to the reverse fault can be clearly seen. In the case with the frictional base the differential vertical displacement was more significant than that of the less frictional case and the vertical displacement largely extended to the foot wall side compared to the less frictional case. It could be attributed to larger horizontal compression for the latter case than the former. This horizontal compression at the base of hanging wall can be also a reason for the rupture emerging at the hanging wall side for Case RDS as shown in Figure 8.

4. CONCLUSIONS

A fault simulator was newly developed, which can simulate dip-slip fault in a centrifuge. The simulator has a soil container of inner dimensions of 500mm long, 300mm wide and 350 deep, which functions with full of soil with the surcharge pressure of 500kPa under 50G centrifugal acceleration. Maximum relative displacement of 30 mm with the dip angle of 60^o can be imposed both for normal and reverse faulting. From the initial tests using the fault simulator on the rupture propagation and deformation in dry sand, the following conclusions were drawn.

(1) Shape of the rupture surface could be approximated by log-spiral. Rupture propagation rate to bedrock dip-slip movement is larger for normal faulting than reverse faulting. The rupture surfaces propagation by the reverse fault are affected by the overburden pressure; the deeper the depth is, the smaller the propagation rate and the lower the rupture surface. Only one rupture surface reached to the surface for the reverse fault cases, while for the normal fault case two surfaces reached to the ground surface.

(2) Width of differential settlement was wider for the reverse fault than the normal fault, and for the shallow depth than the deep depth. The width became larger as the distance from the bottom increased especially for the reverse fault, and it became narrower as the fault offset increased, which is attributed to the concentration of deformation due to the rupture propagation.

(3) The frictional condition at the interface between base rock and sand affects rupture propagation and the deformation in sand due to the reverse fault. High frictional condition with large mobilized shear force at the base creates clear rupture surfaces with larger differential vertical displacement in sand compared to less frictional condition with small shear force. This difference could be attributed to larger horizontal compression for the latter case than the former.

BASIC STUDY FOR SIMULATION OF BEHAVIOR OF SOIL DUE TO CYCLIC LOADING USING PARTICLE METHOD

Tomohide Takeyama[1)]

1) Assistant Professor, Department of Civil Engineering, Tokyo Institute of Technology, Japan
takeyama.t.aa@m.titech.ac.jp

Abstract: Smoothed particle hydrodynamics (SPH), as a particle method, was originally proposed for modeling astrophysical phenomena, and later widely extended for applications to problems of continuum solid and fluid mechanics. In the SPH method, the problem domain is represented by a set of arbitrarily distributed particles which possess material properties and move according to the governing conservation equations. The field variables are approximation, the formulation of SPH is not affected by the arbitrariness of the particle distribution. Therefore it can naturally handle problems with extremely large deformation. In this research, applying this method, the behavior of soil due to cyclic loading is simulated.

1. INTRODUCTION

The Smoothed Particle Hydrodynamics (SPH) was originally proposed for modeling astrophysical phenomena by Lucy (1977). In the present it is widely used for applications to problems of fluid mechanics. In the SPH method, the problem domain is represented by particles. The field variables are calculated at the position of particles. These particles move according to the governing equations. The SPH method is one of meshless Lagrangian method. Therefore it can naturally handle problems with extremely large deformation such as liquefaction or land slide which is hardly simulated by FEM. Additionally,

In order to apply the SPH method to the geotechnical problems, the simple simulations employed the Modified Cam-Clay model with subloading surface as the constitutive model were carried out in this research.

2. SPH Method

2.1 Formulation of SPH

Smoothed Particle Hydrodynamics (SPH) was developed by Lucy (1977) and Gingold and Monaghan (1983) for the simulation of astrophysical problems. SPH is the method to evaluate the field variables such as density, velocity and so on at the arbitrary time by regarding the continuum as particle aggregate as shown in Figure 1.

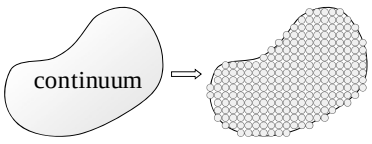

Figure 1 Basic concept of Smoothed Particle Hydrodynamics (SPH)

According to SPH formulation, a function at an arbitrary point $f(\mathbf{x})$ is interpolated in an integral form as

$$f(\mathbf{x}) = \int_{\Omega} f(\mathbf{x}')W(\mathbf{x}-\mathbf{x}',h)dV\,. \tag{1}$$

In the equation (1), Ω is the domain of integral that contains $\mathbf{x}$. The function $W(\mathbf{x}-\mathbf{x}',h)$ is so-called the smoothing kernel function. In the smoothing kernel function, h is the smoothing length defining the influence area of the smoothing kernel function. It should satisfy following conditions. The first one is the normalization condition. The integral of smoothed kernel function become 1.

$$\int_{\Omega} W(\mathbf{x}-\mathbf{x}',h)dV = 1\,. \tag{2}$$

The second one is the Delta function condition. In the limit for $h \to 0$, the smoothing kernel function become the Dirac delta function.

$$\lim_{h\to 0} W(\mathbf{x}-\mathbf{x}',h) = \delta(\mathbf{x}-\mathbf{x}')\,. \tag{2}$$

The third one is the compact condition. The smoothing kernel function becomes 0 outside a certain area.

$$W(\mathbf{x}-\mathbf{x}',h) = 0\,, \text{ when } |\mathbf{x}-\mathbf{x}'| > \kappa h \tag{3}$$

where κ is a constant. According to this condition, the value of function inside the circle (2D) or sphere (3D) with radius of κh is influence in calculating $f(\mathbf{x})$ by the equation (1). In the other words, it is not necessary to

consider the variables outside the domain which is called a support domain. Therefore the cost of computation can makes small.

The integral representation for $f(\mathbf{x})$ can be spatially descretized by particle approximation as

$$f(\mathbf{x}) \approx \sum_{j=1}^{N} \frac{m_j}{\rho_j} f(\mathbf{x}_j) W(\mathbf{x}-\mathbf{x}_j, h). \quad (4)$$

The subscript j iterates over all particles neighboring the particle i. N is the number of particles neighboring the particle i. m_j, ρ_j and $\mathbf{x}_j$ are the mass, the density and the position of particle j respectively. Therefore a field quantity at the position of particle i, $\phi_i = \phi(\mathbf{x}_i)$ can be written as

$$\phi_i = \sum_{j=1}^{N} \frac{m_j}{\rho_j} \phi_j W_{ij} \quad (5)$$

where

$$W_{ij} = W(\mathbf{x}_i - \mathbf{x}_j, h). \quad (6)$$

In order to simulate the motion of particles, the spatial derivative of field quantity is required. The spatial derivative of a function is obtain by substituting $\nabla f(\mathbf{x})$ with $f(\mathbf{x})$ in equation (1), which gives

$$\nabla f(\mathbf{x}) = \int_\Omega \{\nabla f(\mathbf{x}')\} W(\mathbf{x}-\mathbf{x}', h)\, dV. \quad (7)$$

Applying the Gaussian divergence theorem to the equation (7), the following equation is obtained.

$$\nabla f(\mathbf{x}) = \int_S f(\mathbf{x}') W(\mathbf{x}-\mathbf{x}', h)\, \mathbf{n}\, dS - \int_\Omega f(\mathbf{x}') \nabla W(\mathbf{x}-\mathbf{x}', h)\, dV. \quad (8)$$

S is the surface of support domain and $\mathbf{n}$ is the normal vector. The first term of right hand side of equation (8) becomes 0 due to the compact condition. As well as the procedure to descretize $f(\mathbf{x})$, the spatial derivative of a function is approximated as

$$\nabla f(\mathbf{x}) \approx -\sum_{j=1}^{N} \frac{m_j}{\rho_j} f(\mathbf{x}_j) \nabla W(\mathbf{x}-\mathbf{x}_j, h). \quad (9)$$

The spatial derivative of field quantity at the particle i, $\nabla\phi_i = \nabla\phi(\mathbf{x}_i)$ is written as

$$\nabla\phi_i = \sum_{j=1}^{N} \frac{m_j}{\rho_j} \phi_j \nabla_i W_{ij}. \quad (10)$$

2.2 Smoothing kernel function

In SPH method, a cubic spline function is widely adopted as the smoothing kernel function.

$$W(R,h) = \alpha_d \begin{cases} 2/3 - R^2 + R^3/2 & 0 \le R < 1 \\ (2-R)^3/6 & 1 \le R < 2 \\ 0 & R \ge 2 \end{cases} \quad (12)$$

where $R = |\mathbf{x}-\mathbf{x}'|/h$, $\alpha_d = 1/h$, $15/7\pi h^2$ and $3/2\pi h^3$ in one, two and three dimensional space. α_d is defined so that the unity condition is satisfy. The spatial derivative of smoothing kernel function is described as

$$\nabla W(R,h) = \frac{\alpha_d}{h^2} \begin{cases} -2 + 3R/2 \\ -2/R + 2 - R/2 \\ 0 \end{cases} \begin{matrix} 0 \le R < 1 \\ 1 \le R < 2 \\ R \ge 2 \end{matrix} (\mathbf{x}-\mathbf{x}'). \quad (13)$$

The smoothing kernel function $W(R,h)$ and the spatial smoothing kernel function $\nabla W(R,h)$ adopted the cubic spline function are shown in Figure 2.

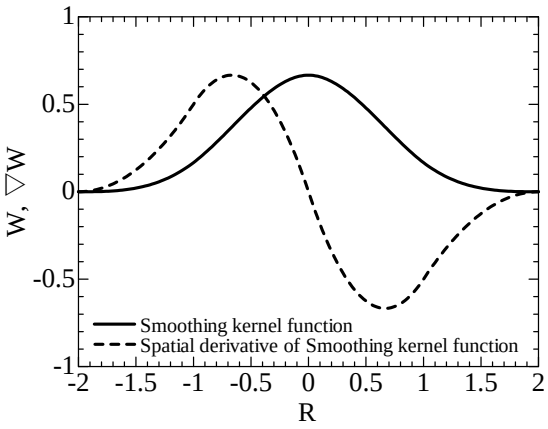

Figure 2 The smoothing kernel function and its spatial derivative

2.3 Governing equations

The governing equations in calculating the behavior of continuum are as follows.

$$\rho\dot{\mathbf{v}} = \nabla\cdot\boldsymbol{\sigma} + \rho\mathbf{g} \quad (14)$$

$$\dot{\rho} = -\rho\nabla\cdot\mathbf{v} \quad (15)$$

$$\dot{\boldsymbol{\sigma}} = \mathbf{C}^{ep} : \dot{\boldsymbol{\varepsilon}} \quad (16)$$

The equations (14), (15) and (16) are the equation of motion, the conservative low of mass and the constitutive equation respectively. ρ, $\mathbf{v}$, $\mathbf{g}$, $\boldsymbol{\sigma}$, $\boldsymbol{\varepsilon}$ and $\mathbf{C}^{ep}$ are density, velocity, acceleration of gravity, stress tensor, strain tensor and elasto-plastic constitutive tensor.

The divergence of $\boldsymbol{\sigma}/\rho$ is described as

$$\nabla \cdot \left(\frac{\boldsymbol{\sigma}}{\rho} \right) = \frac{1}{\rho} \nabla \cdot \boldsymbol{\sigma} - \frac{\boldsymbol{\sigma}}{\rho^2} \cdot \nabla \rho \,. \tag{17}$$

Applying the equation (10) to the left hand side and the second term of right hand side of equation (17), following equations are obtained.

$$\left\langle \nabla \cdot \left(\frac{\boldsymbol{\sigma}}{\rho} \right) \right\rangle_i = \sum_{j=1}^{N} \frac{m_j}{\rho_j} \frac{\boldsymbol{\sigma}_j}{\rho_j} \cdot \nabla_i W_{ij} \tag{18}$$

$$\left\langle \frac{\boldsymbol{\sigma}}{\rho^2} \nabla \cdot \rho \right\rangle_i = \frac{\boldsymbol{\sigma}_i}{\rho_i^2} \cdot \sum_{j=1}^{N} \frac{m_j}{\rho_j} \rho_j \nabla_i W_{ij} \tag{19}$$

By substituting the equations (18) and (19), the divergence of stress dividing by density at the position of particle i can be written as

$$\left\langle \frac{1}{\rho} \nabla \cdot \boldsymbol{\sigma} \right\rangle_i = \sum_{j=1}^{N} m_j \left(\frac{\boldsymbol{\sigma}_i}{\rho_i^2} + \frac{\boldsymbol{\sigma}_j}{\rho_j^2} \right) \cdot \nabla_i W_{ij} \,. \tag{20}$$

The equation of motion (14) can be descretized.

$$\frac{D\mathbf{v}_i}{Dt} = \sum_{j=1}^{N} m_j \left(\frac{\boldsymbol{\sigma}_i}{\rho_i^2} + \frac{\boldsymbol{\sigma}_j}{\rho_j^2} \right) \cdot \nabla_i W_{ij} + \mathbf{g} \tag{21}$$

Therefore, we can calculate the acceleration of particle i from the mass, the density, the coordinates and the stress tensor at each particle which is contained in the support domain of particle i based on the equation (21). As well as the equation of motion, the conservative low of mass (15) can be descretized as

$$\frac{D\rho_i}{Dt} = \sum_{j=1}^{N} m_j \left(\mathbf{v}_i - \mathbf{v}_j \right) \cdot \nabla_i W_{ij} \,. \tag{22}$$

The strain rate is described as follows based on the small strain theorem.

$$\dot{\boldsymbol{\varepsilon}} = -\frac{1}{2} \left(\nabla \otimes \mathbf{v} + \mathbf{v} \otimes \nabla \right) \tag{23}$$

$\nabla \otimes \mathbf{v}$ can be descretized by particle approximation as

$$\left\langle \nabla \otimes \mathbf{v} \right\rangle_i = \sum_{j=1}^{N} \frac{m_j}{\rho_j} \nabla_i W_{ij} \otimes \mathbf{v}_j \,. \tag{24}$$

In order to symmetrize, by subtracting

$$\sum_{j=1}^{N} \frac{m_j}{\rho_j} \nabla_i W_{ij} \otimes \mathbf{v}_i \,, \tag{25}$$

we can obtain

$$\left\langle \nabla \otimes \mathbf{v} \right\rangle_i = \sum_{j=1}^{N} \frac{m_j}{\rho_j} \nabla_i W_{ij} \otimes \left(\mathbf{v}_j - \mathbf{v}_i \right). \tag{26}$$

The benefit of this symmetrization is the reduction of errors arising due to the inconsistency of particles. The strain rate is descretized as

$$\dot{\boldsymbol{\varepsilon}}_i = -\frac{1}{2} \sum_{j=1}^{N} \frac{m_j}{\rho_j} \left\{ \nabla_i W_{ij} \otimes \left(\mathbf{v}_j - \mathbf{v}_i \right) + \left(\mathbf{v}_j - \mathbf{v}_i \right) \otimes \nabla_i W_{ij} \right\} \tag{27}$$

In coding the SPH method, some special treatments is employed for enhancing the stability properties of numerical algorithms. The first one is the artificial viscosity. The formulation of SPH induces the unphysical oscillations in the numerical result. Monaghan and Gingold (1983) applied it to SPH to remove this unphysical oscillations. This Monaghan type artificial viscosity is the most widely used so far in the SPH literatures. The detailed formulation is as follows.

$$\Pi_{ij} = \begin{cases} \dfrac{-\alpha \bar{c} \phi + \beta \phi^2}{\bar{\rho}} & \left(\mathbf{v}_i - \mathbf{v}_j \right) \cdot \left(\mathbf{x}_i - \mathbf{x}_j \right) < 0 \\ 0 & \left(\mathbf{v}_i - \mathbf{v}_j \right) \cdot \left(\mathbf{x}_i - \mathbf{x}_j \right) \geq 0 \end{cases} \tag{28}$$

where

$$\phi = \frac{\bar{h} \left(\mathbf{v}_i - \mathbf{v}_j \right) \cdot \left(\mathbf{x}_i - \mathbf{x}_j \right)}{\left| \mathbf{x}_i - \mathbf{x}_j \right|^2 + \left(0.1 \bar{h} \right)^2} \tag{29}$$

$$\bar{h} = \left(h_i + h_j \right) / 2 \,, \quad \bar{\rho} = \left(\rho_i + \rho_j \right) / 2 \,, \quad \bar{c} = \left(c_i + c_j \right) / 2$$

In the above equation, α, β are constants. c is the speed of sound. The second one is XSPH technique proposed by Monaghan (1994). In XSPH method, the position of particles is updated according to the following equation.

$$\frac{d\mathbf{x}_i}{dt} = \mathbf{v}_i - \varepsilon \sum_{j=1}^{N} \frac{m_j}{\rho_j} \left(\mathbf{v}_i - \mathbf{v}_j \right) W_{ij} \tag{30}$$

where ε is a constant. It is clear that the velocity of neighboring particle contributes in updating the position of the particle i. Therefore the XSPH technique can keep the particles more orderly and avoid the penetration between approaching particle.

2.3 Constitutive equation

The constitutive equation employed in this research is the Modified Cam-Clay model (MCC) proposed by Roscoe et al. (1968). The yield function of MCC model is described as

$$f = \mathrm{M}D\ln\frac{p'}{p'_0} + \mathrm{M}D\ln\left\{1+\left(\frac{q}{\mathrm{M}p'}\right)^2\right\} - \varepsilon_v^p = 0 \qquad (31)$$

in which the plastic volumetric strain ε_v^p plays a role of hardening parameter. M is the critical state parameter defined by Roscoe, Schofield and Thurairajah (1963). D is the coefficient of dilatancy proposed by Shibata (1963). p', p'_0 and q are the effective mean stress, the effective mean stress in the pre-consolidated state and the deviatoric stress. The yield surface of MCC model in ax-symmetric stress plane is shown in Figure 3.

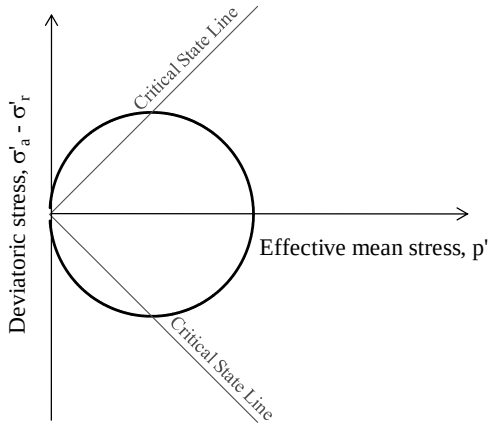

Figure 3 Yield surface of Modified Cam-Clay model in axi-symmetric stress plane

If the stress state is inside the yield surface, a non-linear elastic stress-strain relationship is applied.

$$\dot{\boldsymbol{\sigma}}' = \mathbf{C}^e : \dot{\boldsymbol{\varepsilon}}^e \qquad (32)$$

where

$$\mathbf{C}^e = K\mathbf{1}\otimes\mathbf{1} + 2G\mathbf{A} \qquad (33)$$

In the equation (33), K and G are elastic bulk modulus and elastic shear modulus. $\mathbf{1}$ is Croneker's delta. $\mathbf{A} = \mathbf{I} - (\mathbf{1}\otimes\mathbf{1})/3$ is 4th order deviatoric tensor where I is 4th order identity tensor. Applying the associate flow rule to the consistency condition $df = 0$, the stress-strain relationship in elasto-plastic state is obtained as

$$\dot{\boldsymbol{\sigma}} = \mathbf{C}^{ep} : \dot{\boldsymbol{\varepsilon}} \qquad (16)$$

where

$$\mathbf{C}^{ep} = \mathbf{C}^e - \frac{\mathbf{C}^e : \partial f/\partial\boldsymbol{\sigma}' \otimes \partial f/\partial\boldsymbol{\sigma}' : \mathbf{C}^e}{\mathbf{1} : \partial f/\partial\boldsymbol{\sigma}' + \partial f/\partial\boldsymbol{\sigma}' : \mathbf{C}^e : \partial f/\partial\boldsymbol{\sigma}'}. \qquad (34)$$

During the earthquake, the shear deformation occurs in the ground and the pore water pressure arises due to the dilatancy. Thus the effective mean stress decreases. And then the liquefaction occurs when the effective mean stress becomes 0. Therefore it is need that the constitutive model can represent at least the decrease of the effective mean stress in undrainage shear deformation by cyclic load. However, the constitutive model which I mentioned above cannot represent this feature. In order to represent that feature, the subloading surface proposed by Hashiguchi et al. (1998) is employed in this research. The subloading surface is always inside the normal yield surface and the current stress is on the subloading surface. The plastic strain is developed although the stress is inside the normal yield surface by applying subloading surface. Therefore the reduction of effective pressure due to cyclic load can be calculated. The function of subloading surface is as follows.

$$f = \mathrm{M}D\ln\frac{p'}{p'_0} + \mathrm{M}D\ln\left\{1+\left(\frac{q}{\mathrm{M}p'}\right)^2\right\} - \varepsilon_v^p - MD\ln R = 0 \qquad (35)$$

where $R = p'_y / p'_c$ is called the similarity ratio of subloading surface which indicates the ratio of size between the subloading surface and normal yield surface. The subloading surface of $R = 0.8$ and the normal yield surface on axi-symmetric stress plane are shown in Figure 4.

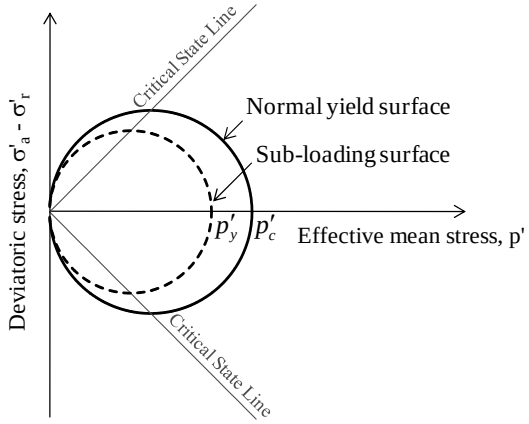

Figure 4 Subloading surface and normal yield surface in axi-symmetric stress plane

The similarity ratio R change according to the developing low which is also proposed by Hashiguchi et al. (1998)

$$\dot{R} = -\frac{m}{D}\ln R\left\|\dot{\boldsymbol{\varepsilon}}^p\right\| \qquad (36)$$

where m is the parameter which controls the speed of the subloading surface to achieve the normal yield surface.

3. Result of simulation

In this chapter, the simulation result of constant volume shear test applied cyclic load by using SPH method. The material parameters used in the simulation are listed in Table 1.

Table 1 Material parameters used in the simulation

Critical state parameter	M	1.00
Irreversible ratio	Λ	0.80
Coefficient of dilatancy	D	0.08
Poisson's ratio	ν'	0.33
Compression index	λ	0.20
Void ratio at pre-consolidated state	e_0	1.00
Earth pressure at rest at pre-consolidated state	K_0	1.00
Earth pressure at rest at initial	K_i	1.00
Vertical stress at pre-consolidated state (kPa)	σ'_{v0}	98.0
Vertical stress at initial (kPa)	σ'_{vi}	98.0
Parameter for sub-loading surface	m	2.0

In the simulation, the increment of time is set to be 1.0×10^{-7} sec. The number of step is 1000000, the number of particles is 6160. The computation time is not so long because calculation process is parallelized by GPUs (Graphic Processing Units).

3.1 Constant volume shear test

The simulation of constant volume shear test are performed. The initial configuration of particles is shown in Figure 5. The height and width of specimen is 0.1m and 0.06m.

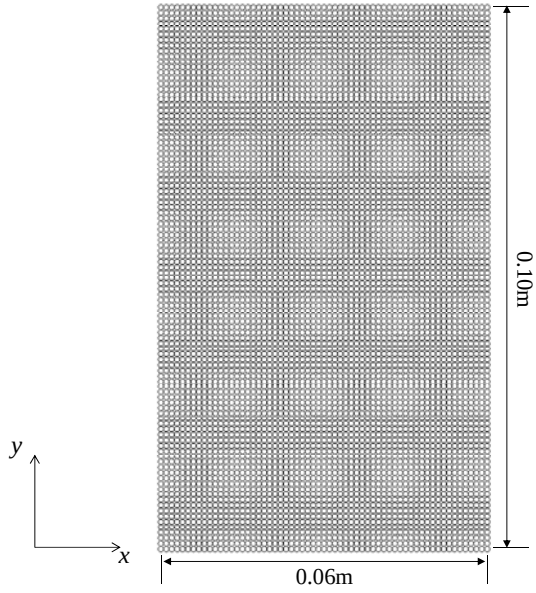

Figure 5 Initial configuration of particles (6060 particles)

The displacements are given at particles which placed on the boundary of specimen. In order to simulate the cyclic loading, given displacements are turned to opposite direction when the deviatoric strain is over 1.5%. Figure 6 shows the velocity vectors in compression shearing and extension shearing process. Figure 7(a) and (b) are shown the stress path and stress-strain relationship of the particle which is located the center of specimen.

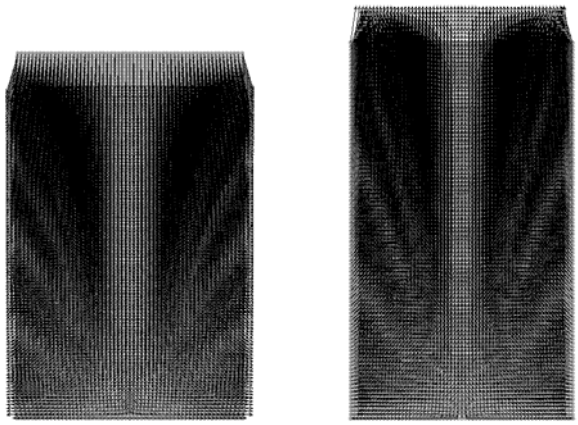

Figure 6 Velocity vectors of particles in compression shearing process: right hand side, extension shearing process: left hand side

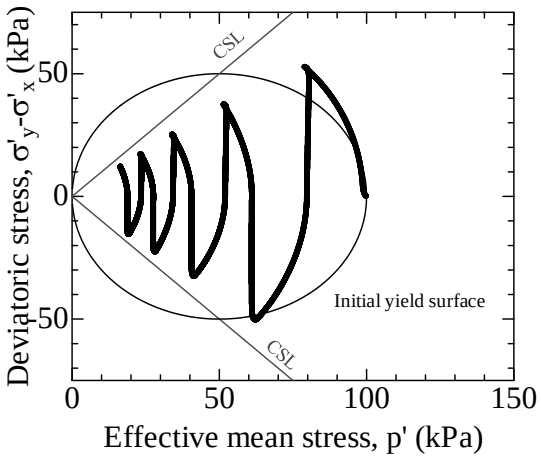

Figure 7(a) Effective stress path

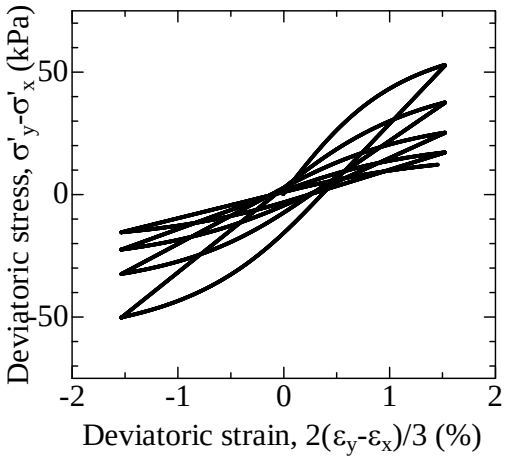

Figure 7(b) Stress-strain relationship

The reduction of effective mean stress due to cyclic load can be simulated as shown in Figure 7(a). The reduction

of the shear modulus during cyclic deformation also can be seen in Figure7(b).

4. CONCLUSIONS

In this research, the simulations of constant volume shear test employed the Modified Cam-Clay model with subloading surface as the constitutive model was performed by using the SPH method.

It is confirmed that the decrease of effective mean stress and the shear modulus during cyclic deformation can be reproduced by this method.

In order to applying this method to more practical geotechnical problems, it is necessary to develop the method which can solve the soil/water coupled problem. That is the future work.

SEISMIC HAZARD FOR MAXIMUM SHEAR STRESSES IN SOIL LAYERS AT OAKLAND INTERNATIONAL AIRPORT

Tadahiro Kishida

JST-JICA Assistant Professor, Graduate School of Engineering, Chiba University, Japan
tkishida@faculty.chiba-u.jp

Abstract: Seismic shear stresses in soil layers are studied at Oakland International Airport where thick Young Bay Mud deposit exists under the landfill. Site response analyses are performed with the wide range of input ground motions to compute maximum shear stresses in soil layers. Stress reduction coefficients are calculated from the site response analyses and compared with the predictive equations. Regression analyses are performed for maximum shear stresses and those intensities are incorporated into the probabilistic seismic hazard analysis to describe the variations of ground motion intensities with the depth. Conditional mean spectra are calculated with 10 % probability of exceedance in 50 years, and the methodology to calculate the design spectra with the conditional probability distribution is described.

1. INTRODUCTION

Oakland International Airport is located at 7 km south of the central city of Oakland providing the service for more than 10 million people and 700 thousand tons of cargo for a year. The construction of airport was started at 1927 and expanded until middle of 1960's. At the early stage of construction, the airport was built with the dredged sand and clay over the Young Bay Mud in San Francisco East Bay. Since the airport is located at 8 km west of Hayward Fault and 20 km east of San Andreas Fault, the relatively high seismic intensity is expected with the amplification of seismic wave by thick Young Bay Mud deposit.

As a typical design procedure, maximum shear stresses in soils layers are calculated for the design ground motions to estimate the liquefaction potential and seismic deformations. Simplified procedure, which is suggested by Seed and Idriss (1971), uses the peak ground acceleration (PGA) and stress reduction coefficient (r_d) to estimate the maximum shear stresses in soil layers. PGA is generally obtained by the probabilistic seismic hazard analysis (PSHA) and r_d is calculated given PGA and earthquake magnitude from disaggregation results. However, ground motion intensity changes for maximum shear stresses in soil layers since those depends on the depth of soil layer and earthquake magnitude or ground motion frequency (Idriss (1999), Cetin et al. (2004), Kishida et al. (2009)). Therefore, it is important to understand the variation of ground motion intensities in providing the design spectra.

This paper describes the characteristics of maximum shear stress distributions at Oakland International Airport by performing the site response analysis with the equivalent linear method of SHAKE (Schunable, 1972), and those results are compared with the simplified procedure for estimating the maximum shear stress distribution. The vector intensities of maximum shear stresses are introduced as a linear combination of spectral accelerations, and those intensities are incorporated into the probabilistic seismic hazard analysis. Effects of variation of ground motion intensities are described by the conditional mean spectra and the rational procedure for calculating the design spectra from the probabilistic seismic hazard analysis are presented.

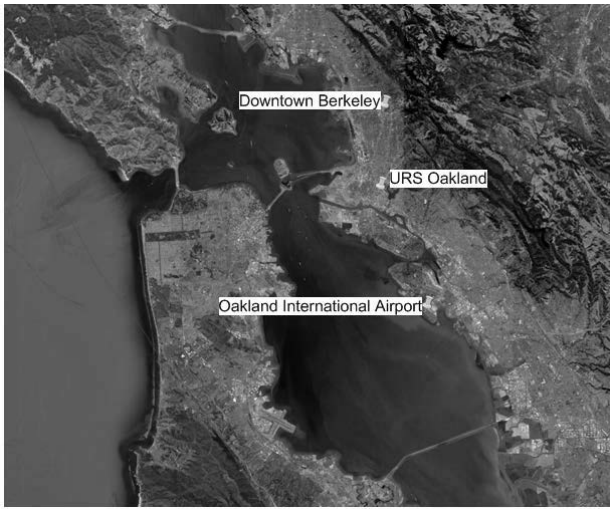

Figure 1. Location of Oakland International Airport

2. MAXIMUM SHEAR STRESSES IN SOIL LAEYRS

2.1 Site Conditions

Oakland International Airport is located at the San Francisco East Bay as shown in Figure 1. Airport is surrounded by the perimeter dike to protect from the

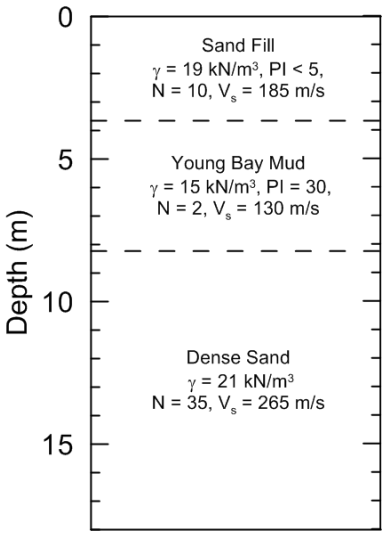

Figure 2. Representative Soil Profile

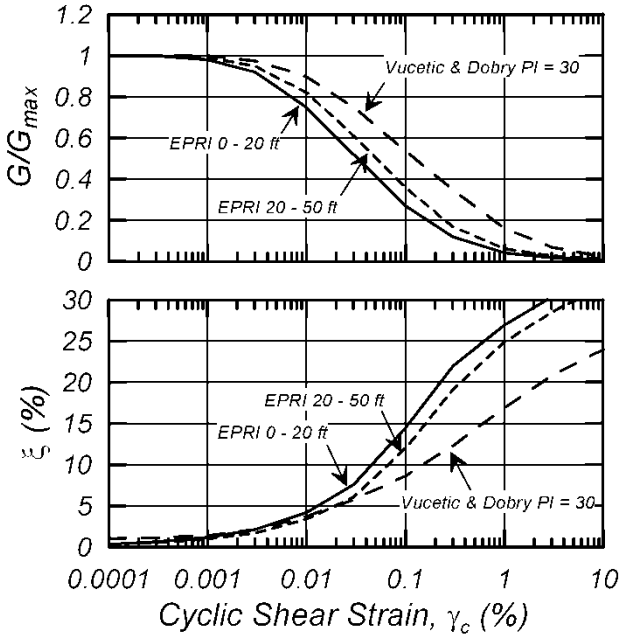

Figure 3. Modulus Reduction and Damping Ratio

flooding and wind surge, and runway is located about 180 m away from the perimeter dike. Figure 2 shows the representative soil profile and properties near the runway. At the ground surface, landfills were 3 to 5 m thick and comprised primarily of sands and silts which had SPT blow counts (N) of 6 to 20. Young Bay Mud layers were 3 to 8 m thick showing the very soft clay characteristics with Plasticity Index (PI) of 17 to 50. Young Bay Mud layers were sometimes underlain by a layer of stiff silty clays, which is called as Old Bay Mud, to dense sand layers those had N values of 20 to 50. Unit weight (γ) for the landfill, Young Bay Mud, and underlying dense sand deposits ranged from 17 to 22 kN/m^3, 14.5 to 16 kN/m^3, and 20 to 22 kN/m^3, respectively.

2.2 Site Response Analyses

Site response analyses were performed by SHAKE91 (Idriss and Sun, 1992) with the soil profile in Figure 2.

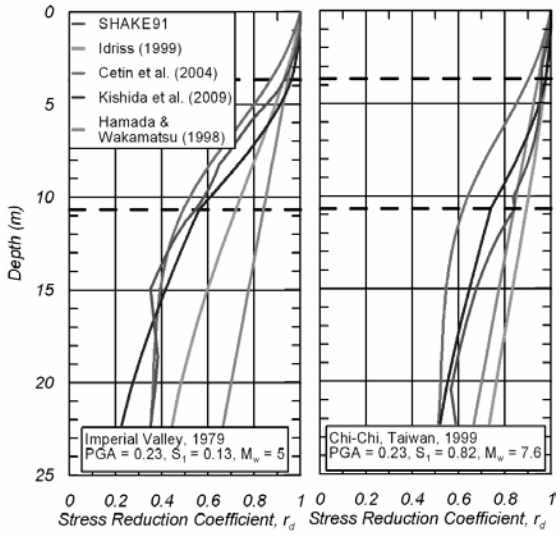

Figure 4. Variation of Stress Reduction Coefficient

Figure 3 shows the modulus reduction curves and damping ratio curves for sand layers from EPRI (1993), and Young Bay Mud from Vucetic and Dobry (1989). More than 2,500 input ground motions were selected from PEER strong motion database (PEER, 2005) from Site conditions of D (NEHRP, 2003). Figure 4 shows the representative analysis results showing the variation of r_d by SHAKE with the comparison of predicted values by Kishida et al. (2009), Idriss (1999), Cetin et al. (2004), and Hamada and Wakamatsu (1998), where r_d is defined as follows.

$$r_d = \frac{\tau_{\max} g}{\sigma_{vo} PGA} \tag{1}$$

SHAKE results clearly show two physical trends for the variation of r_d. One is that the reduction of r_d is relatively small in sand layers compare to that in Young Bay Mud layer. This is because that the sand layer tends to behave rigidly with a shorter period of a soil column by high shear wave velocity than Young Bay Mud layer. The other trend is that r_d becomes higher with the increase of earthquake magnitude due to the increase of predominant period of ground motions, by which a soil columns also tends to behave rigidly.

These physical trends can be evaluated for the presented predictive equations. Kishida et al. (2009), Idriss (1999), and Cetin et al. (2004) include the ground motion period or magnitude effects, but Hamada & Wakamatsu (1998) does not consider those effects. Kishida et al. (2009) and Cetin et al. (2004) includes the soil profile effects those tend to reduce the r_d values with the decrease of shear wave velocities, but Idriss (1999) and Hamada and Wakamatsu (1998) do not consider those effects.

Figure 5 shows the variation of residuals against depth where residuals are defined as differences between maximum shear stresses by SHAKE and estimated values by predictive equations in natural logarithm. Figure 5 also shows the expected values of residuals obtained by fitting residuals with smooth spline function. It is noted that Idriss

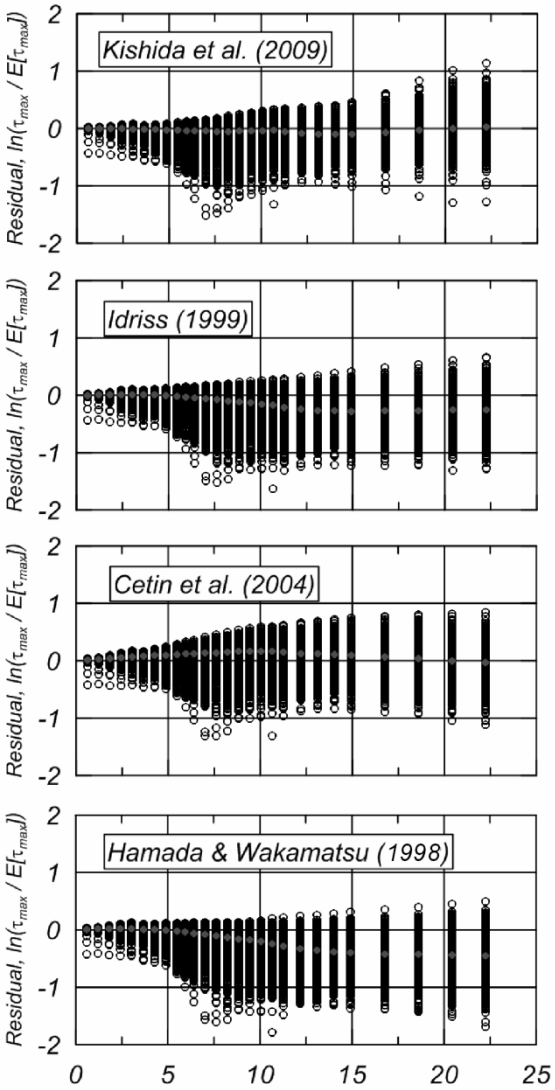

Figure 5. Variations of Residuals of r_d

(1999) and Hamada & Wakamatsu (1998) tend to overestimate the maximum shear stresses beneath the Young Bay Mud layer by 24% and 33%, respectively since these equations do not consider the effects of soft soil layers. It is also observed that the equation by Cetin et al. (2004) underestimates the maximum shear stress by 6% at the depth of 3 m and that bias increases up to 19% at the depth of 10 m. One of the reasons for this bias is because that Cetin et al. (2004) consider the soft layer effects by averaging shear wave velocities for upper 12 m instead of considering the period changes in soil columns. Kishida et al. (2009) shows the smallest bias that overestimates 10% at the depth of 14 m. It is mentioned that equations by Kishida et al. (2009), Idriss (1999) and Hamada and Wakamatsu (1998) do not have any bias in a sand layer less than 3.5 m depth, but Cetin et al. has a bias. Although these observations are obtained based on the single soil profile, those are explained by physical understandings of soil responses.

3. SEISMIC HAZARD ANALYSIS AND DESIGN SPECTRA

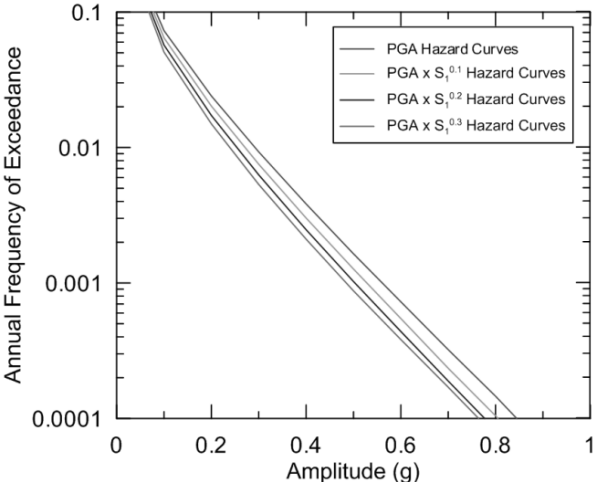

Figure 6. Seismic Hazard Curves for Vector Intensities

3.1 SEISMIC HAZARD OF VECTOR INTENSITIES

Regression analyses were performed for maximum shear stresses at depth of 3, 6, and 18 m after the site response analyses. Following equations are obtained with predictor variables of PGA and S_1 where S_1 is defined as $S_a(1.0)$ divided by $S_a(0.2)$ (Kishida et al., 2009).

$$\ln \tau_{\max} = \begin{bmatrix} 4.00 \\ 4.57 \\ 5.15 \end{bmatrix} + \begin{bmatrix} 1.00 \\ 0.992 \\ 0.964 \end{bmatrix} \ln PGA + \begin{bmatrix} 0.0184 \\ 0.0926 \\ 0.238 \end{bmatrix} \ln S_1 \qquad (2)$$

where τ_{max} is in the unit of kPa. It is noted that the fractional contribution of S_1 to PGA for the maximum shear stresses increases with the increase of depth from 0 to 0.25, which indicates that the longer period of ground motions becomes more important for the deeper soil layer.

Probabilistic seismic hazard analyses were performed for these intensities with the fault parameters obtained from URS Corporation, Oakland (Wong, 2010) after the study by Working-Groups on California Earthquake Probabilities (WGCEP, 2002). Attenuation relationships for ground motion intensities of maximum shear stresses are obtained as follows, those are expressed as a linear combination of spectral accelerations.

$$E[\ln I] = \mathbf{c}'\boldsymbol{\mu} \qquad (3)$$

$$\sigma_I^2 = \mathbf{c}'\mathbf{V}^{1/2}\boldsymbol{\rho}\mathbf{V}^{1/2}\mathbf{c} \qquad (4)$$

where $\mathbf{c}$ and $\mathbf{u}$ are vectors of coefficients for the linear combination and expected values of spectral acceleration. Matrix of $\mathbf{V}$ and $\boldsymbol{\rho}$ are diagonal matrix of standard deviations and correlation matrix of spectral accelerations, respectively. In the analysis, the attenuation relationships by Abrahamson and Silva (2008) with the correlation relationships by Baker and Jayaram (2008) are used.

Figure 6 shows the variation of hazard curves for ground motion intensities with different combinations of S_1 and PGA. It is noted that hazard values slightly decrease with the increase of S_1 to PGA since S_1 is generally smaller than 1.0.

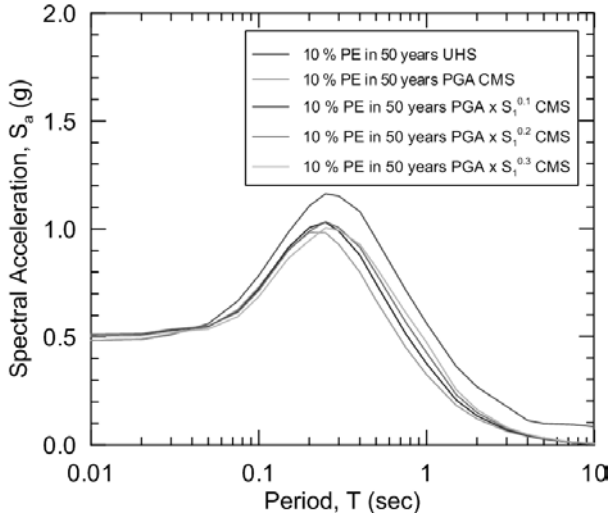

Figure 7. Variation of Conditional Mean Spectra

Based on these results, maximum shear stresses can be directly estimated by substituting the hazard values from Figure 6 into Equation (2). For example, the maximum shear stress at 6 m depth with the 10 % probability of exceedance in 50 years is obtained as follows.

$$\tau_{\max} = \exp\left[4.57 + 0.992\left(\ln PGA \cdot S_1^{0.0933}\right)\right] = \exp\left[4.57 + 0.992\left(\ln 0.45\right)\right] = 44 \quad (5)$$

The calculated shear stress by Equation (2) with the hazard value in Figure 6 will provide the same value to that by the simplified procedure if the soil layer exists at the ground surface, but deviate with the increase of the depth of soil layers.

3.2 CONDITIONAL MEAN SPECTRA

Effects of variation of seismic intensity with depth are further illustrated with the conditional mean spectra, those are calculated as follows.

$$\ln \mathbf{S_a} = E\left[\ln \mathbf{S_a}\right] + \boldsymbol{\Sigma}\left(\sigma_I^2\right)^{-1}\left(\ln I - E\left[\ln I\right]\right) \quad (6)$$

where, σ_I is a standard deviation of ground motion intensity and $\boldsymbol{\Sigma}$ is a vector of the covariance between spectral accelerations and ground motion intensity. Figure 7 shows Uniform Hazard Spectra (UHS) and the variation of conditional mean spectra (CMS) obtained by Equation (6) given the hazard values at 10 % probability of exceedance in 50 years. It is noted that the relatively longer period component around 0.7 second increases and the shorter period component around 0.1 second decreases with the increase of the contribution of S_1. This is corresponding to the fact that the longer period of components in ground motions tends to be more important with the increase of the depth for soil layers. Therefore, it is understood that the general design procedures do not envelop the range of ground motion intensities in a soil column since that uses the PGA from seismic hazard analysis with the earthquake magnitude from disaggregation results. It is also mentioned

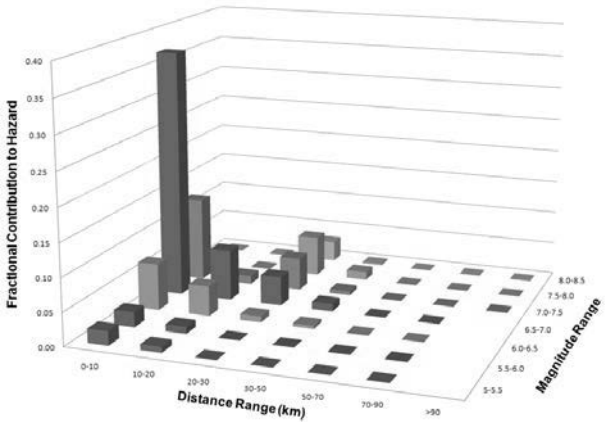

Figure 8. Disaggregation of Hazard for PGA

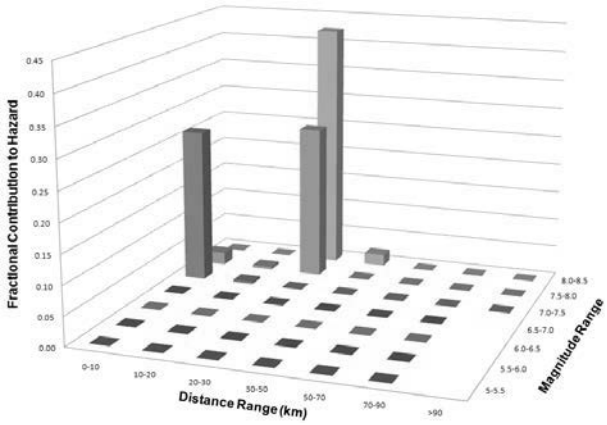

Figure 9. Disaggregation of Hazard for S_a(3.0)

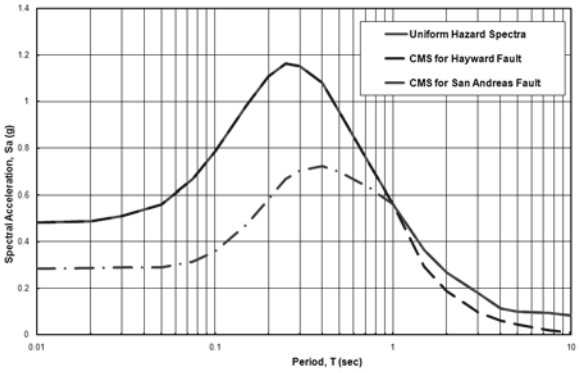

Figure 10. Conditional Mean Spectra for Hayward Fault and San Andreas Fault

that this discussion never been applied if the earthquake magnitude is used as a ground motion characteristic since there is no conditional probability distributions for spectral accelerations given PGA and earthquake magnitude.

3.3 DESIGN SPECTRA

Figure 8 and 9 shows the disaggregation results of hazard curves at 10 % probability of exceedance in 50 years for PGA and S_a(3.0). There are two distinguished sources around magnitude of 6.5 with distance of 10 km, and 7.5 with distance of 20 km, those are corresponding to Hayward fault and San Andreas Fault. It is observed that Hayward

fault is a dominant source of the hazard value of PGA, and San Andreas Fault is a dominant source of $S_a(3.0)$. Therefore, it is conservative if the uniform hazard spectra are used in a design procedure, but will be unconservative if the conditional mean spectra given the spectral acceleration at the specific period are used as discussed in the previous section, which method is similar to that discussed by Baker (2010). Therefore, it is reasonable to cover the range of spectral accelerations in Uniform Hazard Spectra for Hayward Fault and San Andreas Fault separately in producing the conditional mean spectra since the ground motion intensity changes with a depth of the soil layer and there is a wide range of possible consequences of seismic deformations as discussed by Idriss and Boulanger (2008).

Figure 10 shows the conditional mean spectra given the range of Uniform Hazard Spectra for each fault with the expected earthquake magnitude and distance. It is noted that the conditional mean spectra are lower than Uniform Hazard Spectra if the earthquake scenario is not the major contribution to the seismic hazard value. As a result, two spectral accelerations are generated for Hayward Fault and San Andreas Fault for the design purpose to cover the variation of seismic intensities in a soil column.

4. CONCLUSIONS

This paper describes the variation of seismic intensities for maximum shear stresses in soil layers at Oakland International Airport where thick Young Bay Mud deposit exists under the landfill. Variation of stress reduction coefficients (r_d) are studied by performing the site response analysis with the comparison of predictive equations. Regression analyses were performed for maximum shear stresses in soil layers and the variation of ground motion intensities with depth is described. Seismic hazard analyses were performed for vector intensities of maximum shear stresses, and those variations are illustrated with conditional mean spectra showing the different ground motion characteristics with depth. The methodology to obtain the design spectra from uniform hazard spectra was presented when the hazard was contributed by multi earthquake scenarios for different periods.

Abstract: Dynamic centrifuge shaking table tests were performed using soil-foundation-superstructure models to examine ground settlement distribution around a building subjected to strong ground shaking as well as earth pressure acting on embedded foundations during and after shaking. Based on the test results and discussions, the following conclusions are made: (1) The dynamic passive earth pressure acting on a rigid wall during strong shaking increases with increasing ground acceleration and becomes almost equal to the value estimated by the Mononobe-Okabe method only when the ground acceleration exceeds about 6 m/s^2 accompanied by a shear strain of about 2.5 % (2) The static earth pressure acting on a rigid wall after strong shaking may vary from less than to more than twice the original "at rest" value, depending on the stress state developed on each side of the foundation and (3) The ground settlement along the excitation direction increases towards the building, due to strong soil-structure interaction that prevails within a horizontal distance of 0.3-0.6 times the foundation embedment, creating a steeper dipping slope in dense sand than in loose sand.

1. INTRODUCTION

The Niigata-ken Chuetsu-oki earthquake (Mj=6.8) that occurred on July 16, 2007, with an epicenter off the Niigata Prefecture affected the coastal areas of the southwestern Niigata prefecture, including Kashiwazaki city and Kariwa village as well as the Kashiwazaki-Kariwa nuclear power plant of Tokyo Electric Power Company (TEPCO). A matter of utmost concern was the performance of the Kashiwazaki-Kariwa nuclear power plant during and after the earthquake. The peak ground acceleration recorded at the site was as large as 12.2 m/s^2. Three reactors in full operation as well as one in a start-up state were automatically shutdown and all the critical structures seemed to be in good condition; however, a fire broke out around a house electric transformer and many non-critical structures as well as incidental components such as pipes and ducts were damaged, retarding the re-operation of the plant. The major cause of the damage seems to be not only the near field strong ground motions but also the settlements of backfill around the critical buildings.

Based on the field reconnaissance made after the quake, Tokimatsu (2007) showed that: (1) ground settlements appeared to occur wherever backfilled with sand particularly near the critical buildings, causing unacceptable settlements of numerous non-critical structures and incidental components such as pipes and ducts, all of which were directly founded on the backfill and (2) the ground settlement was particularly larger near the building and tended to decrease rapidly with distance from the building, suggesting that soil-structure interaction significantly affected the resulting ground settlement variation.

Ishihara (2009) pointed out that when a soil deposit in contact with a vertical rigid wall is shaken horizontally, the soil near the wall will fall down into the aperture created at the interface and will be compressed and packed by the relative movement of the outer soil mass, thereby exerting a greater earth pressure on the wall. There is some concern, therefore, that dynamic soil-foundation interaction would produce an earth pressure which is by far greater than the pressure at rest, or even more than the pressure normally considered in the design of walls against seismic shaking (Ishihara, 2009). A little is known, however, about ground settlement variation around a building with embedded spread foundation subjected to extremely strong shaking and the resulting effects on earth pressures during and after shaking.

The objective of this paper is to examine the ground settlement distribution around a building subjected to strong ground shaking as well as earth pressure acting on the embedded foundation during and after shaking. For this purpose, two series of centrifuge shaking table tests were

performed in which a building with spread foundation is embedded into either a loose or dense sand layer and founded on the underlying dense sand layer.

2. CENTRIFUGE SHAKING TABLE TEST SETUP AND PROCEDURE

In order to investigate ground settlements and earth pressure changes around an embedded foundation during and after strong ground shaking, two series of centrifuge shaking table tests (series L and D) were performed at a centrifugal acceleration of 50*g* using the geotechnical centrifuge at the Disaster Prevention Research Institute, Kyoto University. Figure 1 shows the test setup and instrumentation for series L prepared in a laminar shear box with inner dimension of 450 mm (length) × 150 mm (width) × 200 mm (height). Dry Toyoura sand (D_{50}=0.21 mm) was pluviated to form a 142 mm thick dense sand layer with D_r=90%. A foundation-superstructure model was then placed directly on the surface of the dense sand. Dry Toyoura sand was further pluviated to form an additional 52 mm thick loose sand layer around the building so as to embed the foundation into the ground to a depth of 52 mm. The relative density of the surface layer surrounding the embedded foundation was 40 %.

Series D was done with identically the same test setup and instrumentation as series L but with only one exception: the relative density of the surface layer surrounding the embedded foundation was 90 % instead of 40%. The internal friction angle of Toyoura sand is ϕ=36° for D_r =40% and ϕ=42° for D_r=90%.

The foundation was made of aluminum alloy having a dimension of 124 mm (length) x 64 mm (width) x 60 mm (height). The surface of the foundation was rough with a static friction coefficient of 0.69 against Toyoura sand. The superstructure was of rigid brass with a dimension of 82 mm long x 58 mm wide x 50 mm high which was connected to the foundation with two plates 35 mm high. The masses of the foundation and superstructure were 1.0 kg and 2.0 kg, respectively. The natural frequency and the damping ratio of the superstructure under the fixed base condition were about 105 Hz and 0.5%.

The foundation was modeled so that normal and shear forces acting on the base and both lateral sides of the foundation can be measured separately. This is achieved by securing small two-axis load cells (Tokyo Sokki Kenkyujo Co., Ltd.) behind the base and lateral side plates of the foundation as shown in Fig. 1 (Tamura et al, 2011). The base of the foundation consists of two separate plates of equal size, each connected to one two-axis load cell, while each of the left and right lateral surfaces of the foundation consists of one plate connected to another two-axis load cell.

The input motion used for the tests was Rinkai92, which is a synthesized ground motion for the Tokyo Bay area. According to the similitude law, the time axis of the motion was scaled down to a factor of 1/50. Shaking table tests were conducted in four consecutive stages with increasing acceleration amplitude of the input motion from about 0.7, 1.5, 3.7, to 6.5 m/s^2. During the shaking table tests, the horizontal accelerations of the superstructure and the foundation as well as those in the soil and the vertical accelerations of the foundation and the ground surface and the base of the laminar shear box were measured along with the forces acting on the base and both sides of the foundation. All data presented hereafter are of prototype scale, unless otherwise noted.

3. CENTRIFUGE SHAKING TABLE TEST RESULTS AND DISCUSSIONS

3.1 Time Histories of Selected Values

Figures 2 and 3 show the time histories of selected parameters including: the horizontal acceleration of the input motion, the ground surface and at depth of 1.5 m, foundation and superstructure; the earth pressures on both side of the foundation, horizontal relative displacement between the foundation and the ground; and the shear stress and shear strain at a depth of 1.5 m for series L and D subjected to the largest input motion with a peak acceleration of 6.5 m/s^2. The horizontal ground acceleration time histories were double integrated to determine their horizontal displacement time histories. The horizontal relative displacement between the foundation and the ground was determined by subtracting one from the other in the time domain. The corresponding shear strain time history was determined by dividing the differential horizontal displacement by the distance between the ground surface and a depth of the base of the foundation. The corresponding shear stress time history was calculated by integrating the product of horizontal acceleration and mass density of the soil with depth. It is to be noted that the displacement time histories shown in this paper correspond to the dynamic component and do not reflect the permanent one.

The maximum horizontal accelerations of the foundation for series L and D were about 5 m/s^2, which are apparently smaller than those of the ground surface (about 7 m/s^2), suggesting soil-structure interaction effects. Not only the peak horizontal accelerations of the superstructure and foundation, but also the earth pressure acting on the

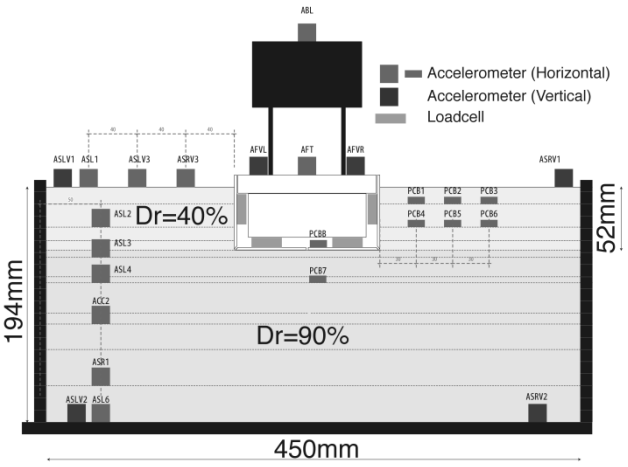

Figure 1 Test setup in laminar shear box (Series L)

foundation are almost the same in the two tests, in spite of the difference in soil density around the foundation between the two tests.

3.2 Dynamic Earth Pressures

Figures 4 and 5 show the relation of the dynamic earth pressures acting on both sides of the foundation with the relative displacement between the foundation and soil for series L and D subjected to the largest input motion with a peak acceleration of 6.5 m/s^2. When the foundation pushes the soil on the right thereby increasing positive relative displacement, the earth pressure on the right increases with decreasing earth pressure on the left. This creates a passive side stress condition on the right with an active side stress condition on the left. When the foundation pushes the soil on the left, all stress conditions are reversed.

The peak earth pressure occurring at each peak relative displacement is slightly larger on the left than on the right. The earth pressure coefficients corresponding to the largest earth pressure are 8 to 9 on the left side and 6 to 7 on the right side, irrespective of the relative density of the surface layer. The reason why the earth pressure becomes independent of relative density is unknown but may be due to densification of loose sand and dilatation of dense sand due to cyclic loading. The reason why the passive earth pressure coefficient is larger on the left side is also unknown but it may be associated with a possible permanent displacement that might have prevailed on the left side of the foundation.

Figure 6 shows the relation of the maximum passive side earth pressure coefficient with the maximum ground acceleration at a depth of 1.2 m during each excitation.

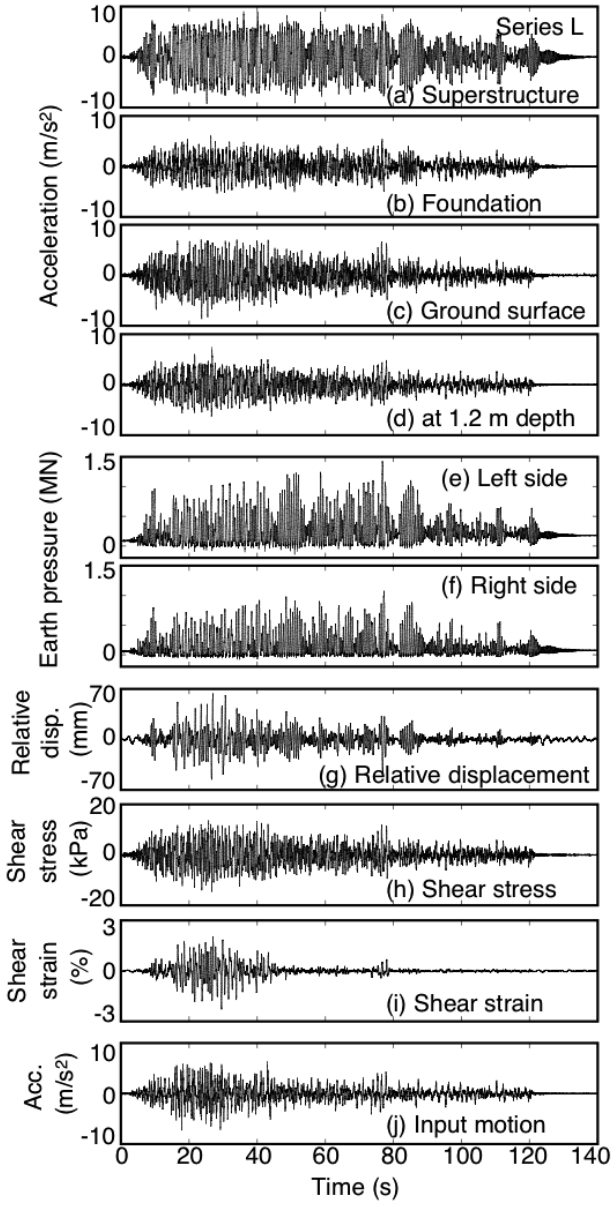

Figure 2 Time histories of selected parameters for series L with input acceleration of 6.5 m/s^2

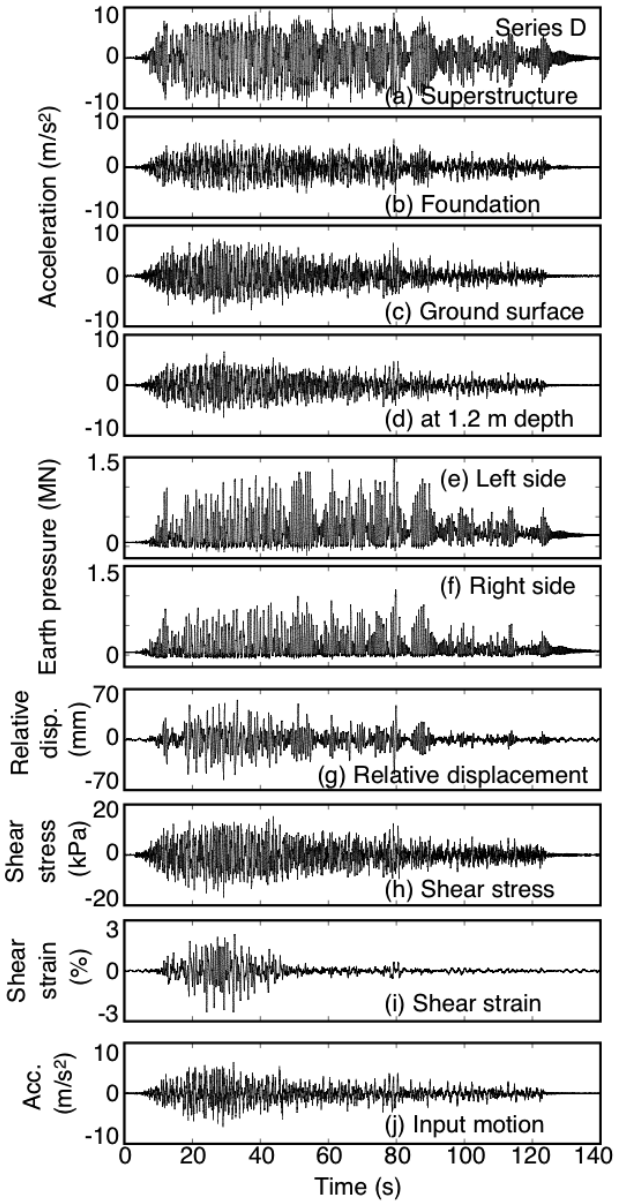

Figure 3 Time histories of selected parameters for series D with input acceleration of 6.5 m/s^2

Also shown in the figure with lines are the relation determined by the Mononobe-Okabe (1924) method with $\delta=2\phi/3$. The observed passive side earth pressure coefficients at the final excitation with a ground acceleration of about 6 m/s^2 accompanied by a shear strain of 2.5% are consistent with those determined by the Mononobe-Okabe (1924) method. The observed passive side earth pressure coefficients at other excitation with smaller input motions are, however, far less than those determined by the Mononobe-Okabe (1924) method. This is probably because the relative displacement between the soil and foundation was significantly less than that required to mobilize the full passive earth pressure.

3.3 Ground Settlement Distribution

Figures 7 and 8 illustrate the settlement distribution around the building for the two series after the final shaking. Despite almost the same response between the two tests, the settlement distributions from the two tests are significantly different from each other in the following aspects:

(1) The ground settlements away from the building along the excitation direction as well as those along the orthogonal direction for series L with Dr= 40% are about 5 mm (10 % of the thickness of the surface layer), while those for series D with Dr= 90% are almost zero. These settlements mainly reflect one-dimensional volume change of the surface layer due to cyclic loading.

(2) The ground settlement along the direction parallel to the excitation tends to increase towards the building, whereas those along the orthogonal direction do not show such a trend. The former trend is probably caused by strong soil-structure interaction that occurs along the direction of excitation. They increase from about 5 mm to 10 mm (20 % of the thickness of the surface layer) over a distance of 0.4-0.6 times the embedment depth in series L, creating a gentler slope (about 1/5) for loose sand. In contrast, it increases from about zero to 10 mm over a distance of 0.3-0.4 times the embedment depth in series D,

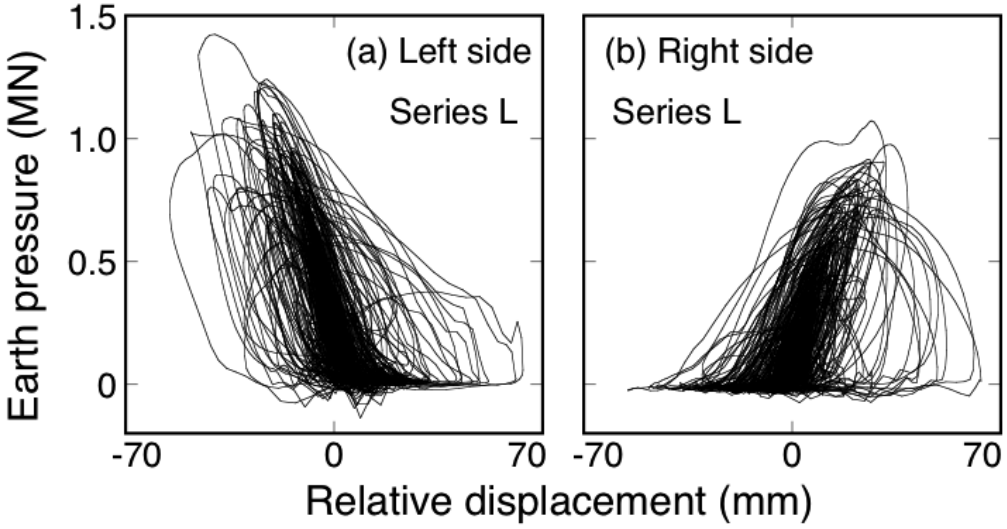

Figure 4 Relation between dynamic earth pressures acting on both sides of foundation and relative displacement between foundation and soil for series L

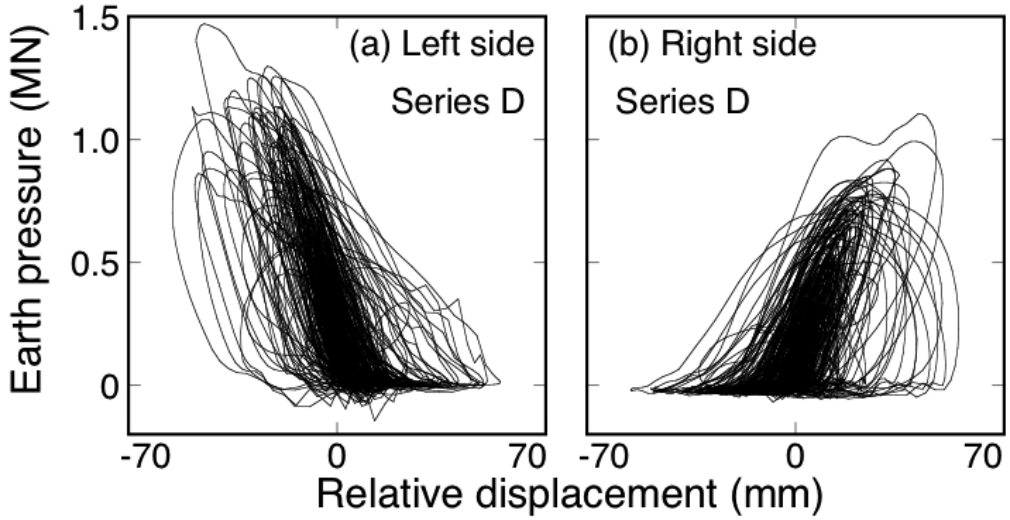

Figure 5 Relation between dynamic earth pressures acting on both sides of foundation and relative displacement between foundation and soil for series D

creating a steeper slope (about 1/2) for dense sand.

(3) A close examination of the ground settlement along the direction of shaking further indicates that the ground heaves at the left edge of the building, causing the largest ground settlement slightly away from the building rather than at the edge of the building. Such ground heave does not occur on the right side of the building. The difference in ground settlement distribution between both sides of the building may be associated with the difference in stress condition between the two sides of the foundation after shaking, i.e., the passive side stress state may develop on the left with the active side stress state on the right.

Assuming an active thrust created behind the embedded wall using the internal friction angle of Toyoura sand (ϕ =36° for Dr =40% and ϕ =42° for Dr =90%), the affected distance would be 0.51 and 0.45 times the embedment depth for series L and D, respectively. These values are consistent with those observed in the tests, suggesting that the ground settlements affected by dynamic soil-structure interaction would be mainly limit to the active thrust created behind the embedded wall.

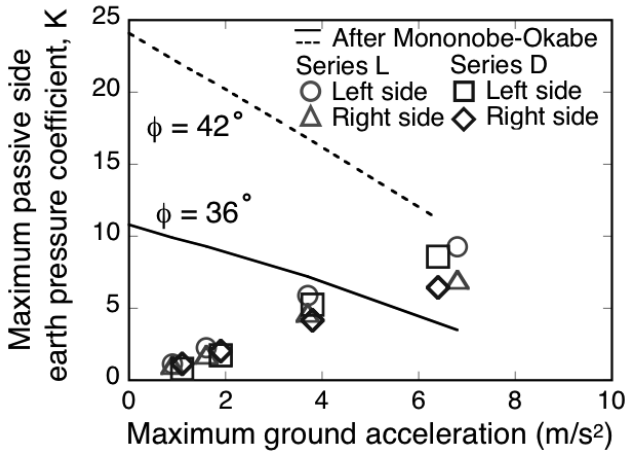

Figure 6 Relation of maximum passive side earth pressure coefficient with maximum ground acceleration at a depth of 1.2 m during each excitation

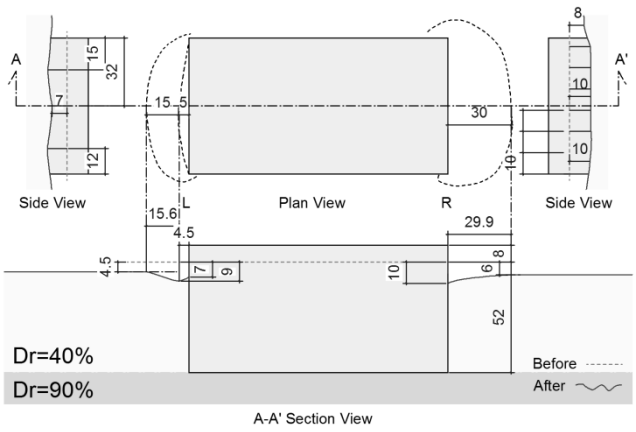

Figure 7 Ground settlements around building after final excitation for series L (Dr =40%, Model scale in mm)

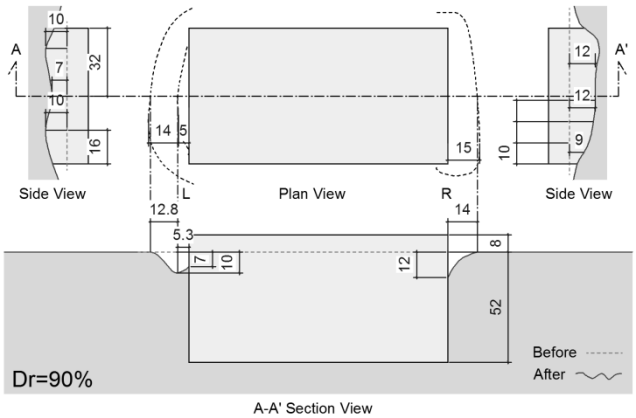

Figure 8 Ground settlements around building after final excitation for series D (Dr =90%, Model scale in mm)

3.4 Earth Pressures after Strong Shaking

Figure 9 shows the relation of earth pressure coefficients on both sides of the foundation after each excitation against the maximum shear strain developed in the surface layer during the excitation. The observed earth pressure coefficients after the final excitation that induced a shear strain on the order of 2.5 % in the surface layer are about 1.2 on the left and 0.4 on the right side, with an average value of about 0.8, which is significantly greater than the initial value of about 0.5. This seems in general

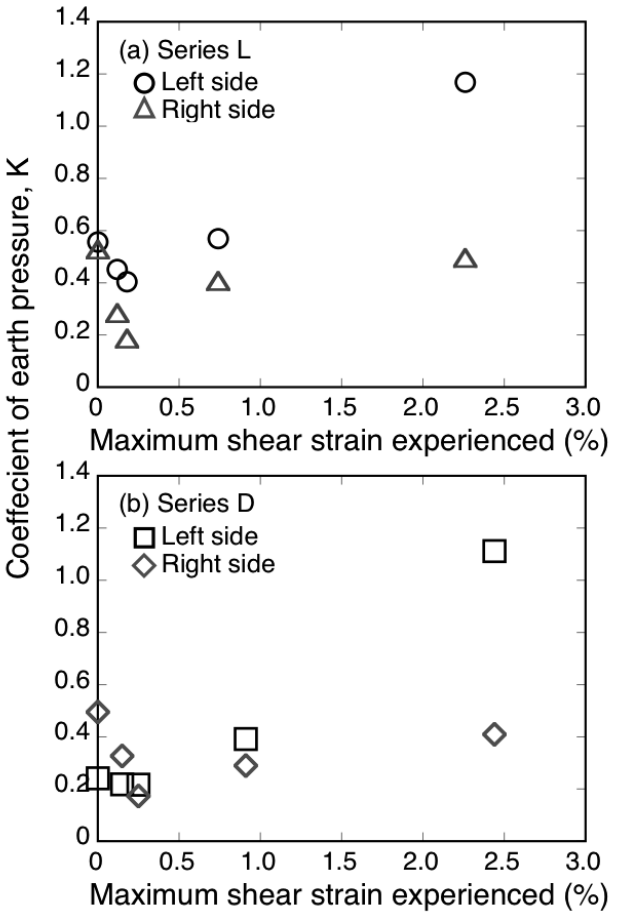

Figure 9 Relation of earth pressure coefficients on both sides of foundation after each excitation against maximum shear strain experienced

consistent with the finding by Youd and Craven (1975) that the earth pressure coefficient at rest of a sand increased from 0.3 to 0.8 when subjected to one hundred cycles of shear strain of about 1 %. The earth pressure coefficients after other excitation with a smaller peak acceleration, however, seem to decrease from the original "at-rest" value, which is inconsistent with the finding by Youd and Craven (1975).

The reason why the earth pressure coefficient at the end of last shaking varies from less than to more than twice the original "at rest" value is probably due to a possible permanent displacement that might have prevailed on the left side of the foundation. It is conceivable from the ground displacement pattern shown in Figures 7 and 8 that, after the end of the final excitation, the passive side stress state might have developed on the left of the foundation with the active side stress state on the right.

4. CONCLUSIONS

Dynamic centrifuge shaking table tests were performed using the soil-foundation-superstructure model to examine ground settlement distribution around a building subjected to strong ground shaking and earth pressures acting on its embedded foundation during and after shaking. Based on the test results and discussions, the following conclusions are made:

(1) The dynamic passive earth pressure acting on a rigid wall during strong shaking increases with increasing ground acceleration but becomes almost equal to the value estimated by the Mononobe-Okabe method only when the ground acceleration exceeds 6 m/s^2 accompanied by a shear strain of about 2.5 %.

(2) The static earth pressure acting on a rigid wall after strong shaking may vary from less than to more than twice the original "at rest" value, depending on the stress state developed on each side of the foundation at the end of shaking.

(3) The ground settlements away from the building along the excitation direction as well as those along the orthogonal direction would mainly reflect one-dimensional volume change characteristics of the surface layer due to cyclic loading.

(4) The ground settlement along the excitation direction increases towards the building, mainly due to strong soil-structure interaction that prevails near the building. This creates a slope dipping to the building with a slope angle much larger in dense sand than in loose sand. The horizontal distance within which the ground dips to the building due to dynamic soil-structure interaction is about 0.3-0.6 times the foundation embedment depth. The affected distance is well explained by assuming the active thrust behind the wall of the embedded foundation.

Abstract: This paper presents the results of a series of dynamic centrifuge model tests investigating the behaviour of single degree of freedom structures founded on dry sand. The paper highlights the benefits that can be accrued from allowing deformation between the building foundation and the soil. Specifically, rocking of the foundation can both dissipate energy through damping and can isolate the superstructure from large peak accelerations by lifting off from the soil below. This behaviour is examined by means of moment-rotation loops derived from centrifuge model test data which illustrate the variation in behaviour for different bearing pressures and earthquake characteristics.

1. INTRODUCTION

The seismic design of shallow foundations is well established, however there are improvements to the current design practice which can yet be made. The disconnection between structural and geotechnical engineering in seismically active regions has resulted in a design practice which can be inefficient and is potentially inadequate. This research project aims to tackle this problem by investigating the behaviour of the soil-foundation interface and how this affects the response of the building superstructure. Soil-structure interaction provides a potential means to dissipate energy and to isolate the structure from the full magnitude of the earthquake shaking. However the misconceptions associated with allowing movement in the soil-structure interface have thus far prevented this from being fully exploited. Current design codes generally advise that the foundation be designed in such a way as to act rigidly with the soil that it is founded on. Rubber bearings and other structural isolation techniques are often implemented at great cost to isolate the superstructure from the foundation. With a complete soil-foundation-structure analysis, the soil itself can be used to achieve results comparable to structural isolation techniques with a greatly reduced cost.

The majority of geotechnical failures involving shallow foundations are associated with soil liquefaction. The research presented here involves dry sand beds. Geotechnical failures are much rarer with dry sand, the main issue being excessive settlements. Far more common is the structural failure of a superstructure on shallow foundations sited on dry sand. One such example from the 2005 Pakistan Earthquake was presented by Ali et al. 2010, the failure being shown in Figure 1.

Figure 1 Damage from the 2005 Pakistan Earthquake
Ali et al. (2010)

Much research has already been conducted into shallow foundations subject to dynamic shaking. However, much of that research focused on saturated problems where liquefaction is important. The majority of that research also studied simple strip foundations with no superstructure mass. The benefits of studying the entire superstructure-foundation-soil system have recently been recognised and an increasing amount of research is being conducted to investigate the overall system behaviour.

A significant volume of research has focused on deriving an analytical mechanism to model the soil-structure interface. Many questions have arisen with the approaches

taken including whether a trapped wedge is present under the shallow foundation. None of the proposed mechanisms in the literature has so far been heavily scrutinised by comparison with centrifuge model test data, nor has the actual mechanism ever been observed during centrifuge modelling by, for example, conducting particle image velocimetry (PIV) (White et al. 2003) on images collected with a high speed camera. However, one mechanism which has been verified by 1g testing is that proposed by Paolucci and Pecker (1997) entitled 'Mec 2'. Testing conducted at 1g by Knappett et al. (2006) utilising PIV to measure foundation soil movements found that Mec 2 modelled the deformation mechanism accurately. There have also been significant numbers of centrifuge studies conducted to investigate the same problem. Earlier research such as that conducted by Zeng and Steedman (1998) was focused on estimating settlements resulting from dynamic shaking. More recent research has focused on the soil-structure interaction, involving allowing displacement to occur between the soil and foundation. The resulting rocking and sliding of the foundation as well as the structures' self-centering characteristics have been investigated by Gajan and Kutter 2008. Further work is required, however, to ensure an analytical mechanism can be proposed which could be used by industry and to ensure that any proposed mechanism has been tested robustly against a wide range of loading scenarios through physical modelling studies. Furthermore, methods to quantify energy dissipation in the soil-structure interface need developed.

2. METHODOLGY

A series of four centrifuge tests were conducted using the 10m Turner Beam Centrifuge at the University of Cambridge. To induce dynamic shaking in the models, a Stored Angular Momentum (SAM) Actuator (Madabhushi et al. 1998) was used. The tests were run at a nominal centrifugal acceleration of 50 g. During dynamic tests, boundary effects can influence the response of the specimen being tested, hence, to minimise these effects an Equivalent Shear Beam (ESB) box was used. An ESB box consists of Aluminium rings connected, and separated with layers of rubber. The stiffness of the ESB box used in this series of tests was tuned to match the natural frequency of a sand column with a voids ratio of 0.77 (I_D=58% for Hostun sand) at 50g.

Models were prepared with dry Hostun HN31 sand at a target relative density of either 50% or 80%. Sand pouring was completed using an automatic sand pourer (Madabhushi et al. 2006) to ensure uniformity throughout the depth of the sand column .

During pouring of the sand, an array of piezoelectric accelerometers and micro-electromechanical system (MEMS) accelerometers were located at specified locations to allow the response of the sand column to be monitored during shaking. Further accelerometers were attached to the model structures to track their dynamic response. Linear variable differential transformer (LVDT) displacement transducers were used to monitor the settlement of the structures and free-field surface. The model layout is shown in Figure 2.

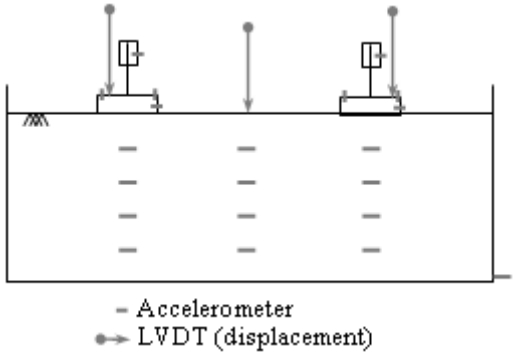

Figure 2 Instrumentation layout

The prototype structure modelled in these tests is an isolated raft footing with an approximately three storey superstructure subjected to lateral shaking along one axis. Lumped mass single degree of freedom structures were placed on the sand surface during the first two tests as shown in Figure 2. For the second set of tests, sway frame single degree of freedom structures were used as they were considered more representative of the prototype being modelled in terms of the rocking-sliding response during shaking. The reasoning for this will not be discussed here. All the model structures had a model foundation size of 80mm x 80mm (4m x 4m at prototype scale). Two model structures with bearing pressures of 50kPa and 100kPa were placed on the sand surface with no embedment for each test. The model structures were tuned to have a fixed base natural frequency of 50 Hz.

Each model was subjected to three earthquakes. The first was a small amplitude 50 Hz shake with a peak ground acceleration (PGA) of 8g (0.16g prototype). This was followed by a larger fixed amplitude shake at 50 Hz with a PGA of 16g (0.32g prototype). These were followed by a sine-sweep earthquake in which the frequency was dropped from 60 Hz to 0 Hz with fixed displacement amplitude and hence a decreasing acceleration magnitude. Data was acquired during each test at a sampling frequency of 4 kHz.

3. OVERVIEW OF RESPONSE

3.1 Settlements

The settlement of a structure will be affected by the bearing pressure that it exerts on the ground and the relative density of the soil. By reference to Figure 3 it can be seen that the settlement traces did respond as expected. Figure 3 shows data for the small structure (50kPa) during the larger 50Hz earthquake. The structure settled by 3.95mm (200mm prototype scale (PS)) on loose sand and only 0.67mm (35mm PS) when sited on dense sand. The free-field settlement follows the structural settlements in pattern however, again, as would be predicted, the differential settlement between the structure and free-field are greater for loose sand, as shown in the lower plot on Figure 3.

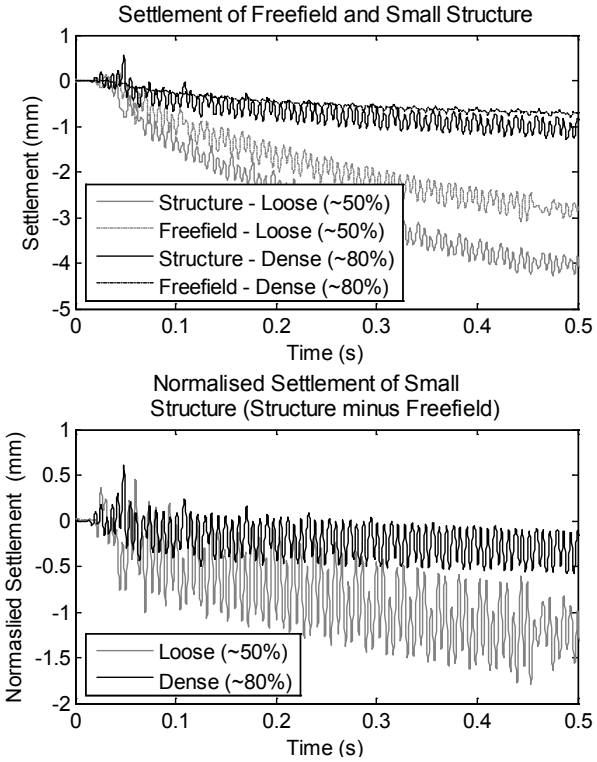

Figure 3 Variation in settlement of 50kPa model structure located on sands beds of varying relative density

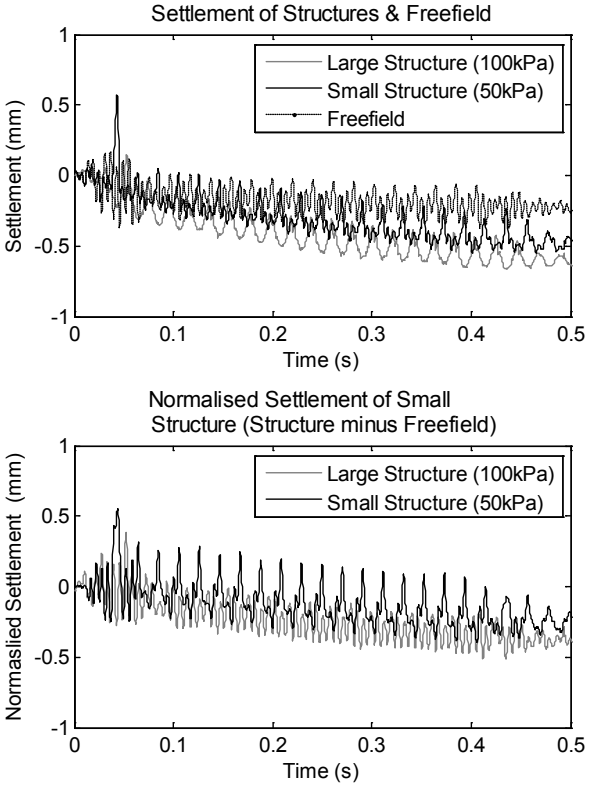

Figure 4 Variation of settlement of model structures with varying bearing pressure

Assuming uniform conditions under a foundation and hence no differential settlements occurring across the footprint of the structure, the most common damage associated with seismic induced settlements is to the services supplying the structure. It is therefore perhaps more relevant to quote differential settlements relative to the free-field. In this case, those settlements were 1mm (50mm PS) and 0.2mm (10mm PS) for the loose and dense sand models respectively. This level of settlement is more relevant and much more modest that the total settlement values quotes above.

Another property affecting settlements is the bearing pressure of the structure. The effect of bearing pressure on a dense sand model is shown in Figure 4. The total settlement values were 0.5mm (25mm PS) and 0.6mm (30mm PS) for the 50kPa and 100kPa structures respectively. Differential ultimate settlements relative to the free-field were 0.3mm (15mm PS) and 0.4mm (20mm PS) respectively. These settlement values are well within the serviceability limit state of current design practice.

3.2 Frequency Response

By analyzing the data collected during the sine-sweep shaking, the natural frequency of the superstructure-foundation-soil (SFS) system can be determined. Figure 5 shows the response of the superstructures of the lumped mass SDOF structures sited on dense sand during a sine-sweep earthquake. It can be clearly seen that the peak amplitude response of both superstructures occurs when the input acceleration magnitude has dropped significantly. As the frequency reduces during the sine-sweep earthquakes, the spike in response of the superstructures is being driven by the input frequency passing through the natural frequency of the SFS system. At this spike in response, it would be expected that the input frequency and superstructure vibration frequency would be the same. The lower plots on Figure 5 display the frequencies present in the input and superstructure accelerations during the period of peak superstructure response. It can be observed that indeed the input and superstructure frequencies do match during the period of peak response.

In the methodology section of this paper, it was specified that the model structures had a fixed base natural frequency of 50Hz. The natural frequencies of the SFS systems as determined from Figure 5 are much lower than this at 39Hz and 43Hz for the large and small structures respectively. Basic mechanical vibration theory tells us that the higher the mass the lower the natural frequency for the same stiffness of system. Therefore the observed response is as would be predicted. What this highlights is the importance of carrying out a coupled structure-foundation-soil analysis when designing buildings in seismically prone areas. If the foundation had been assumed to act rigidly with the soil beneath and hence a fixed base analysis conducted of the structure, the frequency at which the building is most vulnerable would have been significantly overestimated. Soil-structure interaction must be taken into consideration when conducting any seismic design or analysis.

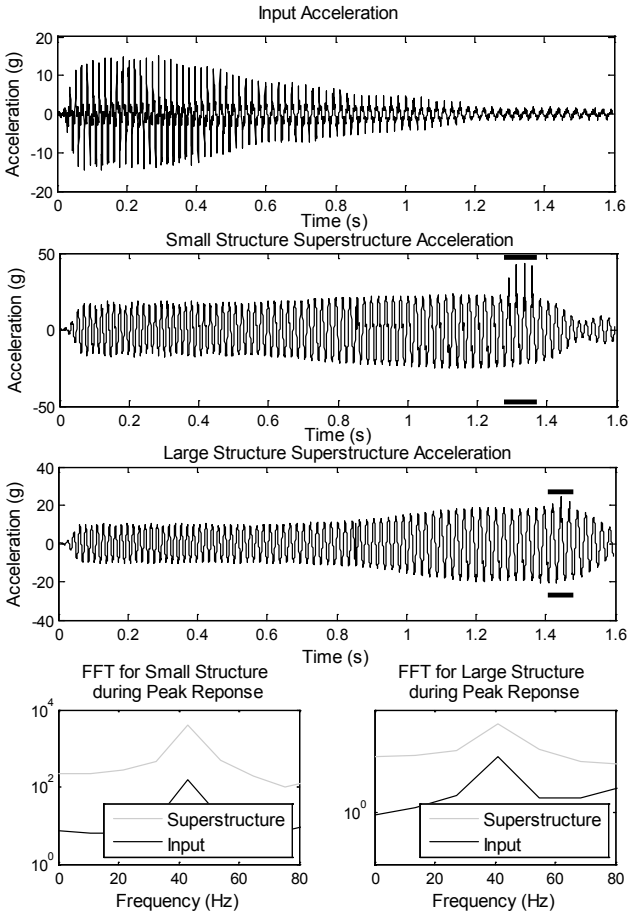

Figure 5 Natural frequency of soil-structure system for larger and smaller model structures

4. MOMENT-ROTATION DERIVATION

The impact of the foundation performance on the behaviour of the structure can be quantified by investigating the relationship between the foundation rotation and the moment being applied to the soil.

The acceleration of the superstructure and resulting d'Alembert force result in a moment being applied by the foundation onto the sand beneath. Further, the rotational moments of inertia of the superstructure and the foundation add to this moment. These moments result in a rotation of the foundation with one edge lifting off and the other embedding into the sand. Lift-off of footings is not commonly allowed for in seismic design codes, instead, foundations are designed to be large enough to act rigidly with the ground beneath, allowing neither rotation nor sliding. The benefits of allowing such relative motion between the foundation and the soil will be discussed later.

In generating the moment-rotation loops presented in the following section, the rotations were calculated using the double-integral of two vertical accelerometers which were located on either edge of the foundation. A problem with calculating the rotation with this method is that heavy filtering of the acceleration signals is required in order for the integral not to drift. This filtered results in reduction in the peak displacements and hence the peak rotations being evaluated. This problem will be solved in future tests, however, for this analysis, qualitative comparisons can still be made between the moment-rotation plots, although when examining the plots presented later in this paper, it must be remembered that more accurate loops would be stretched outwards in the horizontal direction. The same vertical accelerometers also allowed the rotational mass moment of inertia to be calculated. The acceleration of the superstructure measured during shaking was multiplied by the mass of the superstructure to provide a force and further multiplied by the distance between the centre of the superstructure and the soil to provide a moment value.

The usefulness of the moment-rotation loops is that the area within the loops provides a representation of the energy dissipation. The slope of the loops also provides an indication of the rotational stiffness of the foundation system.

5. BEHAVIOUR OF MOMENT-ROTATION LOOPS

Comparison of moment rotation loops from different tests allows the effects of three different parameters on the soil-foundation interaction to be investigated.

5.1 Bearing Pressure

Increasing the bearing pressure of the model structure has a two fold effect. The larger bearing pressure results in an increase in small strain stiffness of the sand beneath the footing due to the higher confining stress. In addition, the increased bearing pressure means an increased superstructure mass and hence an increased moment being applied to the foundation when subjected to the same magnitude of acceleration.

Figure 6 shows the moment-rotation loops for the two SDOF model structures during a test on loose sand. For clarity, the moment-rotation loops shown are only for the middle third of the shaking duration. It is observed that the moment applied by the smaller (50kPa) structure is indeed smaller than that for the larger structure (100kPa).

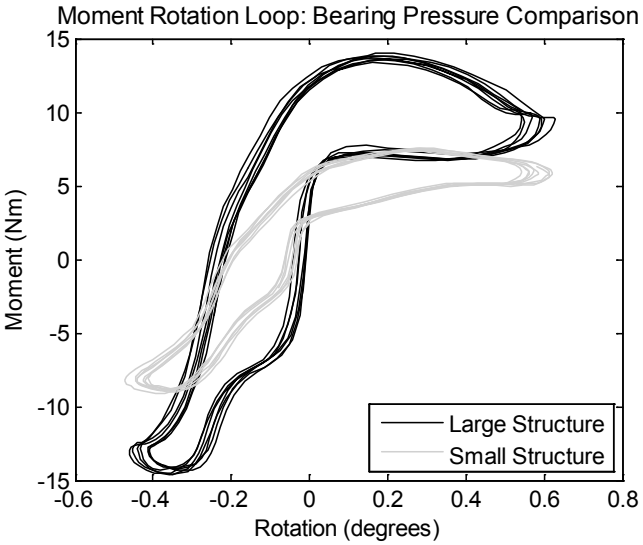

Figure 6 Variation of moment-rotation plot with bearing pressure

The superstructure to foundation mass (SSFM) ratios are the same and the centres of gravity are similar for both model structures. The lighter structure's superstructure is therefore half the mass of the larger structure's superstructure. It could be assumed that both superstructures would experience similar acceleration magnitudes. However, the large structure applies a moment which is only approximately 50% higher than that of the smaller structure. When the acceleration traces are examined, it is observed that the larger superstructure experiences an acceleration which is about 25% smaller in magnitude than the smaller superstructure. As shown earlier the natural frequency for the two structure-soil systems are different. Given that this model was shaken at 50 Hz and the smaller system's natural frequency is 45 Hz, (compared to 39 Hz for the larger system), this proximity of the excitation frequency to the natural frequency will result in greater superstructure acceleration.

There is one further moment component which should be added into the calculation. This is created when the foundation lifts off at one edge and hence the centre of the contact area moves. The self-weight of the structure thus applies a moment about the new foundation centre. This effect is not included in this analysis as the instrumentation was inadequate to determine the centre of rotation. It is interesting to observe that the peak rotation is the same for both structures, a result which is consistently seen across all the tests conducted thus far. This limit on rotation, independent of bearing pressure could be a function of the self-centering nature of the structures. With similar centres of mass and SSFM ratios, it would be expected that the self-centering and d'Alembert forces would balance each other at a similar level of rotation, however this assumes an equal acceleration magnitude in each of the superstructures which we have already seen not to be true. Therefore, in reality the peak rotations may turn out to be marginally different between the two structures and the apparent identical peak rotations shown in Figure 6 may be a function of the data processing and filtering. This will be examined in future tests when the rotations are measured more accurately.

The area within moment-rotation loops gives an indication of the energy dissipated. When the area within the loops for the entire duration of shaking is calculated, it is found that the larger structure dissipated more than twice the energy of the smaller structure. Once again, this would be expected due to its mass being doubled. The larger structure's increased mass will also result in it coupling more rigidly with the sand beneath through frictional forces and hence more energy will be transmitted into the structure.

5.2 Frequency Effects

As discussed in the previous section, the excitation frequency has a major impact on the response of the structures. During one test with the sway frame structures, an additional earthquake was fired with a frequency of 40Hz but with a peak ground acceleration the same as that of the smaller 50Hz earthquake. This allowed the consequence of moving the excitation frequency closer to the natural frequency of the structure to be examined. Figure 7 shows the moment-rotation loops for these two earthquakes for the small structure only. The results show that the loops for the lower frequency earthquake extend much further along the x-axis showing peak rotations increasing three-fold over the rotations experienced during the 50Hz earthquake. This result is not hugely surprising but is rather alarming given, as discussed previously, that fixed base analysis would have shown the structural vulnerability at 50Hz. The energy dissipated during the 40Hz earthquake was almost twice that dissipated during the 50Hz earthquake.

Another variation between the two moment-rotation loops is the apparent change in small strain stiffness between the two earthquakes. It would seem that the higher frequency earthquake resulted in a higher stiffness between the footing and the soil. The loops plotted are again for the middle third of the earthquakes only. The loops have a similar stiffness during the initial couple of cycles of shaking. Therefore, a potential explanation for the variation in small rotation stiffness is that the large soil strains result in increased softening in the soil-structure interface when the structure suffers large rotation amplitudes due to resonance.

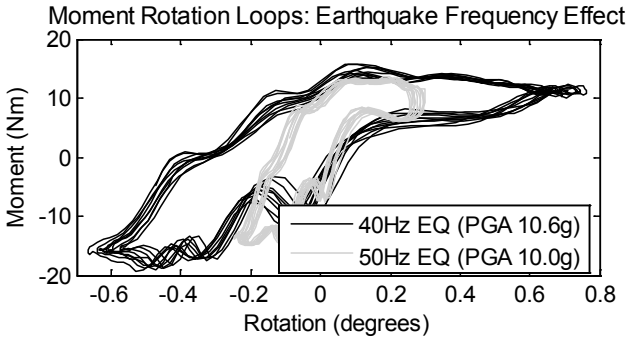

Figure 7 Variation of moment-rotation plot with frequency

5.3 Acceleration Magnitude

Increasing the input acceleration magnitude would be expected to increase the accelerations measured on the structure and hence to increase the moment applied by the structure through the foundation to the soil beneath. Consequently the rotations would also be expected to increase. Figure 8 shows the moment-rotation loops for the small sway frame structure during a test on dense sand. As can be observed, there is only a marginal increase in the applied moment when the larger (16.5g PGA, 0.3g PS) earthquake is fired. However, the rotations increase significantly being approximately twice those experienced during the smaller earthquake (10.0g PGA, 0.2g PS). It is clear therefore that the extra energy being input during the larger earthquake is not being transmitted upwards through the foundation and into the structure. This may be due to the existence of a threshold moment above which lift-off of the foundation occurs giving a very low rotational foundation stiffness. This appears to agree with the shapes of the

moement-rotation loops derived for these experiments. This marginal increase in applied moment demonstrates the foundation system's ability to isolate the building from high accelerations due to high-magnitude earthquakes. The larger rotations resulted in increased energy dissipation during the larger earthquake of 250% compared to the energy dissipation during the smaller earthquake. If the building could be constructed in such a way as to cope with significant rotations during the earthquake, this could offer significant benefits as an earthquake mitigation technique.

It might be expected that a reduction in small strain stiffness would be observed during the larger earthquake compared to the smaller earthquake due to increased shear modulus degradation. However, the slopes of the loops at small strains are very similar for both earthquakes. During the same test two sine-sweep earthquakes of varying magnitude were fired. During the larger magnitude sine-sweep earthquake the natural frequency of the system was found to be 38 Hz compared to 42 Hz during the smaller sine-sweep earthquake. Given that the masses involved remained the same, this reduction in natural frequency during the larger earthquake can only be attributed to a reduction in the stiffness of the soil-structure interface. This change of natural frequency of 10% would correspond to a change in stiffness of approximately 20%. Given the shapes of the moment-rotation loops as currently derived, this small change in stiffness would be difficult to observe.

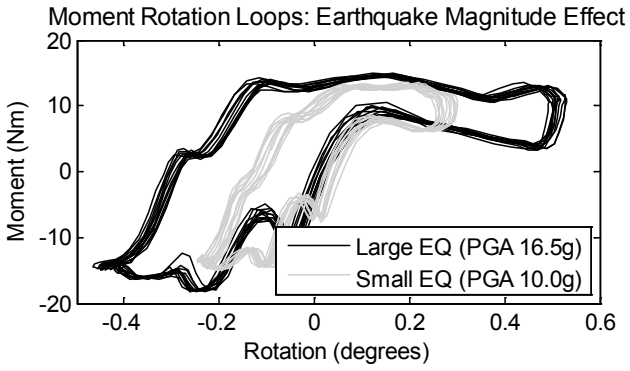

Figure 8 Variation of moment-rotation plot with acceleration

6. CONCLUSIONS

The results of an initial analysis of experiments involving single degree of freedom structures on shallow foundations have been presented. The importance of soil-structure interaction analysis when conducting seismic design due to the major impact the interaction has on the natural frequency of the system has been demonstrated. It was observed that the natural frequency of the system could vary by up to 20% when sited on the sand surface compared to the fixed base natural frequency.

In addition, the coupling of the foundation with the ground beneath is very important. Increasing the displacement and hence acceleration does not directly result in proportionally increased accelerations in the structure owing to the ability of the structure to lift off and rock. This lack of connection is therefore advantageous as it reduces the energy transmission in the structure and hence reduces the ductility requirements of the structure. There are two ways this disconnection between the foundation and the soil can manifest itself. Firstly though relative sliding between the foundation and the soil. This sliding process isolates the structure from the full magnitude of shaking of the soil beneath but also dissipated energy in the process. The degree of relative sliding has not yet been measured but will be in forthcoming centrifuge tests. Secondly the foundation can rock on the sand beneath, as has been observed in the tests conducted thus far. This again dissipated large amounts of energy. Neither of these methods have been included into seismic design due to the fear of excessive settlements, permanently rotated structures and toppling of the structure during rocking. Even when an earthquake was fired at the natural frequency of the system, these model structures never developed large permanent rotations, nor did they reach any degree of rotation which could result in toppling of the structure. In fact, allowing the structure to rock and dissipate the energy through plastic deformation of the soil is particularly safe due to the self centering characteristic which both prevents complete collapse and also minimizes permanent rotations. Establishing a plastic hinge in the soil will not result in permanent deformations whereas a plastic hinge developing within the structure will result in complete collapse.

Future work on this project will allow more accurate moment-rotation loops to be plotted. This will then allow for the confirmation and/or modification of the theories derived thus far based on the current results. The ultimate aim of this research is to derive a general analytical mechanism which is capable of modeling the soil-structure interface in detail and to encourage the development of foundation designs in which deformation is permitted in order to minimize inertial loads on the superstructure.

Abstract: Dynamic centrifuge tests were performed using soil-footing – superstructure models to investigate the effects of footing uplift on the vertical acceleration of a footing during strong shaking. The horizontal shearing and vertical compressive forces on the base of the footing, as well as the earth pressure and wall friction force on both sides of the footing, were measured carefully using newly developed 2D-load cells. The following conclusions were drawn. (1) The foundation uplift induces vertical acceleration of two types on an embedded footing: "impulsive vertical acceleration" caused by the collision impulse between the foundation and soil and "induced vertical acceleration" caused by the height movement of the gravitational center of structure. (2) The amplitude of the impulsive vertical acceleration, more than 12 m/s^2, is much greater than that of the induced vertical acceleration. (3) When the horizontal superstructure acceleration exceeds about 5 m/s^2, the amplitudes of the impulsive vertical acceleration and the induced vertical acceleration increase dramatically, suggesting that a small earthquake will generate only small vertical acceleration but that an intense earthquake will trigger the foundation uplift and generate extremely high vertical acceleration especially by the collision impulse.

1. INTRODUCTION

A slender building supported by a shallow foundation might be uplifted along with rocking during an intense earthquake. Houser (1963), in his pioneering study of the foundation uplift, suggested that the stability of a tall, slender block subjected to earthquake motion is much greater than would be inferred from its stability against a constant horizontal force. Subsequently, many researchers studied the effects of foundation uplift on the seismic response of structures. Based on numerical analyses, Meek (1975) reported that the uplift engenders a favorable reduction in the structural deformation. Based on model nine-story building frame shaking table tests and two-dimensional numerical analyses, Huckelbridge and Clough (1978) reported that the uplift causes a general reduction in the applied loading. To consider the beneficial effects of foundation uplift, Chopra et al. (1985) proposed a simplified analysis of the structure response associated with foundation uplift.

Meek (1975) also predicted negative effects of foundation uplift, as characterized by collision impulses when the foundation slams into renewed contact with the ground. Based on numerical analyses of reactor buildings subjected to both horizontal and vertical input motions, Muto and Kobayashi (1979) reported that foundation uplift can induce vertical acceleration of two types: a collision impulse caused by the foundation uplift and induced vertical acceleration caused by the height movement of the gravitational center of the structure. They also reported that the former can have greater acceleration amplitude than the latter. Despite numerous numerical analyses, few experimental studies have examined the collision impulse generated by the foundation uplift.

The objective of this study is to examine the vertical acceleration of those two types caused by foundation uplifting that occurs during strong shaking. A dynamic centrifuge test on a superstructure–footing model was performed, with the footing embedded in the sand layer.

2. CENTRIFUGE TEST

2.1 Test Model

A dynamic centrifuge test was conducted using a soil-foundation – superstructure model at 40 × g centrifugal acceleration with the geotechnical centrifuge at the Disaster Prevention Research Institute, Kyoto University. Figure 1 shows the test setup and instrumentation. The soil-footing – superstructure system was prepared in a laminar shear box with inner dimensions of 450 mm

(length) × 150 mm (width) × 200 mm (height). Table 1 presents the weights and dimensions of the footing–superstructure model in the model and prototype scales. The footing was modeled with aluminum alloy of 124 mm (shaking direction) × 64 mm (width) × 52 mm (height). The superstructure modeled with rigid brass of 82 mm (shaking direction) × 58 mm (width) × 50 mm (height) was supported by two 35-mm-high plate springs. The superstructure weight was 2.0 kg. That of the footing was 1.0 kg. The natural frequency and damping constant of the superstructure under the fixed footing condition were, respectively, about 105 Hz and 0.5%. Dry sand was air-pluviated to prepare a uniform soil layer with Dr=90%. Toyoura sand with D_{50}=0.21 mm was used for the test. The soil model heights were 198 mm; the footing was embedded 50 mm into the dry sand layer. The static friction coefficient between Toyoura sand and the footing surface was 0.37.

2.2 Earth Pressure, Base Friction, and Soil-structure Responses Measurements

Figure 2 portrays a detailed cross section of the foundation in the plane parallel to the direction of shaking, with two base plates and two active/passive side plates. Each of these four plates was connected to the main body of the foundation with a newly developed load cell (Tokyo Sokki Kenkyujo Co. Ltd.), as shown in Photo 1, to identify forces acting on the foundation. Each load cell was designed to measure normal and shear forces acting on the attached plate separately. The two load cells on the base plates therefore provided the horizontal shear and vertical forces. The remaining two attached on the side walls provided the earth pressure and wall friction force on the active and passive side plates. The base lines of the forces measured by the load cells were set to zero before the start of centrifuge test.

The shaking test was run using Rinkai92, i.e., a synthesized ground motion for the Tokyo Bay area, as the input horizontal motion with no vertical motion to the base of the container. The peak acceleration was scaled to about 5 m/s^2 in prototype scale. In addition to forces acting on the footing described in the preceding paragraph, the horizontal and vertical accelerations of superstructure, footing, soil and container base were measured, as well as the horizontal and vertical displacement of the footing (Fig. 1). All data presented herein are of prototype scale.

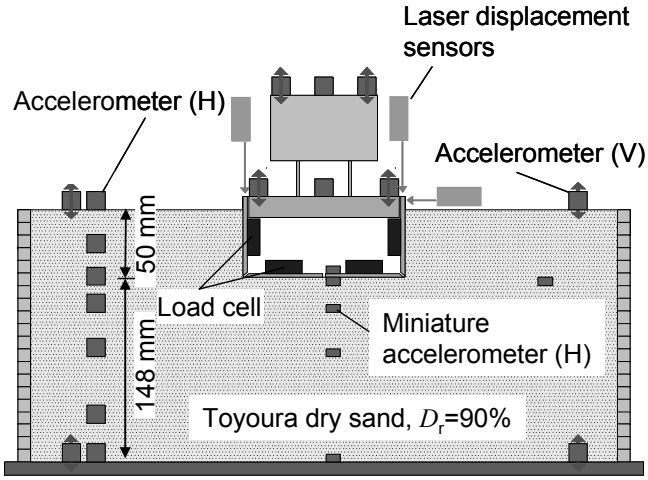

Figure 1 Test model

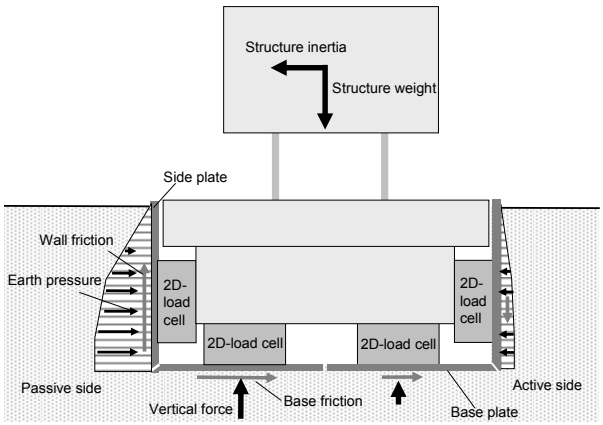
Table 1 Weights and dimensions of the footing– superstructure model in the model and prototype scale

		Unit	Prototype	Model
Footing	Mass	kg	64,000	1.0
	Length (L×B×H)	m	4.96×2.56×2.08	0.124×0.064×0.052
Structure	Mass	kg	128,000	2.0
	Natural frequency	Hz	3.8	105

3. CENTRIFUGE TEST RESULTS

3.1 Horizontal Acceleration and Footing Rotation

Figure 3 depicts the respective time histories of the horizontal acceleration of the input, the ground surface,



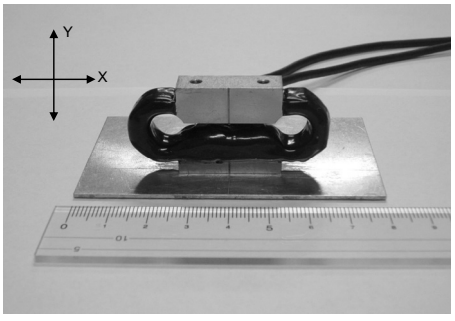


Figure 2 Earth pressure and base friction measurements

Picture 1 Two-directional load cell capable of separate measurements from horizontal and vertical forces

the top of the footing and superstructure, and the footing rotation. The footing rotation was evaluated as the ratio of the relative displacement between the vertical displacements on the left and right sides of the footing, which were calculated by double integration of the accelerations, to the distance between the two sensors (clockwise rotation = positive). The peak horizontal accelerations of the ground surface and the superstructure are, respectively, 7.5 m/s^2 and 8.3 m/s^2. The amplitude of the horizontal superstructure acceleration tends to be nearly constant for T=20–40 s. However, the amplitude of the footing rotation, generated by the superstructure inertia, tends to change with time. The waveform of the footing rotation angle differs greatly from that of the superstructure.

3.2 Vertical Acceleration

Figure 4 shows the time histories of the vertical acceleration of the container base, the ground surface, and the footing, which are the average of the two values measured on the left and right sides and on the left and right sides of footing. The peak average vertical ground surface acceleration is about 2.8 m/s^2 despite extremely small values on the container base (about 0.3 m/s^2). The peak average vertical acceleration of the footing (7.4 m/s^2) is apparently larger than that of the ground surface. The peak vertical accelerations of both sides of the footing were extremely high: greater than 12 m/s^2. It is noteworthy that the positive vertical footing acceleration was spiky and much greater than the negative acceleration.

Figure 5 shows the wavelet frequency spectra of the horizontal acceleration of superstructure and the vertical acceleration of the footing left side. The wavelet frequency spectrum of the vertical acceleration is quite different from that of the horizontal acceleration. The horizontal acceleration always contains low frequency components, from 1 Hz to 3 Hz. On the other hand, the vertical acceleration have wide frequency range from 1 Hz to 20 Hz and occurred intermittently.

To investigate the vertical acceleration of the footing, the relation between the peak vertical acceleration of the footing left side and the predominant frequency at the same instance is shown in Fig. 6. The positive vertical acceleration tends to contain higher frequency component than the negative vertical acceleration. The predominant frequency of the positive high acceleration whose amplitude is greater than 5 m/s^2, is 3-12 Hz. On the other hand, the predominant frequency of the positive high acceleration is 3-7 Hz, which is about two times that of the superstructure horizontal acceleration.

4. VERTICAL ACCELERATION CAUSED BY FOOTING UPLIFT

4.1 Footing Rotation and Vertical Acceleration on Footing

The centrifuge test results show that high vertical acceleration exceeding 12 m/s^2 occurs on the footing in spite of the absence of the vertical input motion. To discuss why such high vertical acceleration was induced on the footing, Fig. 7 depicts selected time histories of important values for a period of 3 s (T=22–25 s) during which the footing rotation has a peak value. These include the horizontal acceleration of the superstructure, vertical accelerations of left and right sides of footing and their average, the vertical shear force acting on active/passive sides (wall friction), the vertical forces acting on the left and right sides of footing base and their sum, and the footing rotation. The vertical solid lines (T=p1, p2) and the dotted lines (T=m1, m2) in the figure correspond respectively to the instants at which the average vertical

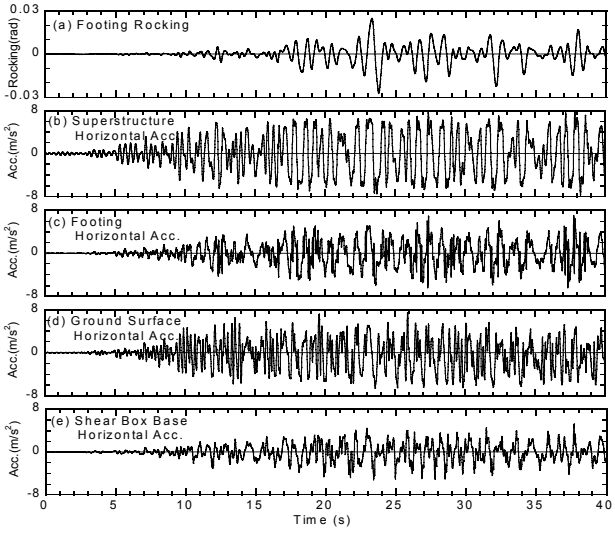

Figure 3 Time histories of horizontal accelerations and footing rotation

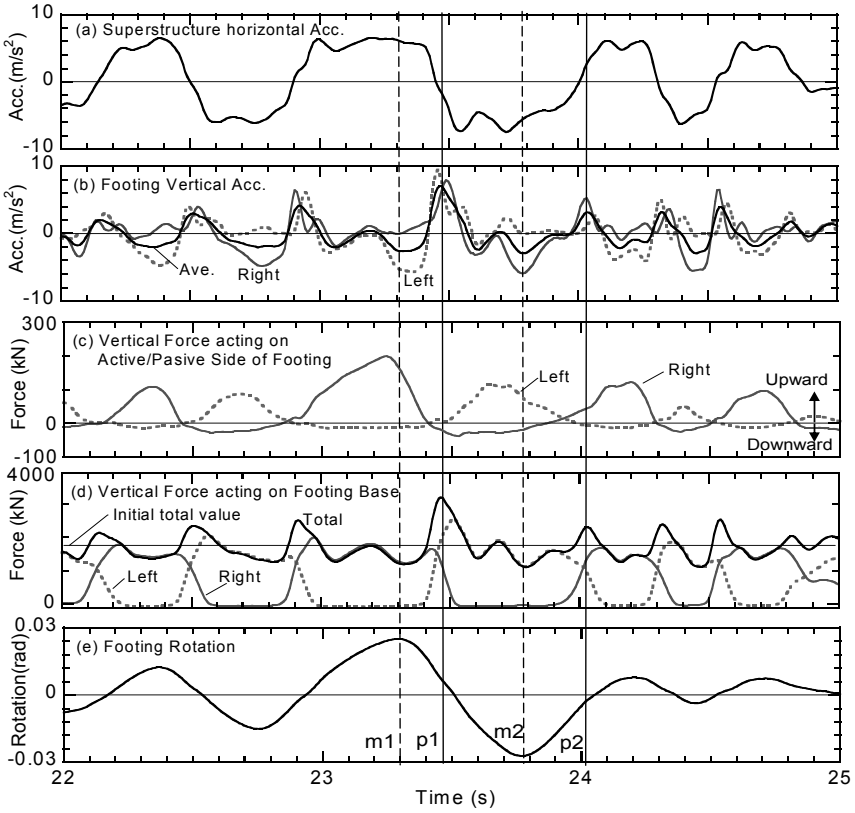

Figure 7 Time histories of footing responses and vertical force acting on the footing base for T=22– 25 s

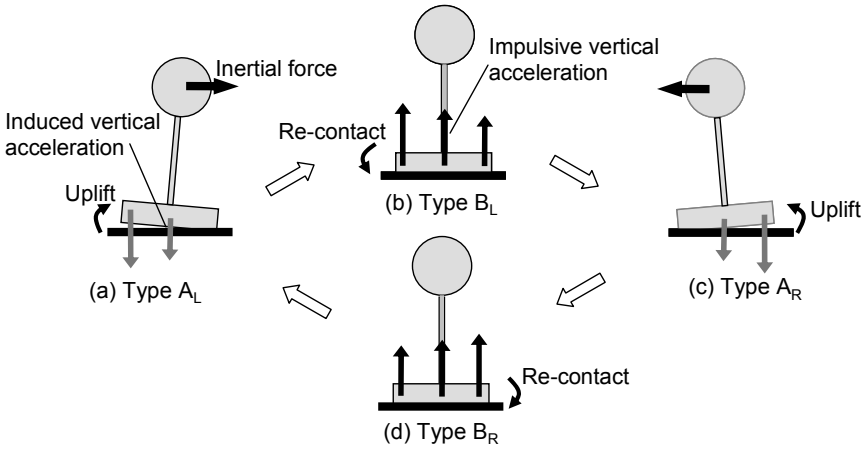

Figure 8 Schematic figure showing footing rotation, superstructure inertia force, and vertical accelerations

acceleration of the footing has a positive peak and negative peak. It is noteworthy that the peak average vertical acceleration is significantly greater on the positive side than on the negative side, as discussed in the following paragraph.

The footing rotation (Fig. 7(e)) has positive peaks at T=m1. The vertical force on the footing base is almost zero on the left side (the blue dotted line in Fig. 7(d)), indicating that the footing was uplifted on this side. The wall friction force on the footing's right side (passive side) has a greater value and acts upward; that on the left side (active side) has a smaller value and acts downward, indicating that the former wall friction reduces the settlement of the footing's right side, but the latter wall friction does not reduce the uplift of the footing's left side. The vertical acceleration on the footing has a large negative peak on the left side (blue dotted line in Fig. 7 (b)), but with a very small value on the opposite (right) side (red solid line in Fig. 7(b)).

The horizontal acceleration of the superstructure and the footing rotation (Figs. 7(a) and 7(e)) has a negative peak at T=m2. The trends observed at this instant, if horizontally reversed, are fundamentally the same as those observed at T=m1. That is, the vertical force on the footing base is almost zero on the right side, indicating that the footing did uplift on this side. The vertical acceleration, in contrast, has a large negative peak on the right side, but was almost zero on the opposite (left) side (Fig. 7(b)), which indicates that the negative vertical acceleration at this instant varies within the foundation. Further examination reveals that the average of the negative peak vertical acceleration (black solid line in Fig. 7(b)) would be approximately half of that occurring at the same instance on either side of the foundation.

In spite of the fact that the horizontal acceleration of the superstructure and the footing rotation are almost zero at T=p1and p2 (Figs. 7(a) and 7(e)), the vertical accelerations on the footing have large positive peaks (Fig. 7 (b)) on both sides. Unlike the instants producing negative peak vertical acceleration, positive peaks do occur on both sides. The average of the positive peak vertical acceleration (black solid line in Fig. 7(b)) would be approximately the same as that occurring anywhere on the foundation. The wall friction forces on the footing's both sides have a small value, probably because an extremely small superstructure inertia causes the earth pressure, which is nearly at rest state.

Based on the findings and discussions presented above, Fig. 8 portrays a schematic diagram showing the relation among the footing rotation, the superstructure inertia force, and the vertical accelerations acting on a shallow foundation. In Types A_L and A_R, a large inertial force acting on the superstructure might trigger an uplifting of the footing on the side opposite to the direction of the inertia force, which could cause varying downward accelerations within the footing. The resultant vertical acceleration is "induced vertical acceleration", the amplitude of which corresponds to the movement of the gravitational center of the structure following the footing uplift (Muto and Kobayashi, 1979). In Types B_L and B_R, with no horizontal inertial force from the superstructure, larger upward accelerations with almost same amplitude develop throughout the footing. The vertical acceleration of this type seems to result from the collision impulse between the footing and soil because it occurs when the footing reattaches to the soil. For that reason, high vertical accelerations occur during strong shaking on the footing without the presence of the vertical input motion, which also explains why the peak average vertical acceleration is significantly greater on the positive side than on

the negative side.

4.2 Impulsive Vertical Acceleration

To discuss the positive vertical acceleration in detail, a free body (mass m) falling from a specific height touches the ground at a velocity v_0, and comes to rest. Based on the law of conservation of momentum, the momentum, mv_0 is equal to an impulse as

$$\int_0^{t_f} F(t)dt = m \cdot v_0 \qquad (1)$$

where F(t) is the impulsive force when the body contacts the soil and t_f is the interval between the contact and the rest. In fact, F(t) can be expressed as follows.

$$F(t) = m \cdot a_v(t) \qquad (2)$$

In that expression, a_v(t) is the impulsive vertical acceleration of the free body. Eqs. (1) and (2) suggest that the impulsive vertical acceleration on the footing caused by the collision impulse depends on the vertical footing velocity immediately before re-attachment.

Figure 9 presents the relation between the peak vertical velocity of the re-contact side of the footing and the corresponding average positive vertical acceleration of the footing. The vertical acceleration increases concomitantly with the vertical velocity, indicating that the positive vertical acceleration was actually generated by the collision impulse between the footing and soil, as predicted numerically by Meek (1975) and Muto et al. (1979). The positive vertical acceleration will be called "impulsive vertical acceleration".

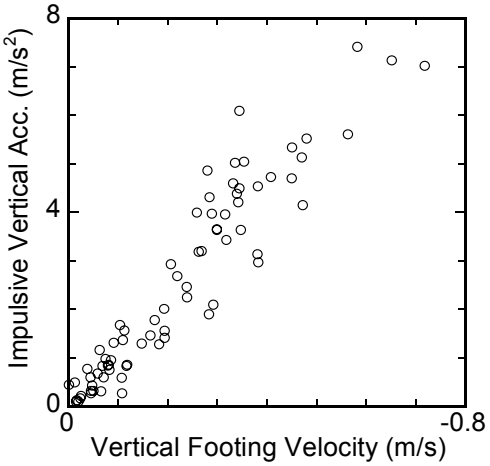

Figure 9 Relation between peak average vertical footing velocity immediately before re-contact and the corresponding average vertical acceleration of footing

5. IMPULSIVE VERTICAL ACCELERATION AND INDUCED VERTICAL ACCELERATION

Figure 10 shows the relation between the preceding peak footing rotation angle and the peak impulsive vertical acceleration on the footing's left and right sides, in addition to the relation between the footing rotation angle and the peak induced vertical acceleration at the same instance. The peak impulsive acceleration tends to increase concomitantly with increased footing rotation angle and exceeds 12 m/s^2. The peak induced vertical motion also tends to increase concomitantly with increased footing rotation angle but reaches an upper limit of about 8 m/s^2. The peak impulsive vertical acceleration

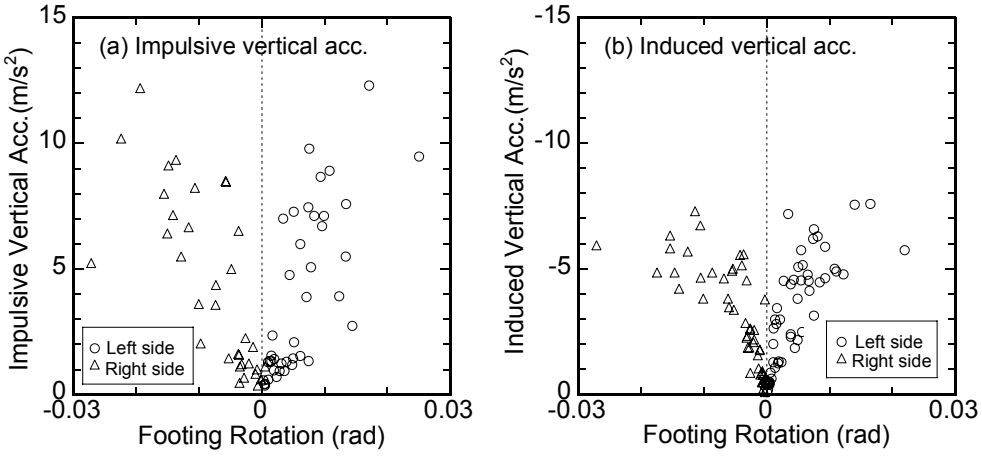

Figure 10 Relation between the preceding peak footing rotation angle and the peak impulsive vertical acceleration, and the relation between the footing rotation angle and the peak-induced vertical acceleration at the same instance

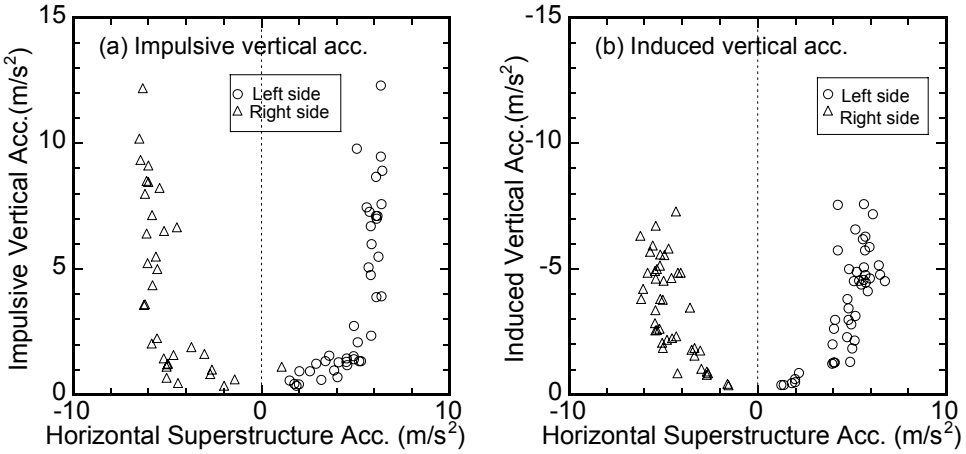

Figure 11 Relation between preceding peak horizontal superstructure acceleration and peak impulsive vertical acceleration, and the relation between peak horizontal superstructure acceleration and peak induced vertical acceleration at the same instance

tends to be larger than that of induced vertical acceleration at the same footing rotation angle, indicating that not only the effects of the induced vertical acceleration but also those of the impulsive vertical acceleration on facilities of important structures such as nuclear plants should be investigated.

Figure 11 portrays the relation between the preceding peak horizontal superstructure acceleration and the corresponding peak impulsive vertical acceleration, in addition to the relation between the horizontal superstructure acceleration and the peak induced vertical acceleration at the same instance. When the horizontal superstructure acceleration exceeds about 5 m/s^2, the amplitudes of the impulsive vertical acceleration and the induced vertical acceleration rise dramatically. The explanation above suggests that a small earthquake will generate only slight vertical acceleration, but that an intense earthquake will trigger the foundation uplift and generate extremely high vertical acceleration, especially because of the collision impulse.

To investigate the effects of horizontal superstructure inertia on the footing rotation, the relation between the peak rotation angle of the footing and the overturning moment of the footing-superstructure at the same instance is presented in Fig. 12. The moment-rotation relationship shows strong non-linear behavior. The footing rotation angle increases significantly when the overturning moment is greater than about 3000 kNm. The overturning moment, 3000 kNm, is mainly caused by the superstructure inertia whose horizontal acceleration amplitude is about 5 m/s^2. This indicates that the footing rotation angle increases rapidly when the superstructure horizontal acceleration amplitude is greater than 5 m/s^2.

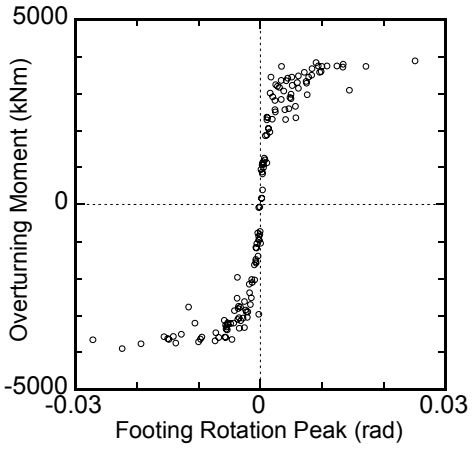

Figure 12 Relation between peak footing rotation and overturning moment of footing-superstructure at the same instance

Therefore, the amplitudes of the impulsive vertical acceleration and the induced vertical acceleration rise dramatically, when the horizontal superstructure acceleration exceeds about 5 m/s^2, as presented in Figs. 10 and 11.

6. CONCLUSION

Dynamic centrifuge tests were performed using soil-footing – superstructure models to investigate the effects of the footing uplift on the vertical acceleration of the footing during strong shaking. The horizontal shearing and vertical compressive forces on the base of the footing, in addition to the earth pressure and wall friction force on both sides of the footing, were measured care-

fully using newly developed 2D-load cells. The following conclusions were drawn.

(1)The foundation uplift induces vertical acceleration of two types on an embedded footing: "impulsive vertical acceleration" caused by the collision impulse between the foundation and soil and "induced vertical acceleration" caused by the height movement of the gravitational center of the structure.

(2)The amplitude of the impulsive vertical acceleration, more than 12 m/s^2, is much greater than that of the induced vertical acceleration.

(3)When the horizontal superstructure acceleration becomes greater than about 5 m/s^2, the amplitudes of the impulsive vertical acceleration and the induced vertical acceleration rise dramatically, suggesting that a small earthquake will generate only small vertical accelerations but that an intense earthquake will trigger the foundation uplift and generate extremely high vertical acceleration, especially by the collision impulse.

(4)The amplitudes of both vertical accelerations increase with the induced rotation angle of the footing.

Abstract: Effects of sway-rocking motion on pile stresses are estimated through large shaking table tests in which a structure supported by a 3x3 pile group was set in a dry sand deposit prepared in a cylindrical laminar box with a height of 6.5 m and a diameter of 8.0 m. Presence of foundation embedment and input motions were variable in the tests. The test results have shown that foundation embedment restrains sway motion more than rocking motion. As a result, the foundation embedment decreases its displacement but increases ratios of rocking component against sway component. This induces a unique bending strain distribution of piles in which it decreases toward the pile head. This contrasts well with the bending strain distribution without foundation embedment in which it increases toward the pile head. Sway and rocking stiffness increases with decreasing predominant period of input motion, with stiffness increase being more significant in sway than in rocking. This makes effects of rocking motion on pile stresses more significant with shorter period motion than with longer period motion.

1. INTRODUCTION

In order to establish reasonable seismic design of pile foundations, it is important to estimate soil-pile-structure interaction during earthquakes, in which both kinematic forces from the ground and inertial forces from structures act on the piles. Such kinematic and inertial forces depend on various factors, such as foundation embedment and structure response including sway-rocking motions. To estimate effects of sway-rocking motion on soil-structure interaction, many studies have been made based on physical model tests and numerical analyses for spread foundation models (e.g., Toki et al. 1980, Hayashi 1996, Kutter et al. 2010, Tamura et al. 2010). Hayashi (1996) and Kutter et al. (2010) have shown that rocking motion of slender buildings or bridge columns with spread foundation could act as effective energy dissipation components of structure systems. If the structure is founded on piles, its rocking motion might have affected pile stresses. Iiba et al. (2003) has investigated sway-rocking motion of pile-structure systems through shaking table tests. Studies on sway-rocking motion of pile-structure systems based on physical model tests, however, have been rare.

To investigate inertial and kinematic effects on pile groups during three-dimensional shaking, physical tests on soil-pile-structure models were conducted using E-Defense at the Hyogo Earthquake Engineering Research Center of the National Research Institute for Earth Science and Disaster Prevention (NIED) (Tabata and Sato 2006, and Tokimatsu et al. 2007). In the shaking table tests using E-Defense, structure models as well as input motion and its maximum acceleration were variable. The objectives of this study are to investigate factors influencing sway-rocking motion and the effects of sway-rocking motion on pile stresses through the shaking table tests conducted at E-Defense.

2. LARGE SHAKING TABLE TESTS

The E-Defense shaking table platform has a dimension of 15 m length and 20 m width. It is supported on fourteen vertical hydraulic jacks and connected to five hydraulic jacks each in the two orthogonal horizontal directions. A soil-pile-structure model was constructed in a cylindrical laminar box with a height of 6.5 m and a diameter of 8.0 m. The container consists of forty-one stacked ring flames, enabling shear deformation of the inside soil during two-dimensional horizontal shaking. Figures 1 and 2 show the test model prepared in the cylindrical laminar box placed on the shaking table. The superstructure was supported on a 3x3 pile group that penetrated into a dry sand deposit, as shown in Figure 2.

Dry Albany sand, imported from Australia, was used for the sand deposit. The sand had a mean grain size D50 of 0.31 mm. After setting the pile group in the laminar box, the sand was air-pluviated and compacted to a relative soil density of about 70 % so as to form a uniform sand deposit with a thickness of 6.4 m. The natural period of the ground surface was about 0.2 s. Each pile of the pile group was made of stainless steel and had a diameter of

152.4 mm and a wall thickness of 2.0 mm. The piles were set up with a horizontal space of four-pile diameters center to center. Their tips were jointed to the laminar box base with pins and their heads were fixed to a foundation of a weight of 10 tons. The piles were labeled A1 to C3 according to their locations within the pile group, as shown in Figure 2(a).

A total of five test series was conducted, in which the presence of foundation embedment (0.5 m) and of superstructure (28 tons) as well as the natural period of the superstructure were varied. In this study, factors influencing sway-rocking motion and effects of sway-rocking motion on pile stresses are discussed, based on the test series YM and NM. Both had the same superstructure but series YM had foundation embedment but series NM did not.

The tests were conducted under one-, two- or three-dimensional shaking with three different ground motions recorded at (i) Takatori in the 1995 Kobe earthquake (Takatori), (ii) Lincoln School in the 1952 Taft earthquake (Taft) and (iii) Akasaki in the 2000 Tottori earthquake (Tottori). In each test series, either or both of the two horizontal or three-component motions were used as inputs to the shaking table with the largest horizontal acceleration being scaled to 0.3~6 m/s^2. The NS and EW components of the ground motion were applied to the NS and EW directions as shown in Figure 2, with the UD component to the vertical direction. This paper describes the effects of the presence of foundation embedment and input motions on sway-rocking motion and pile stresses based on test series YM and NM with Takatori (TK) or Tottori (TT) motions having maximum horizontal input accelerations of 0.8 m/s^2 under three dimensional loading. These tests are, hereafter, called YM-TT, YM-TK and NM-TK.

Many strain gauges, accelerometers, velocity meters, earth pressure transducers, displacement transducers, settlement meters and load cells, about 900 sensors in total, were placed in the sand deposit as well as on the pile-structure model, as shown in Figure 2. Further details of the test apparatus and procedure have been described elsewhere (Tabata and Sato, 2006).

3. DIFFERENCE IN SOIL-PILE-STRUCTURE RESPONSE BETWEEN MODELS

Figure 3 shows the acceleration response spectra of the superstructure, the foundation, the ground surface and the shaking table for Tests YM-TT, YM-TK and NM-TK. Tottori motion dominates only in the short period range with a sharp spectral peak at less than 0.1 s (YM-TT, Figure 3(a)(b)). In contrast, Takatori motion dominates over the wide period range covering from 0.1 s to 1.0 s (YM-TK, NM-TK, Figure 3(c)-(f)). Figure 4 shows amplitude ratios of the superstructure acceleration with respect to the shaking table acceleration for the three tests. Among the three tests,

Table 1 Test series

	Embedment (0.5 m)	Superstructure (28 tons)	Natural period (s)	Maximum input acceleration (m/s^2)							
				Takatori				Taft and Tottori			
				X	Y	XY	XYZ	X	Y	XY	XYZ
YS	Yes	Yes	0.1 (model S)	0.3, 0.8				-			0.3, 0.8
YL	Yes	Yes	0.6 (model L)								
YN	Yes	No	-								
YM	Yes	Yes	0.2 (model M)					0.3, 0.8			
NM	No	Yes		0.3, 0.8			0.3, 0.8, 6.0, 8.0	-			

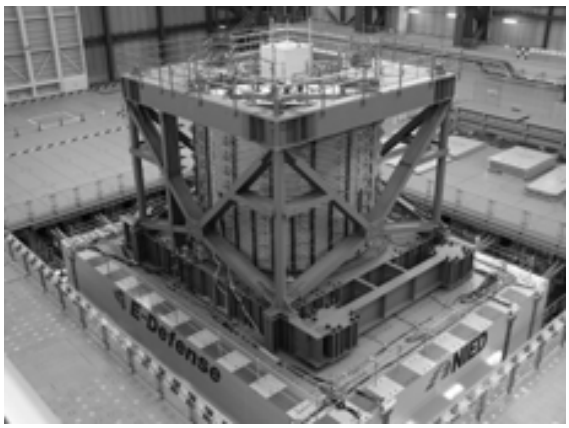

Figure 1 Laminar shear box on shaking table platform

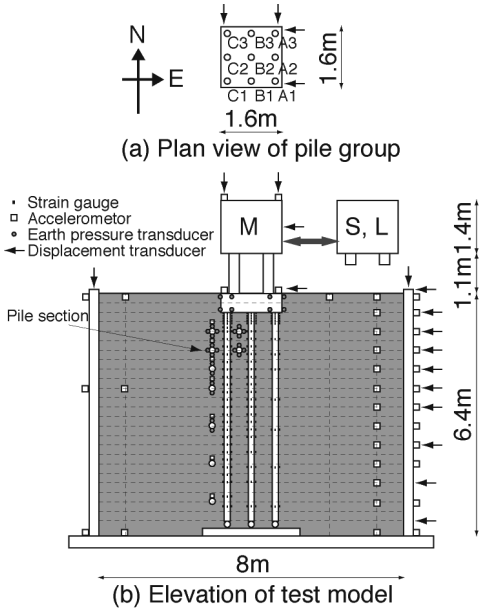

Figure 2 Test model in laminar box

the peak amplitude ratio is the largest in YM-TT and the smallest in NM-TK. It is interesting to note that the period, at which the amplitude ratio takes a peak, is longer in NM-TK than in YM-TT and YM-TK. This suggests that the presence of foundation embedment affects coupled vibration of soil-pile-structure systems.

Figure 5 shows the time histories of bending strains at the head of Pile A1, displacements of foundations and the ground surface and accelerations of superstructures, foundations, the ground surface and the shaking table. Figure 5 indicates that the accelerations and displacements of the ground, the foundation and the superstructure are all larger with Takatori motion (YM-TK, NM-TK) than with Tottori motion (YM-TT) (Figure 5(b)-(f)(i)-(m)(p)-(t)), confirming that the predominant period of input motions affects the soil-structure behavior. A comparison between YM-TK and NM-TK shows that the superstructure acceleration is larger with embedment (YM-TK) than without embedment (NM-TK) but the foundation displacement is smaller when the foundation is embedded (Figure 5(i)(k)(p)(r)). Namely, the foundation embedment decreases the displacement but increases the acceleration as mentioned in the previous study on spread foundations with smooth surface (Tamura et al. 2010).

To investigate the effects of the difference in soil-pile-structure interaction on pile stresses, Figure 6 shows distributions of bending strains with depth for Piles A1, B2 and C3, at instant when the bending strain takes the largest peak in each test. Pile A1 was located on the southeast corner, Pile B2 on the middle and Pile C3 on the northwest corner within a pile group. The bending strain shown in Figure 6 is computed by the sum of NS and EW components. At these instants, the inertial force increases southeastward in all the three tests, making Pile A1 the leading pile and Pile C3 the following pile. As might be expected, Figure 6 indicates that the bending strain is larger in the leading pile than in the trailing pile. These trends confirm that the pile stresses vary within a pile group and that bearing load is the largest in the leading corner pile due to the shadowing effects. A comparison in bending strains

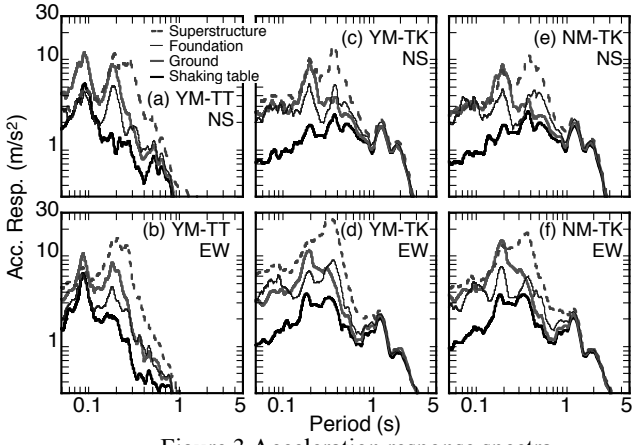

Figure 3 Acceleration response spectra

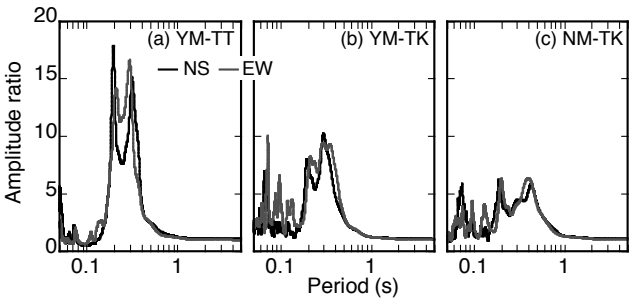

Figure 4 Amplitude ratios of superstructure with respect to input motion

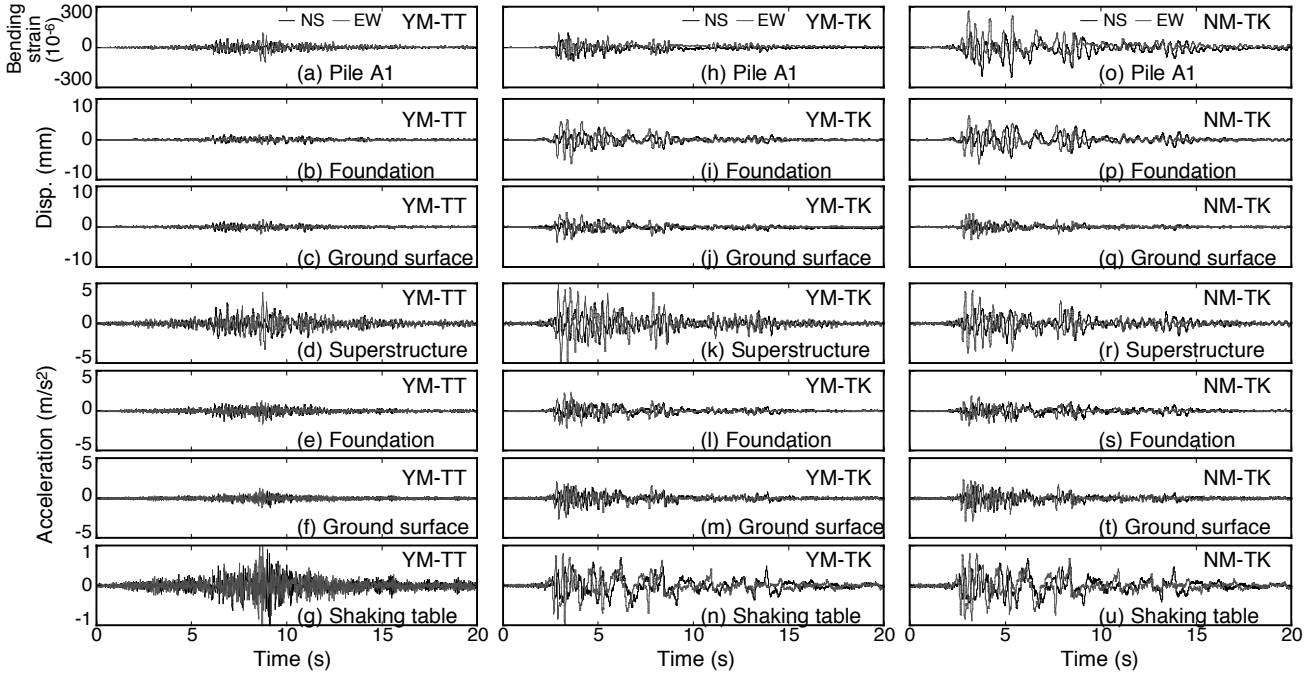

Figure 5 Time histories of major parameters

among the three tests shows that the bending strain in NM-TK is the largest (Figure 6(g)-(i)). This is probably because the foundation embedment affects bending strains in such a way that the earth pressure acting on an embedded foundation reduces the shear force transmitted to pile heads from a superstructure, as mentioned in the previous studies (e.g., Imaoka et al, 1998; Tamura et al, 2002). In contrast, the bending strain in YM-TT is the smallest among the three tests. This is due to its small superstructure acceleration and ground displacement (Figure 3(c)(d)). It is also interesting to note that the bending strain decreases toward pile heads in YM-TT and YM-TK (Figure 6(c)(f)). This contrasts well with the bending strain distribution in NM-TK in which it reaches a peak at the pile head, decreasing with depth (Figure 6(i)). The presence of foundation embedment might have affected the bending strain distributions with depths.

4. SWAY-ROCKING MOTION OF FOUNDATION

Integration of the vertical and horizontal accelerations measured at the four edges on the foundation, yields their vertical and horizontal displacements. The rotational angles of the foundation are then computed from the difference in vertical displacements between the opposite edges of the foundation. Figure 7 shows relation between the inertial force and the rotational angle of a foundation. Figure 7 indicates that the rotational angle of the foundation is related to the inertial force.

Sway and rocking components of the displacements on the top of the foundation are defined by the following equations:

$$Y = Y_S + Y_R \tag{1}$$

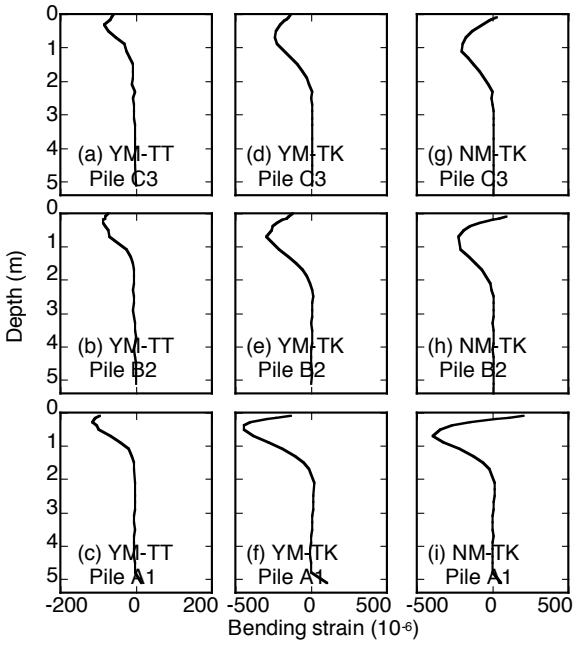

Figure 6 Distributions of bending strains

$$Y_R = \frac{h}{2}\theta \tag{2}$$

in which Y or Y_S is the relative displacement with respect to the ground at the top of the foundation or at the center of the gravity of the foundation, as shown in Figure 8. Y_R is the displacement at the foundation top induced by rotational motion, θ is the rotational angle, and h is the height of the foundation. Since Y can be computed from the observed accelerations of the foundation and the ground surface, and Y_R from Equation (2), Y_S can readily be determined by Equation (1).

Figure 9 shows relations between sway and rocking components in foundation displacements in the three tests. A comparison between YM-TK and NM-TK shows that rocking components are larger but sway components are smaller in YM-TK than in NM-TK (Figure 9(b)(c)). Since the foundation displacement is larger in NM-TK than in YM-TK (Figure 5(i)(p)), the foundation embedment decreases its displacement and thus increases the ratio of rocking components in foundation displacements. The decrease in sway component in foundation displacement in YM-TK is probably caused by the reduction of shear force at pile heads due to earth pressure acting on the embedded foundation. A comparison between YM-TT and YM-TK shows that both rocking and sway components are smaller in YM-TT than in YM-TK (Figure 9(a)(b)), probably due to smaller foundation displacement. In contrast, the ratios of rocking components in foundation displacements are larger in YM-TT than in YM-TK.

A comparison between sway and rocking components in foundation displacement among the three tests (Figure 9) indicates that the difference in bending strain distributions is related to sway-rocking motion of foundations. Namely, in the case with foundation embedment (YM-TT and YM-TK), the increase in rocking component tends to rotate

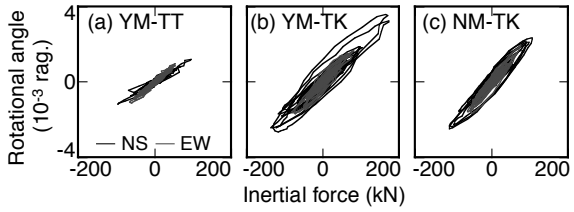

Figure 7 Relationship of inertial force and rotational angle

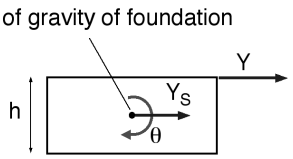

Figure 8 Sway and rocking motions of foundation

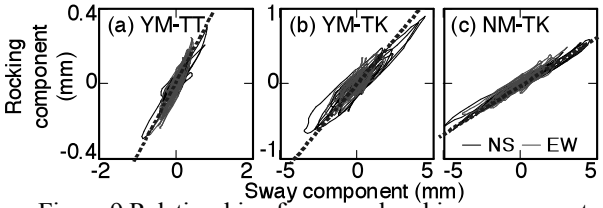

Figure 9 Relationship of sway and rocking components in foundation displacement

the foundation significantly, reducing the bending moment at the pile head. This could induce such a unique trend in which the bending strain does reach a peak at some depth below the pile head rather than at the pile head, thereby decreasing towards the pile head. In contract, the effects of sway motion are significant in the case without foundation embedment (NM-TK), inducing the bending strain distribution in which it reaches a peak at the pile head, decreasing with depth. In addition, a comparison between YM-TT and YM-TK shows that the slope of bending strain below the heads is smaller in YM-TT than in YM-TK.

Figure 10 illustrates the horizontal force, P_Y and the rotational moment, M_X, which are transmitted to the foundation from the superstructure. P_Y and M_X could be estimated by the structure response (Architecture Institute of Japan 1996). Figure 11 shows the relationship between the horizontal force, P_Y and the relative displacements of the gravity center of foundations with the ground and Figure 12 shows the relationship between the rotational moment, M_X and the rotational angles of foundations. The slopes of these relationships correspond to the stiffness of sway and rocking motions. A comparison between YM-TK and NM-TK shows that the rocking stiffness is almost the same but the sway stiffness is larger in YM-TK than in NM-TK (Figures 11 and 12(b)(c)). This suggests that the foundation embedment increases sway stiffness but may not play an important role in controlling rocking stiffness. As a result, sway motion dominates pile stresses in NM-TK but rocking motion dominates pile stresses in YM-TK (Figure 6(d)-(i)).

A comparison between YM-TT and YM-TK shows that sway and rocking stiffness is larger in YM-TT than in YM-TK (Figures 11 and 12(a)(b)). This is related to the previous study on spread foundations (Toki et al. 1980), in which sway and rocking motion decreases, with decreasing predominant period of input motions. In particular, the sway stiffness is significantly large when the predominant period of input motion decreases. As a result, rocking motion dominates pile stresses more significantly in YM-TT than in YM-TT (Figure 6(a)-(f)). This makes the slope of bending strain below the heads smaller in YM-TT than in YM-TK.

5. CONCLUSIONS

To investigate soil-pile-structure interaction during earthquakes, factors influencing sway-rocking motion of pile-structure models and effects of sway-rocking motion on pile stresses are discussed through physical model tests on soil-pile-structure systems using the large shaking table at E-Defense, NIED. The test results and discussions have led to the following conclusions:

Foundation embedment restrains sway motion more than rocking motion. This is because the foundation embedment in these tests increases sway stiffness, but does not play an important role in controlling rocking stiffness. As a result, the foundation embedment decreases its displacement and thereby increasing ratios of rocking components in foundation displacement. In addition, the increased sway stiffness with foundation embedment induces a shorter natural period of the coupled vibration of a soil-pile-structure system and a larger amplitude ratio of the superstructure response than those without foundation embedment.

Rocking motion dominates in a structure with foundation embedment, causing a unique bending strain distribution of piles in which it does reach a peak at some depth below the pile head rather than at the pile head, thereby decreasing towards the pile head. In contract, sway motion dominates in a structure without foundation embedment, making a bending strain distribution, which reaches a peak at the pile head, decreasing with depth.

Sway and rocking stiffness increases with decreasing predominant period of input motion, with the stiffness increase being more significant in sway than in rocking motion. As a result, with decreasing predominant period of input motion, effects of rocking motion on pile stress distributions become significant. This makes the slope angle of bending strain below the heads tend to be smaller with shorter period motion than with longer period motion.

ACKNOWLEDGEMENTS:

The study described herein was made possible through the Special Project for Earthquake Disaster Mitigation in Urban Areas, supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The authors express their sincere thanks to the above organization.

2) Assoc. Professor, DPRI, Kyoto University, Dr. Eng.
hida-t@sds.dpri.kyoto-u.ac.jp, tamura@sds.dpri.kyoto-u.ac.jp

Abstract: Dynamic centrifuge tests were performed to investigate the effects of pile rigidity on the pile stresses and the seismic response of a base-isolated structure during soil liquefaction. Then pseudo-static analyses and single-degree-of-freedom analyses were conducted. The following conclusions were reached. (1) In cases where the structure inertia is large, the bending moment at pile heads and their tips in the high-rigidity pile case are almost identical to those in the low-rigidity pile case. (2) In cases where the natural period of the base-isolated structure is close to the predominant period of the ground, the shear deformation of the isolator in the high-rigidity pile case is smaller than that in the low-rigidity pile case.

1. INTRODUCTION

In recent years, base-isolated structures have been constructed on soft ground that might undergo liquefaction. In such soils, a base-isolated structure can vibrate sympathetically with long-period seismic ground motion, making the shear deformation of the seismic isolator excessively large. A superstructure might then bump against the retaining wall, damaging an isolator (AIJ, 2001, 2007). Furthermore, leaning of a footing can reduce the lateral stiffness of the laminated rubber bearing (AIJ, 2001). A footing might lean when the pile is damaged. Consequently, the seismic adequacy of a pile of a base-isolated structure during soil liquefaction is important knowledge.

Several reports have described that pile rigidity affects pile stress (e.g., Tokimatsu et al., 2005, Fukutake et al., 2004). However, knowledge of pile rigidity effects on pile stresses and the seismic response of a base-isolated structure during soil liquefaction is limited.

This study investigates pile rigidity effects on the seismic response of a base-isolated structure and the bending moment of the piles. For this purpose, dynamic liquefaction tests on a base-isolated structure-footing model supported by 2 × 2 piles that have high and low bending rigidity were performed using a geotechnical centrifuge. Then pseudo-static analyses and response analyses of single-degree-of-freedom systems were conducted.

2. CENTRIFUGE TEST PERFORMED

Centrifuge tests were performed using 40g centrifugal acceleration with the geotechnical centrifuge at the Disaster Prevention Research Institute, Kyoto University. The test model is presented in Fig. 1. The pile specifications are presented in Table 1. Case 1 is the high-

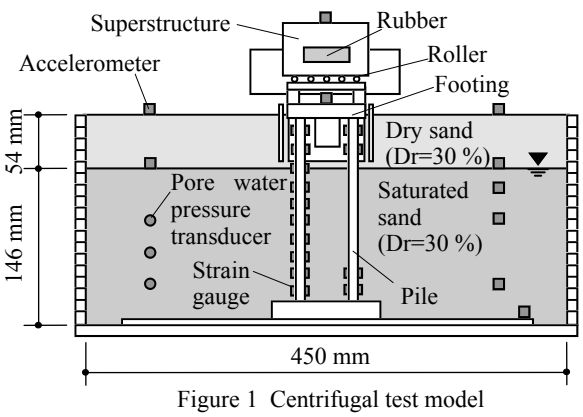

Figure 1 Centrifugal test model

rigidity pile case. Case 2 is the low-rigidity pile case. Piles are of 8 mm diameter and 176 mm length. The footing was supported by 2 × 2 piles. The pile heads were linked rigidly with the footing; their tips were connected rigidly to the base plate. Respective masses of the footing and superstructure were 0.99 kg and 2.0 kg. The superstructure was supported by a roller. To simulate the seismic isolator, the footing and the superstructure were connected by rubber. The natural period and the damping constant of the superstructure under the fixed footing condition were, respectively, 0.125 s and 0.4. The soil used for the tests was Toyoura sand. The relative density of the sand deposit was 30%. The sand deposit was deaerated and Metolose solution with viscosity that was 40 times that of water was infused into the sand deposit. To measure the earth pressure and the sidewall friction acting on the embedded footing, biaxial load cells were set on the footing. Accelerometers were set on the footing, the superstructure, and the ground. The test models were excited using Hachinohe 1968 NS. All data presented in the following sections are adjusted to the prototype scale.

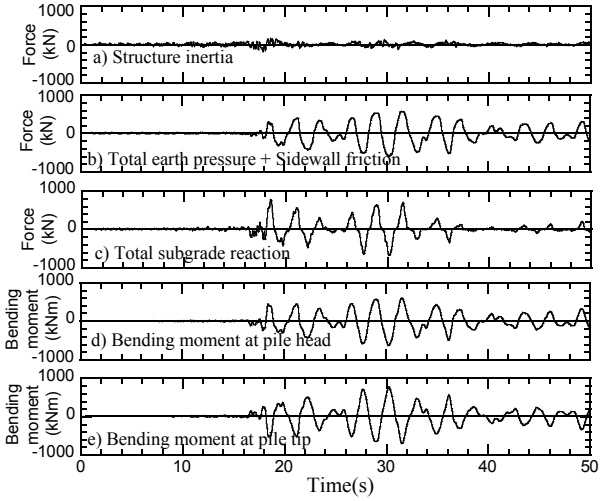

Figure 4 Force and bending moment of pile (Case 1, High rigidity pile)

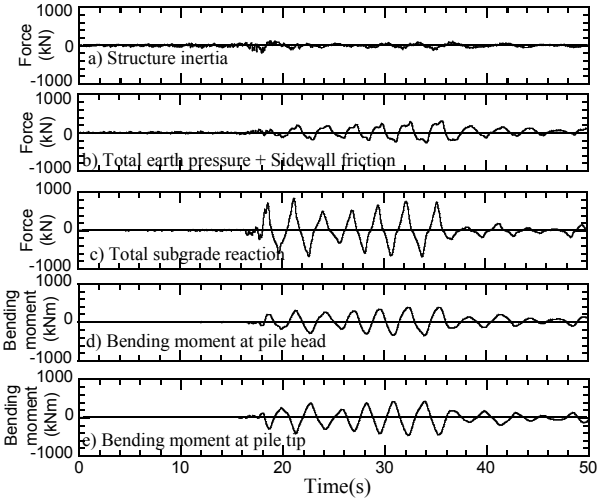

Figure 5 Force and bending moment of pile (Case 2, Low rigidity pile)

tio, superstructure acceleration, footing acceleration, ground surface acceleration, and input acceleration are depicted in Figs. 2 and 3. In both cases, the excess pore water pressure started to increase at 16 s. Ground liquefaction occurred at about 20 s. The amplitude of the superstructure acceleration in Case 2 was greater than that in Case 1. The predominant period of the ground during soil liquefaction was ca. 3 s, which was shorter than the natural period of the superstructure (5 s).

Time histories of the structure inertia (Sum of the superstructure and the footing inertia), the resultant of the total earth pressure and the sidewall friction, the total subgrade reaction (Suzuki et al., 2005) , and the bending moment at pile heads and their tips are shown in Figs. 4 and 5. The total subgrade reaction (Sum of the lateral subgrade reaction acting on the pile) was calculated as the difference between the shear force at pile tips and their heads. The structure inertia was extremely small in both cases. The amplitude of the resultant of the total earth pressure and the sidewall friction, the total subgrade reaction, and the bending moment at pile heads and their tips became extremely large at around 16 s. The amplitude of the resultant of the total earth pressure and the sidewall friction in Case 2 was smaller than that in Case 1. The amplitude of the total subgrade reaction in Case 2 was almost equal to that in Case 1. The bending moment at pile heads and their tips in Case 2 was smaller than those in Case 1.

4. PILE RIGIDITY EFFECTS ON PILE STRESS

To investigate the difference between the bending moment of piles in Case 1 and that in Case 2, the structure inertia, the resultant of the total earth pressure and the sidewall friction, and the total subgrade reaction at the time of maximum bending moment at pile tips are depicted in Fig. 6. The depth distribution of displacement of the ground and the pile is portrayed in Fig. 7. The displacement of the ground was greater than that of the pile and the footing in both cases. Consequently, the total subgrade reaction and the resultant of the total earth pressure and the sidewall friction acted as an external force. The total subgrade reaction in Case 2 was almost identical to that in Case 1. The relative displacement between the ground and the footing in Case 2 was smaller than that in Case 1 because the footing supported by the low-rigidity piles is more likely to follow the ground than that supported by the high-rigidity piles. Consequently, the resultant of the total earth pressure and the sidewall friction in Case 2 was smaller than that in Case 1. As described above, the total subgrade reaction in Case 2 was almost identical to that in Case 1. Moreover, the resultant of the total earth pressure and the sidewall friction in Case 2 was smaller than that in Case 1. Therefore, the bending moments at pile heads and their tips in Case 2 were smaller than those in Case 1.

5. PSEUDO-STATIC ANALYSIS INCORPORATING FOOTING EMBEDMENT EFFECTS

5.1 Subgrade Reaction, Total Earth Pressure and Sidewall Friction

Pseudo-static analyses were performed to investigate the effects of pile rigidity on the bending moment of the pile. The analysis model is presented in Fig. 8. In this study, the total earth pressure and the sidewall friction acting on the embedded footing were considered as a spring between the ground and the footing placed at the pile head. The subgrade reaction acting on the pile was calculated based on the Recommendations for Design of Building Foundations (AIJ, 2001). The *N*-value was

calculated using the following equation (JRA, 2002)

$$V_S = 80 \cdot N^{1/3} \quad (2)$$

where V_S is the shear wave velocity of the ground, and N is the N-value of the ground. The reduction coefficient of the subgrade reaction by soil liquefaction was set to 0.1.

The ultimate lateral resistance was calculated using the following equation.

$$p_y = 3K_P \gamma z \quad (2)$$

Therein, γ is the unit weight of the soil (kN/m³), z stands for the ground depth (m), and K_P represents the coefficient of passive earth pressure calculated using Rankine's equation. The relation between the relative displacement and the subgrade reaction was approximated as a trilinear function.

The total earth pressure acting on the embedded footing was calculated as shown below (Tokimatsu et al., 2003).

$$P_E = P_{Ep} - P_{Ea} = \frac{1}{2}\gamma H^2 B(K_{Ep} - K_{Ea}) \quad (3)$$

In that equation, γ stands for the unit weight of the soil (kN/m³), H denotes the footing height (m), B represents the footing width (m). Also, K_{Ep} and K_{Ea} respectively signify the coefficient of the earth pressure in passive and active sides. In fact, K_{Ep} and K_{Ea} were calculated using the seismic earth pressure theory by Zhang et al (1998). The relative displacement between the ground and the footing at the active and passive earth pressures are set respectively as 0.5% and 5% of the embedment height of the footing.

The sidewall friction acting on the embedded footing, P_{fs}, is calculated as

$$P_{fs} = \mu P_0 \quad (4)$$

and

$$P_0 = \frac{1}{2}K_0 \gamma H^2 B' \quad (5)$$

In those equations, P_0 signifies the earth pressure at rest (kN), γ stands for the unit weight of the soil (kN/m³), H denotes the footing height (m), B' represents the width of sidewall of the footing (m). Furthermore, K_0 is the coefficient of the earth pressure at rest calculated using Jaky's equation. Finally, μ is the friction coefficient between the ground and the sidewall of the footing, as calculated using the following equation (Tamura et al., 2007).

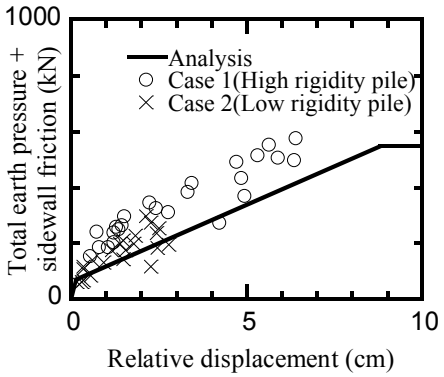

Figure 9 Relation between relative displacement and total earth pressure + sidewall friction

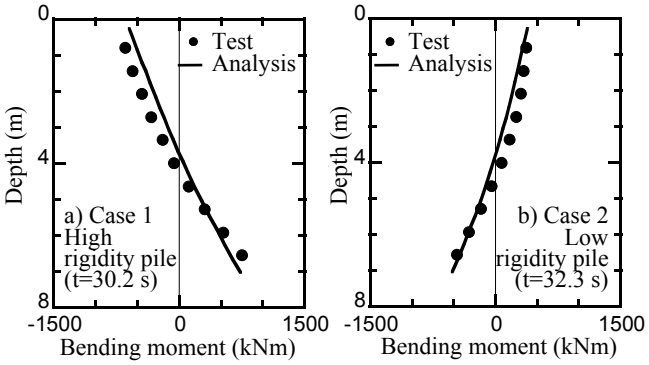

Figure 10 Depth distribution of bending moment

$$\mu = \tan\phi \quad (6)$$

Therein, ϕ is the internal friction angle (34°) of the soil. The relation between the relative displacement and the sidewall friction was set as a bilinear function that reaches constant value (P_{fs}) at 0.15 cm in the relative displacement. In this study, the relation between the relative displacement and the sum of the total earth pressure and the sidewall friction was approximated as a trilinear function. The relation between the relative displacement and the resultant of the total earth pressure and the sidewall friction is shown in Fig. 9. The centrifugal test results are also shown there. The resultant of the total earth pressure and the sidewall friction for analysis approximately agrees with the test results.

Assuming that the structure inertia and the resultant of the total earth pressure and the sidewall friction are evenly allocated to four piles, the analyses were performed for a pile. The ground displacement was set to be constant from the ground surface to 3 m depth. It was approximated by a cosine function from 3 m depth to bottom. The observed structure inertia and the ground surface displacement at the time of maximum bending moment at the pile tip were used for analyses. The structure inertia and the ground displacement were acted on

the pile simultaneously. The analyses were performed using software developed by Kozo Keikaku Engineering Inc.(2009). The depth distribution of the bending moment at the time of maximum bending moment at the pile tip is presented in Fig. 10. The analytical result shows good agreement with the test results in both cases.

5.2 Effects of Structure Inertia on Pile Stresses

To investigate the effects of the structure inertia on pile stress, analyses were performed for cases with various structure inertia. The ground surface displacement was set to 15 cm. In consideration of that the natural period of the superstructure is longer than the predominant period of the liquefied ground, the structure inertia and ground displacement was acted in the opposite phase. The relation between the structure inertia and the bending moment at the pile head is portrayed in Fig. 11. The relation between the structure inertia and the bending moment at the pile tip is presented in Fig. 12. For the case in which the structure inertia is less than 150 kN, the bending moment at pile head and its tip in the high-rigidity pile case are greater than those in the low-rigidity pile case. However, for structure inertia greater than 150 kN, the bending moment at the pile head and its tip in the high-rigidity pile case are almost identical to those in the low-rigidity pile case.

The relation between the structure inertia and relative displacement between the ground and footing is presented in Fig. 13. The minimum relative displacement which required to develop the passive state is also shown in the figure. The relation between the structure inertia and the resultant of the total earth pressure and the sidewall friction is presented in Fig. 14. For the case in which the structure inertia is smaller than 150 kN, the resultant of the total earth pressure and the sidewall friction in the high-rigidity pile case is greater than that in the low-rigidity pile case. For the case in which the structure inertia is greater than 60 kN, the relative displacement in the high-rigidity pile case is greater than the minimum relative displacement which required to develop the passive state. Consequently, the resultant of the total earth pressure and the sidewall friction reached a constant value. For structure inertia larger than 150 kN, the relative displacement in the low-rigidity pile case is larger than the minimum relative displacement which required to develop the passive state. Consequently, the resultant of the total earth pressure and the sidewall friction reached a constant value. Therefore, for structure inertia greater than 150 kN, the resultant of the total earth pressure and the sidewall friction in the high-rigidity pile case accords with that in the low-rigidity pile case.

Secondly, the effects of the structure inertia on the lateral subgrade reaction are investigated. The depth distribution of the subgrade reaction in cases where the structure inertia is 0 kN and 300 kN are presented in Fig. 15. The ultimate lateral resistance calculated using equation (2) is also presented there. The subgrade reaction reaches the ultimate lateral resistance in both cases. The subgrade reaction in the high-rigidity pile case is almost identical to that in the low-rigidity pile case.

As described above, in cases where the structure inertia is small, the lateral subgrade reaction in the high-rigidity pile case is almost identical to that in the low-rigidity pile case. Moreover, the resultant of the total earth pressure and the sidewall friction in the high-rigidity pile case is greater than that in the low-rigidity pile case. Therefore, the bending moment at pile heads and their tips in the high-rigidity pile case are greater than those in the low-rigidity pile case. However, in

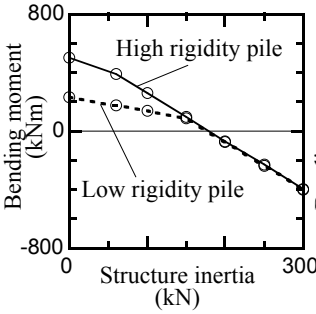

Figure 11 Relation between structure inertia and bending moment at pile head

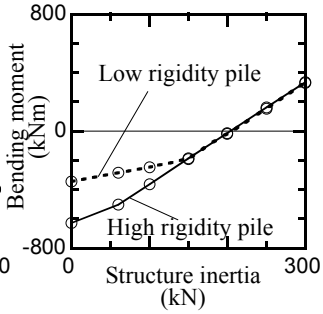

Figure 12 Relation between structure inertia and bending moment at pile tip

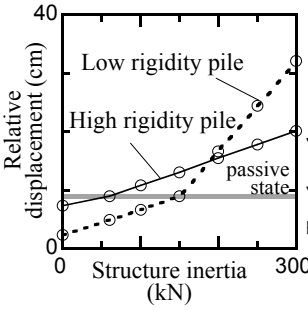

Figure 13 Relation between structure inertia and relative displacement

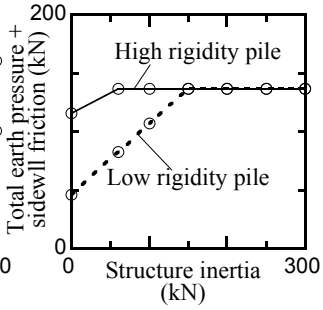

Figure 14 Relation between structure inertia and total earth pressure + sidewall friction

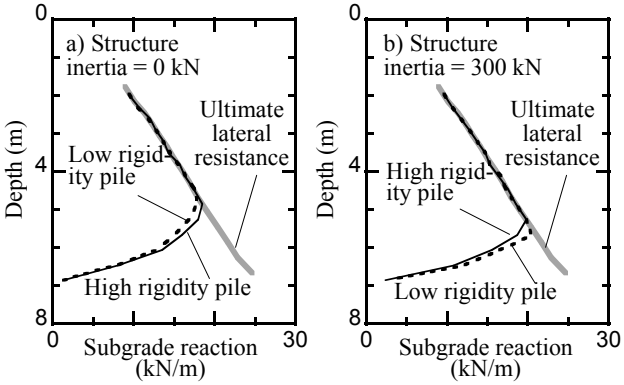

Figure 15 Depth distribution of the subgrade reaction

cases where the structure inertia is large, the subgrade reaction and the resultant of the total earth pressure and the sidewall friction in the high-rigidity pile case are almost identical to those in the low-rigidity pile case. Therefore, the bending moments at pile heads and their tips in the high-rigidity pile case are almost identical to those in the low-rigidity pile case.

6. EFFECT OF PILE RIGIDITY ON SUPERSTRUCTURE SEISMIC RESPONSE

To clarify the cause of which the acceleration in the low-rigidity pile case was greater than that in the high-rigidity pile case (Figs. 2, 3), the acceleration Fourier spectrum of footing, ground surface and shaking table are presented in Fig. 16. The predominant period of the footing was almost identical to that of the ground surface in both cases. Results show that the footing response is strongly affected by the ground response. In the periodic band of 2–5 s, the amplitude of the footing acceleration in the high-rigidity pile case is an intermediary value between that of the ground surface and the shaking table acceleration. On the other hand, in that periodic band, the amplitude of footing acceleration in the low-rigidity pile case was almost equal to that of the ground surface acceleration. This is because the footing behavior when supported by the low-rigidity piles is affected by the ground surface behavior. In the periodic band of 2–5 s, the amplitude of the footing acceleration in the high-rigidity pile case was smaller than that in the low-rigidity pile case. Therefore, the superstructure acceleration in the high-rigidity pile case was smaller than that in the low-rigidity pile case.

To investigate the effect of pile rigidity on the shear deformation of the isolator, seismic response analyses of single-degree-of-freedom systems were conducted. Figure 17 portrays the analytical model. The restoring force characteristic of the isolator was considered to be elastic. That of the damper was considered to be elasto-plastic (AIJ, 2001). The yield shear force coefficient of the damper (α_s) was set to 0.03, 0.04 and 0.05; its yield displacement was set to 1 cm. Viscous damping of the isolator was neglected. As stated previously, the footing response is affected strongly by the ground response. Assuming that the superstructure inertia only slightly affects the footing response, the footing acceleration observed in centrifuge tests was used as the input motion. Figure 18 portrays the relation between the natural period of the structure and the maximum shear deformation of the isolator. The smaller the α_s, the larger the shear deformation. For a natural period of the base-isolated structure of 5 s, The difference between the shear deformation of the isolator in the high-rigidity pile case and that in the low-rigidity pile case is small. In each case, the shear deformation is large for the case in which the natural period of the structure is close to the predominant period of the ground (3 s). That tendency is

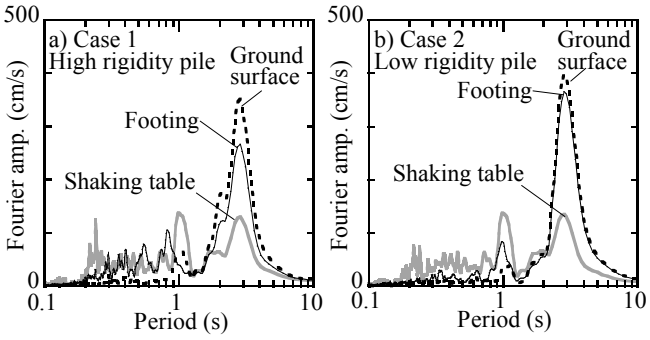

Figure 16 Acceleration Fourier spectrum of footing, ground surface and shaking table

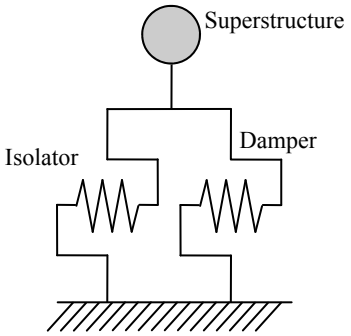

Figure 17 Analytical model

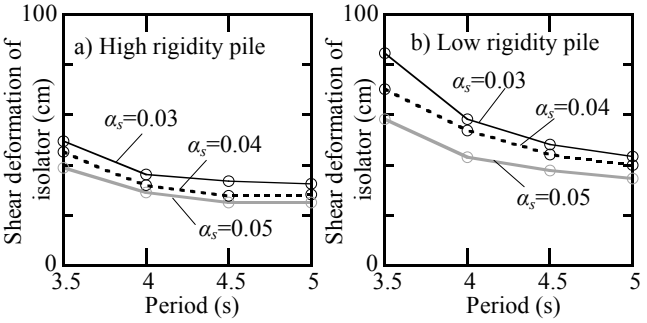

Figure 18 Relation between isolated period and maximum shear deformation of isolator

more apparent in the low-rigidity pile case than in the high-rigidity pile case. For the case in which the natural period of the structure is 3.5 s, the shear deformation in the low-rigidity pile case is much larger than that in the high-rigidity pile case. Particularly, the shear deformation in the low-rigidity pile case reaches about 85 cm when the yield shear force coefficient of the damper is 0.03.

As described above, in cases where the structure inertia is small, the bending moments at pile heads and their tips in the high-rigidity pile case are greater than those in the low-rigidity pile case. In contrast, in cases where the structure inertia is large, the bending moments at pile heads and their tips in the high-rigidity pile case are almost identical to those in the low-rigidity pile case. In cases where the natural period of base-isolated structure is much longer than the predominant

period of the ground, the difference between the shear deformation of the isolator in the high-rigidity pile case and that in the low-rigidity pile case is small. In contrast, in cases where the natural period of the structure is close to the predominant period of the ground, the shear deformation in the high-rigidity pile case is smaller than that in the low-rigidity pile case. Considering those results, the high-rigidity pile is suitable for a base-isolated structure for cases in which the natural period of the base-isolated structure is close to the predominant period of the ground.

7. CONCLUSIONS

Dynamic centrifuge tests were performed to investigate the effects of pile rigidity on the pile stresses and the seismic response of a base-isolated structure during soil liquefaction. Then pseudo-static analyses and single -degree-of-freedom analyses were conducted. They yielded the following conclusions.

For cases where the structure inertia is small, the bending moment at pile heads and their tips in the high-rigidity pile case are greater than those in the low-rigidity pile case. In contrast, in cases where the structure inertia is large, the bending moment at pile heads and their tips in the high-rigidity pile case are almost identical to those in the low-rigidity pile case. For the case in which the natural period of base-isolated structure is much longer than the predominant period of the ground, the difference between the shear deformation of the isolator in the high-rigidity pile case and that in the low-rigidity pile case is small. In contrast, in cases where the natural period of the base-isolated structure is close to the predominant period of the ground, the shear deformation of the isolator in the high-rigidity pile case is smaller than that in the low-rigidity pile case. Considering those results, the high-rigidity pile is suitable for a base-isolated structure for cases in which the natural period of the base-isolated structure is close to the predominant period of the ground.

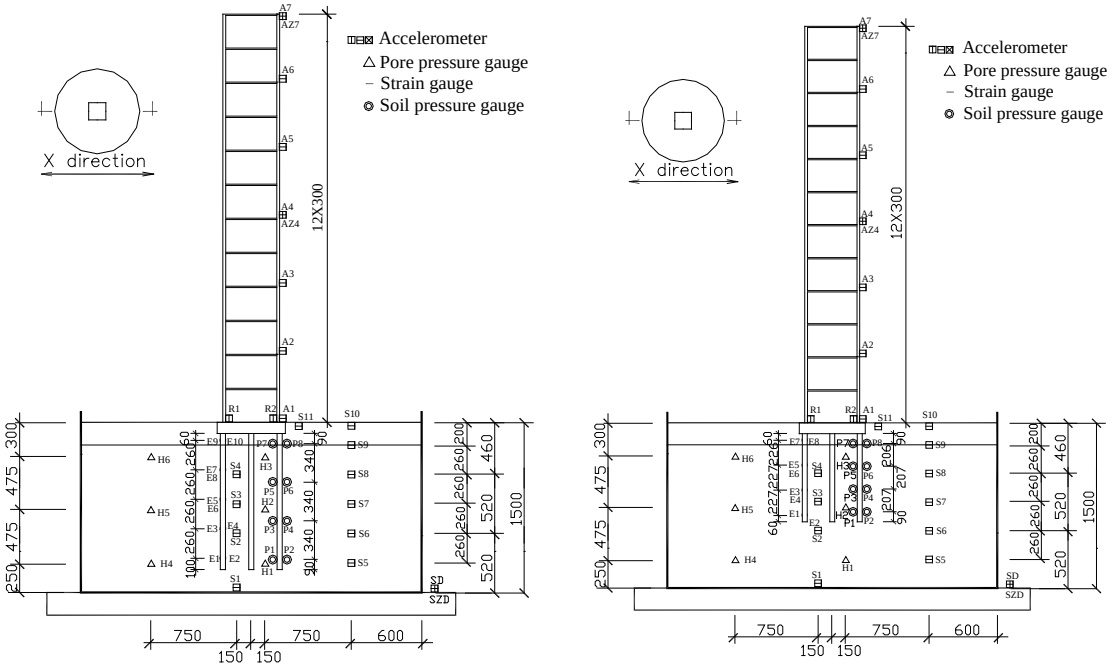
Abstract: Through comparing the shaking table model test results of liquefiable soil-pile-structure interaction system with that of structure on fixed base, the effects of liquefiable Soil-Structure Interaction (SSI) on dynamic characteristics and seismic responses are studied in this paper. Due to the effect of SSI, the natural frequency of the system in liquefiable soil is lower than that of the structure on fixed base and its damping ratio is larger than that of structure. The mode shapes of system in liquefiable soil are notably different from those of the structure on fixed base, and there exists rocking and swing at the foundation in SSI system. When SSI is considered, the seismic responses such as acceleration, shear force, bending moment and strain are commonly less than those of the structure on fixed base, while displacement of SSI system is larger.

1. INTRODUCTION

Seismic dynamic response of the building is a complicated problem of coupling interaction between the structure and soil through the interface. Soil, foundation and the superstructure vibrate as a whole under earthquakes, bind to each other, and affect each other. Typically, the interaction between the soil and structure contains two-fold meaning, one is the vibration characteristics influence of the superstructure from the soil (including the natural frequency, damping ratio and vibration mode, etc.); the other is the feedback from the superstructure due to the input seismic waves from the soil. Researchers have derived a lot of valuable conclusions from shaking table scale model tests of SSI in liquefiable ground (e.g., Koga et al. 1990, Funahara et al. 2000, Kagawa et al. 2000, Tamura et al .2000, Takahiro et al. 2004, Chen et al. 2003, Feng et al. 2005, Meng et al. 2005, Ling et al. 2006). Studies have shown that seismic soil-structure interaction effect (compared with the structure on fixed base) can be generally summed up as the change of the dynamic characteristics of structure-the extension of natural period, changes in mode shape, damping change (usually increase), changes in seismic response-the internal force and displacement change, changes in movement characteristics of the base. The main conclusions of these studies are obtained through theoretical analysis and calculation, only a small amount of information is from the on-site or laboratory test results. Exploring the soil-structure interaction effect in the elastic stage and elastic-plastic stage through shaking table tests is significant to verify the theories of calculation and analysis.

Sponsored by key projects of National Natural Science Foundation of China, a series of shaking table model tests have been carried out including the dynamic system of soil and high-rise structure using the pile foundation and that of high-rise structure on fixed base not considering SSI (e.g., Chen et al. 1999, Soil Dynamic Laboratory 2001, Lu et al. 2002, Li et al. 2006, Li et al. 2008). The emphasis of this paper will focus on dynamic characteristics and seismic response of structure affected by SSI.

2. BRIEF DESCRIPTION OF SHAKING TABLE MODEL TESTS



The shaking table model tests of liquefiable soil-pile-structure system have been carried out (called Test PS10L and Test PS10S). The longer piles (1.2m in length) were used as the foundation in Test PS10L and the shorter piles (0.8m in length) were used in Test PS10S. As a comparison, shaking table test of structure on fixed base (called Test S10L) has also been carried out. In these three tests, 12-story reinforced concrete frame structure with single span was employed to simulate the superstructure with the scaling factor of 1/10. The design of 12-story R.C. frame structure used as the superstructure in test S10L was the same as that in test PS10L and PS10S, and the structures were cast synchronously.

Non-gravity model with similitude rules controlled

materials was adopted in present test. Similitude formulas and similitude factors of all physical quantities were induced from Bockingham π theorem. The scales of models were 1/10. The similitude factor of mass density was 1, and the similitude factor of elasticity modulus for structure was 1/2.668. Saturated sand covered by silt clay was used for the soil model. The top layer was silt clay, 0.2m in depth; while the bottom layer was sand, 1.30m in depth. For the foundation of the superstructure, nine piles of a pile group were used.

Because of wave reflection on the boundary, an error called boundary effects will affect the test results. To reduce the boundary effect, a flexible container and proper constructional details were designed for the model test, and the ratio of the ground plane diameter to the structural plane diameter (i.e., D/d) was set at 5 by controlling the size of the structural plane. The cylindrical container was 3000 mm in diameter, and its lateral rubber membrane was 5 mm thick. Reinforcement loops of 4 mm diameter, spaced at 60 mm, were used to strengthen the outside of the container in the tangential direction.

Accelerometers, displacement meter and strain gauges were used to measure the dynamic response of the superstructure, foundation and soil. Pore pressure gauges were embedded in soil to measure the change of pore pressure. Pressure gauges were used to measure the contact pressure between piles and the surrounding soil. Figure 1 shows the arrangement of measuring points. The photo of Test PS10L is shown in Figure 2. The photo of Test S10L is shown in Figure 3.

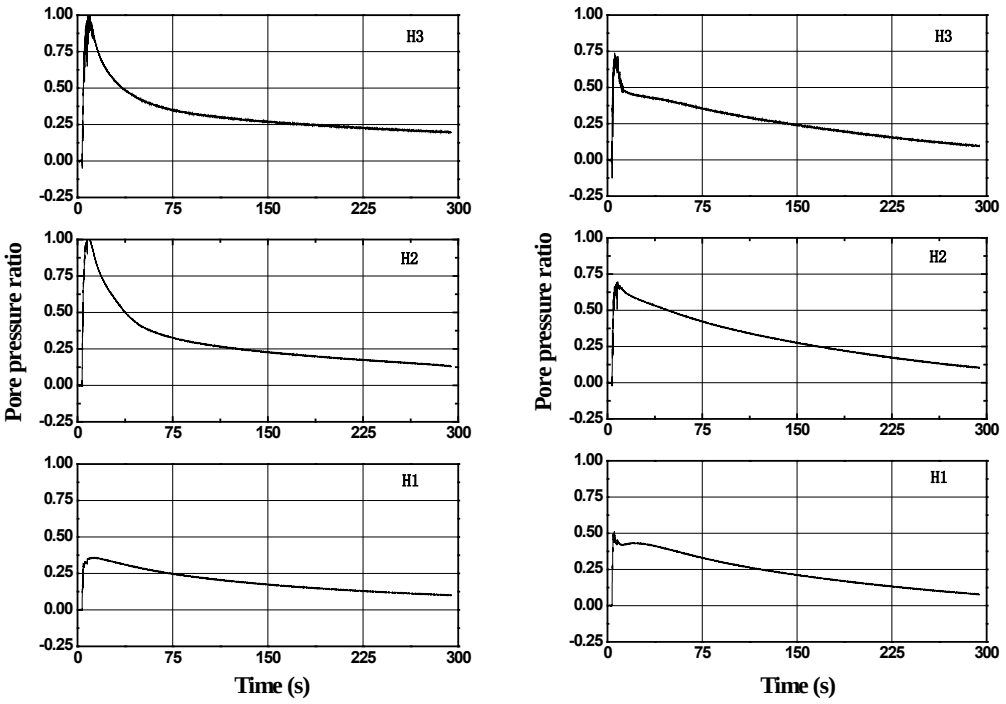
3. TESTS PHENOMENA COMPARISON

By observing and comparing, there exist some similar phenomena between Test PS10L and Test PS10S. The superstructure inclines to some degree after all excitations. The pile is dug out after the test and it can be seen that there are many horizontal cracks along the piles. The crack is dense at the top of the pile and less or none at the tip. The cracks on the two side piles of three rows piles in the vibration direction are much more and larger. However, the cracks on the middle pile are relatively fewer and smaller. The cracks penetrate basically on the plane vertical to the vibration direction and usually not penetrate on the plane horizontal to the vibration direction. The cracks appear to be typical bending cracks. There is almost no crack on the superstructure.

However, on the frame structure on fixed base, the cracks appear much earlier, develop faster. In test S10L, there is not any crack on the structure under the first eight excitations. After the excitation of SJ3, horizontal cracks appear on the east side of the southeast corner column at the 3rd story, and vertical cracks appear on the south part of the east beam, about 0.1mm in width. After the excitation of EL5, original cracks keep on developing. New slight vertical cracks appear on the east part of the south beam at the 1st story, both parts of the north beam at the 1st story, both parts of the beams at the 2nd story, both parts of the south beam at the 3rd story, the east part of the north beam at the 3rd story, both parts of the south beam at the 4th story and the east part of the south beam at the 5th story, and the beams is along the vibration direction. The above vertical cracks develop upwards or downwards, about 0.1~0.2mm in width. Vertical cracks appear on the joint between the southwest column and the south beam at the 6th story, and horizontal cracks appear on the west side of the southwest corner column at the 1st story, the west side of the northwest corner column at the 5th story, the west side of the northwest corner column at the 2nd story, about 0.1~0.2mm in depth. After the excitation of SJ5, vertical cracks appear on the south side of the southwest corner column at the 1st story, the west side of the southwest corner column at the 4th story and the south side of the southwest corner column at the 5th story, about 0.2mm in depth, and original cracks keep on developing.



Comparing test PS10L and PS10S on liquefiable soil-pile-structure interaction system with test S10L on fixed base, conclusion can be drawn as follows. There are no cracks appear on the superstructure in SSI system, while some cracks appear on the superstructure with fixed base. This is mainly resulted from the vibration isolation effect of liquefied sand and effect of SSI on foundation motion. The superstructures of test PS10L and test PS10S are supported on the foundation which placed in saturated sand, and the excitations the superstructure received are obviously less than that of the superstructure directly fixed to shaking table.

The change of pore water pressure ratio in the sand soil is obtained by nine high-sensitivity pore water pressure gauge embedded in the sand soil (The arrangement of the measuring points is shown in Figure 1). Figure 4 show the pore water pressure ratio time histories of the measuring points in PS10L and PS10S tests under the excitation of EL3. From the figures, we can see the pore water pressure ratio of some points reach 1.0, which mean sand soil liquefied in the excitation of EL3.

4. STRUCTURAL DYNAMIC CHARACTERISTICS INFLUENCE OF SSI

Table 2 displays the frequency and damping ratio in each phase of these three tests. It can be seen that, with increasing of times and peak acceleration of input excitation, the frequency of model decrease, while the damping ratio

increases. Through comparing the change of model frequency with the change of structural frequency on fixed base, we can see that, the decreasing of structural frequency in test S10L is faster. This is resulted from the different development of crack on structure.

(a) PS10L (b) PS10S

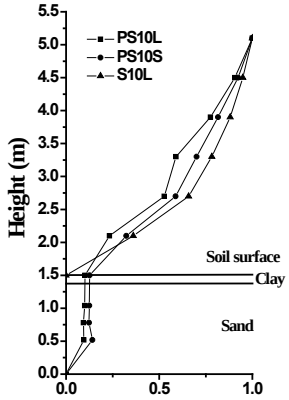


Figure 4 The Pore Pressure Ratio Time History of Different Measuring Points

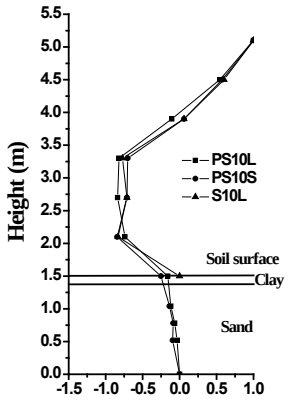
Table 2 Frequency and Damping Ratio of Three Test Models in Each Phase



No.	Excitation Code	Test PS10L		Test PS10S		Test S10L	
		Frequency (Hz)	Damping Ratio(%)	Frequency (Hz)	Damping Ratio (%)	Frequency (Hz)	Damping Ratio (%)
1	1WN	2.977	7.01	2.680	10.16	2.977	10.650
4	4WN	2.977	8.08	2.680	11.01	2.977	6.210
7	7WN	2.680	8.33	2.382	10.14	2.680	9.040
10	10WN	2.084	9.10	2.382	9.26	2.084	7.640
13	13WN	1.786	16.53	2.382	8.45	1.489	18.170
16	16WN	1.786	11.19	2.382	8.93	1.191	13.590

With increasing of times and peak acceleration of input excitation, the model frequency of test PS10L, PS10S and test S10L on fixed base all decrease, while damping ratio increase, but the reasons are different. As to SSI system, the change of dynamic characteristics is the common result of soil softening, pile foundation crack development, and the decreasing the structural rigidity, and soil softening is the main factor. As to the structure on fixed base, the change of frequency is only resulted from the appearance and development of crack on beams and columns.

Figure 5 and Figure 6 display the mode shape curves of test PS10L, PS10S and S10L model under the excitation of 1WN and 13WN. From the figures, the main difference of mode shape between test PS10L, PS10S which taking the effect of SSI into account and test S10L which not taking the effect of SSI into account is that there is obvious translational and rotational movement in the foundation of test PS10L, PS10S model. With increasing of excitation times, the soil continues to soften, the translational and rotational movement of the foundation keeps on increasing and the rotational movement is more obvious. The degree of foundation translation and rotation has relation with the soil condition and the foundation type. The first mode shape of the superstructure is mainly shear type, while there are translational and rotational components in test PS10L, PS10S. With increasing of excitation times, the structural cracks at the lower stories develop, the rigidity decreases, and the height of zero point in the mode shape amplitude descends.

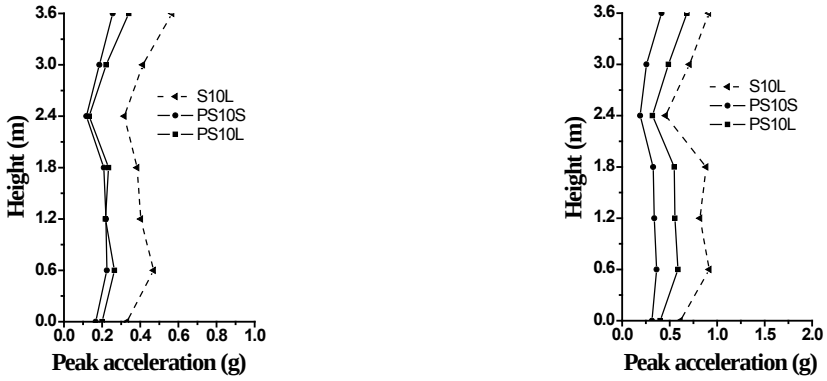
5. STRUCTURAL SEISMIC RESPONSE INFLUENCE OF SSI

Due to the effect of SSI on structural dynamic characteristics, there is some change on the seismic response of the superstructure. Through comparison among the structural acceleration response, displacement response, interstory shear, overturning moment and so on, the effect of SSI in liquefied soil is discussed.

In test S10L on fixed base, the frame structure is directly fixed on shaking table. So the input acceleration of the shaking table is the seismic acceleration of free field at the bottom of the structure. In test PS10L and PS10S, the container is fixed on the shaking table. The frame structure is supported on the foundation in soil. So the input vibration travels from the shaking table, through soil and foundation, to the structural bottom. The comparison of seismic response on superstructure between SSI system and fixed base system should be based on the equality of seismic acceleration in free field.

In test, the acceleration record of foundation top for SSI system is not the "free field" motion. It also includes the effect of SSI on foundation motion. Take the record of measuring point S10 which has a certain distance off the foundation as the seismic acceleration of free field in test PS10L and PS10S. Take the input acceleration of the shaking table as the seismic acceleration of free field in test S10L. Adjust the peak acceleration of free field in test S10L to equal to that in test PS10L. Then the seismic response of superstructure of three tests could be compared as follows.

Due to the effect of SSI, there is great difference in crack development on frame structure for three tests (see former test phenomena). But as comparison base, the frame structure of each test should be at the similar state, so the comparison will be held only under the first and the second input excitation when there is not or only very slight crack on the structure.



5.1 Acceleration Response

Figure 7 displays the comparison of peak acceleration on structure in three tests. It can be seen that, the acceleration response on superstructure for SSI system is obviously smaller than that on fixed base, and this law doesn't change with increasing of excitation.

5.2 Displacement Response

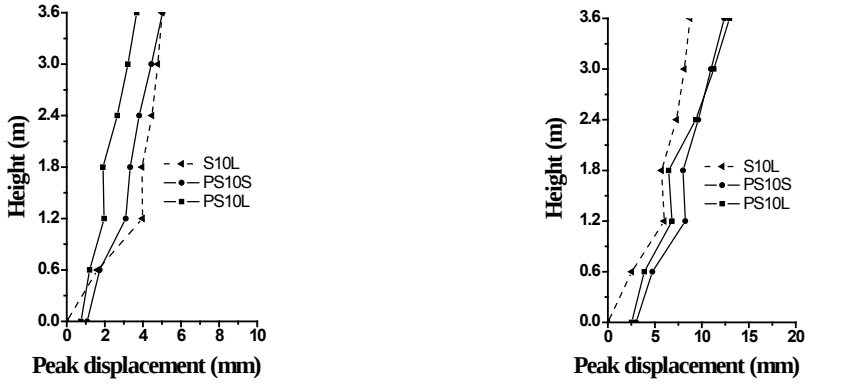


Figure 8 displays the comparison of the displacement peak value on frame structure in three tests. When taking

SSI into account, because the displacement on structure consists of translation and rotation of foundation and structural deformation, the displacement response for SSI system is usually larger than that on fixed base. Under small excitation, the displacement for SSI system differs not much from that on fixed base, and the former is even smaller than the latter. But with increasing of excitation, softening and non-linear development of soil and translational and rotational rigidity descending of pile foundation, the displacement peak value of SSI system is larger than that of fixed base.

(a) Under the Excitation of EL1 (b) Under the Excitation of EL2

Figure 7 Comparison of Peak Acceleration

(a) Under the Excitation of EL1 (b) Under the Excitation of EL2

Figure 8 Comparison of Displacement Peak Value

5.3 Interstory Shear and Overturning Moment

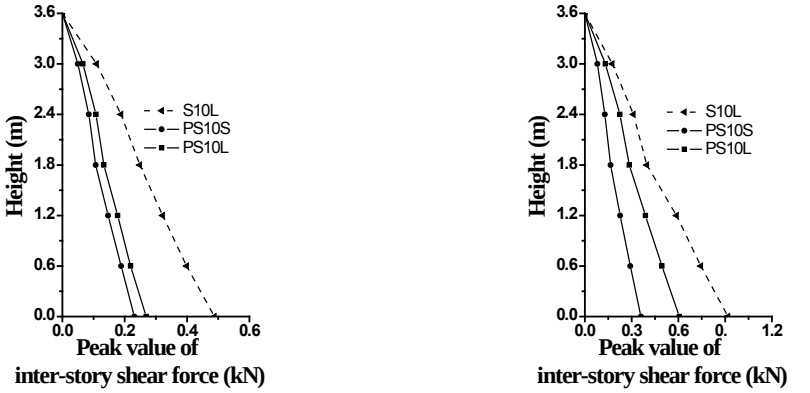
Figure 9 and Figure 10 display the comparison of the interstory shear and overturning moment amplitude on frame structure in three tests. It can be seen that, the interstory and overturning moment on superstructure for SSI system are smaller than that of fixed base, and this law doesn't change with increasing of excitation.

5.4 Strain Response on the Bottom of the Column at the Ground Story

Table 3 displays the comparison of the strain amplitude on the bottom of the column at the ground story in three tests. It can be seen that, the strain on superstructure for SSI system is obviously smaller than that of fixed base.

Table 3 Comparison of Strain on the Bottom of the Column at the Ground Story

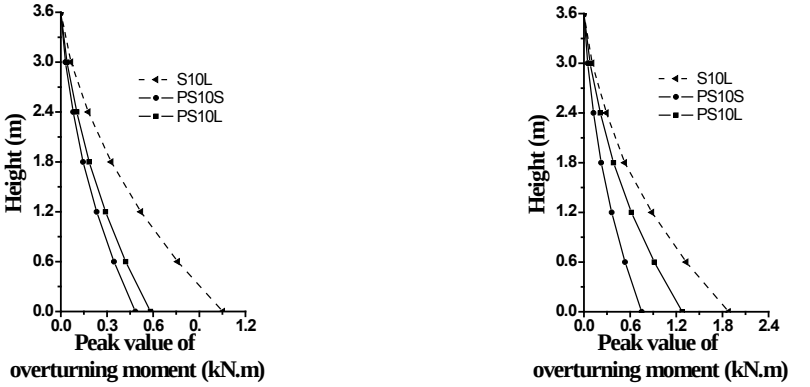
Test Code	Under Excitation of El Centro Wave		Under Excitation of Shanghai Bedrock Wave	
	EL1	EL2	SJ1	SJ2
PS10L	109.1	235.5	101.3	216.1
PS10S	75.6	126.8	72.2	66.8
S10L	413.2	625.0	182.9	459.1



6. CONCLUSIONS

Through comparing the shaking table model test results of liquefiable soil-pile-high-rise structure interaction system with that of high-rise structure on fixed base, the effects of Soil-Structure Interaction (SSI) on dynamic characteristics and seismic response are studied further. Some important findings from the present tests are as follows.

(1) The effect of the dynamic liquefiable soil-structure interaction has relation with many factors. The effect with shorter pile is larger than that with longer pile. The larger the peak acceleration of excitation is, the larger the effect is.



(2) Under the same excitation, compared with the structure on fixed base, the superstructure of SSI system generates cracks much later, smaller and fewer, develops more slowly.

(3) The interaction results in the change of structural dynamic characteristics, the damping ratio increases, and the mode shape changes. Under the same excitation, the acceleration, interstory shear, overturning moment and strain

Abstract: Dynamic centrifuge model tests are conducted using pile-supported building models to investigate the seismic behavior of buildings with semi-rigid pile head connections in liquefiable soil. The dynamic test results show that (1) The semi-rigid pile head connection is effective for reducing the bending moment of piles in liquefied soil; and (2) The maximum acceleration of superstructure with semi-rigid pile head connections is about 40% of that of superstructure with rigid pile head connections in liquefied soil.

1. INTRODUCTION

In these days, various semi-rigid pile head connection methods have been developed that permit the rotation of pile heads as more effective pile design methods. Their effectiveness for reducing damage to piles has been verified by structural tests (Hara et al. 2002, Ohtsuki et al. 2001, Hiraide et al. 2004). The existing researches have, however, made studies focusing only on the static structural properties of pile head connections. Few examples are available of verifying in tests the effectiveness of semi-rigid pile head connection methods for reducing damage using the whole building while considering the dynamic soil-pile-structure interaction. In the previous study by authors (Ishizaki et al. 2006), shaking table tests of pile-supported building model in dry sand were conducted to investigate the seismic behavior of buildings with semi-rigid pile head connection method. In this study, dynamic centrifuge model tests are conducted using pile-supported building model in liquefiable soil to examine the effectiveness of semi-rigid pile head connection method for reducing seismic damage to piles, and the effects on the response of the building.

2. TEST OUTLINE

Dynamic centrifuge model tests are performed using soil-pile-structure systems at 50g centrifugal acceleration. Two soil-pile-structure models are used in the tests; the one is a building model with semi-rigid pile head connections (S-model) and the other is a building model with rigid pile head connections (R-model). The model is prepared in a laminar shear box 560mm in length, 210mm in width and 400mm in depth.

2.1 Models

Figure 1 shows the soil-pile-structure system used in the tests. The soil model is created using Toyora sand, and it consists of two layers with different relative densities. The target relative densities are set at 60% in the upper layer and 90% in the lower layer. The relative densities of the upper layer before excitation are 65% in S-model and 60% in R-model. Therefore the soil model in S-model is more dense than that in R-model. The soil models are saturated with silicon oil with 40 times viscous than water.

The mass of the superstructure is 5.2kg and that of the foundation is 2.7kg. The natural period of the superstructure in small excitation is 0.003s (0.15s in prototype scale). The models of pile and pile head are shown in Figure 2. Pile group consists of 2×2 stainless steel pipes. Each pipe has a diameter of 16mm with a 1mm wall thickness. The elastic coefficient of the pipe is 1.97×10^{8}kN/m^{2}. The pile tips are connected to the base of the laminar box with pin joints. The pile heads are connected to the foundation (pile cap) either semi-rigidly or rigidly according to the model type. In S-model, the foundation is simply placed on the pile heads. In R-model, the pile head is sandwiched between divided sections of foundation and fastened by bolts.

The rotation characteristics at the pile head connections are identified in preliminary static bending tests. A cantilever beam composed of the pile and the foundation is used as a specimen. The pile tip is subjected

to loading and unloading in a direction perpendicular to the axis. The bending moment and the rotation angle at the pile head are measured. Several initial axial forces of 1kN (2.5MN in prototype scale), 0.4kN (1.0MN in the scale) and 1.6kN (4.0MN in the scale) are applied to the semi-rigid pile head connection. Figure 3 shows the relationships between the bending moments and the rotation angles at pile heads in the both pile head connections. In the semi-rigid pile head connection, the initial rigidity is small, and the rotation angle increase drastically as the bending moment increase. The relationship is represented by nearly the same curve either in loading or unloading.The maximum resistance of moment *Mu* is given by the following equation:

$$M_u = \frac{D}{2} \cdot N \qquad (1)$$

in which *D* is the pile diameter, and *N* is the axial force. *Mu* at each axial force is showed in Figure 3. The bending moments at semi-rigid pile head connection are close to the *Mu* for the respective axial forces.

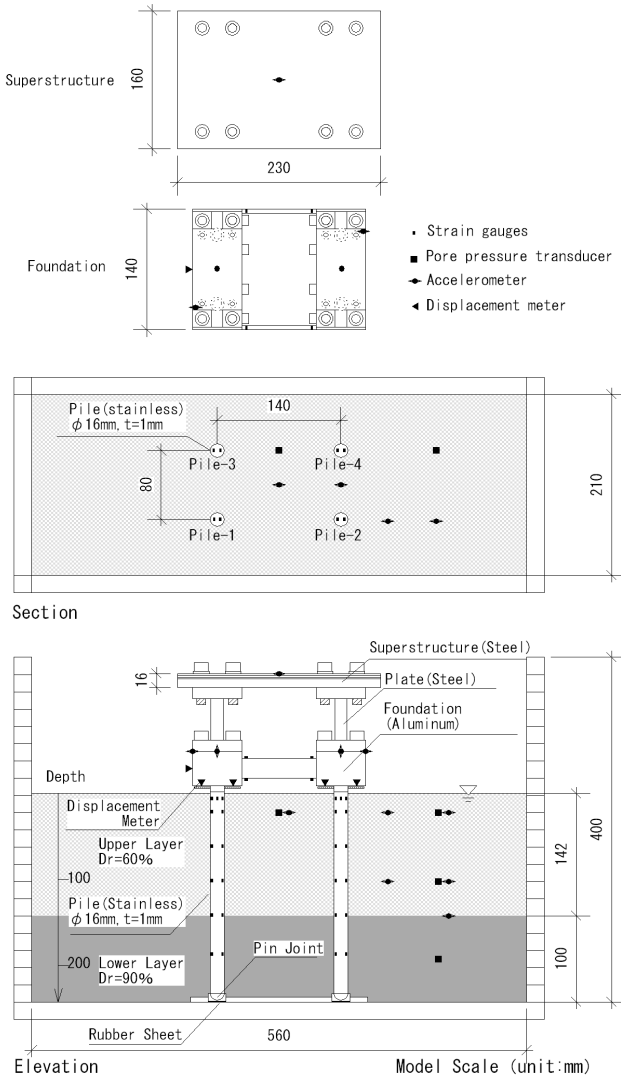

Figure 1 Model Layout

2.2 Measurement Parameters

Measurement parameters are shown in Figure 1, and strain gauges attached to the inner surfaces of piles are shown in Figure 2. The horizontal accelerations of soil and structure, the vertical accelerations of foundation, the strains of piles, the rotation angles of pile heads, and the pore water pressures of soil are measured. The displacements of structure and soil are found by double integration of the accelerations with respect to time.

2.3 Input Motion

Rinkai wave is used as an input motion. The amplitude is adjusted to obtain a maximum horizontal acceleration of 200 cm/s^2 in prototype scale. The initial vibration characteristics of the soil-pile-structure models are identified under tiny vibration.

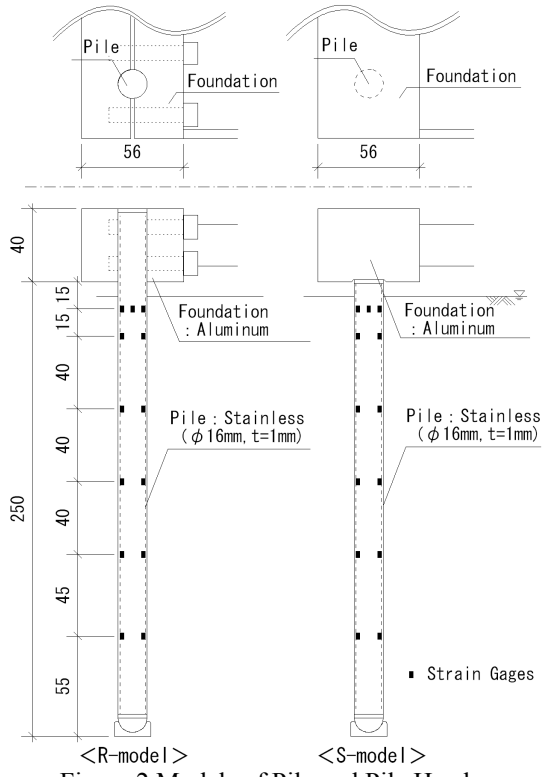

Figure 2 Models of Pile and Pile Head

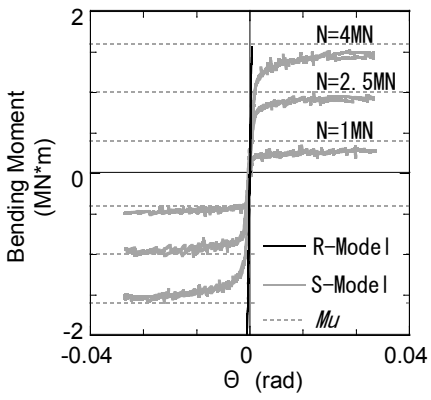

Figure 3 Relationships between Bending Moments and Rotation Angles at Pile Heads in Preliminaly Tests

3. TEST RESULTS AND DISCUSSIONS

All data presented in this section are of prototype scale. The results of excitation using Rinkai with a peak input acceleration of 200 cm/s^2 are compared in S-model and R-model. The initial axial forces on pile heads in S-model are almost the same (Table 1).

3.1 Time Histories of Accelerations, displacements and excess pore water pressures of soil

The time histories of the accelerations of soil and shaking table, the displacements of soil and the excess pore water pressures of soil are shown in Figure 4. The excess pore water pressures of soil at 1.1m and 5.1m depths reach the respective initial effective vertical stresses, then the upper layers are liquefied in the both models. The excess pore water pressure of soil at 5.1m depth in S-model rise later than that in R-model. This is because the relative density of the upper layer in S-model is higher than that in R-model. Therefore the accelerations of soil in S-model decrease after the time of 20s, on the other hand, those in R-model decrease after 12s.

The excess pore water pressures at 9.6m depth in both models reach the initial effective vertical stress at the time of 30s, but decrease gradually during the shaking.

The displacements of soil at 1.1m depth in both models increase drastically during soil liquefaction, especially from 77s to 88s.

3.2 Time Histories of Acceleration of Superstructure, Displacement of Foundation, Bending Moment of Pile Head and Rotation Angel of Pile Head

Figure 5 Shows the time histories of the acceleration of the superstructure, the displacement of the foundation, the bending moment of and the rotation angle of the pile head. The acceleration of the superstructure in S-model agrees with that in R-model before 20s. But after 23s when the soil liquefaction almost occurrs in the upper layer, the acceleration of the superstructure in S-model tends to decrease and delay than that in R-model. After 30s, a maximum acceleration of the superstructure in S-model is 0.47m/s^2 and that in R-model is 1.09m/s^2, i.e., the maximum acceleration of the superstructure in S-model decreases to 40% of that in R-model.

The displacements of the foundations in the two models mostly agree before 20s. However, after 20s, the displacement of the foundation in S-model tends to increase and delay than that in R-model. This tendency is especially clear from 77s to 88s. The displacement of the foundation in S-model corresponds to that of the soil at 1.1m depth in the model after 20s (Fig. 4(b)).

Table 1 Initial Axial Forces on Pile Heads in S-model

Pile	Initial Axial Force	Pile	Initial Axial Force
Pile-3	2100kN	Pile-4	2320kN
Pile-1	2350kN	Pile-2	2200kN

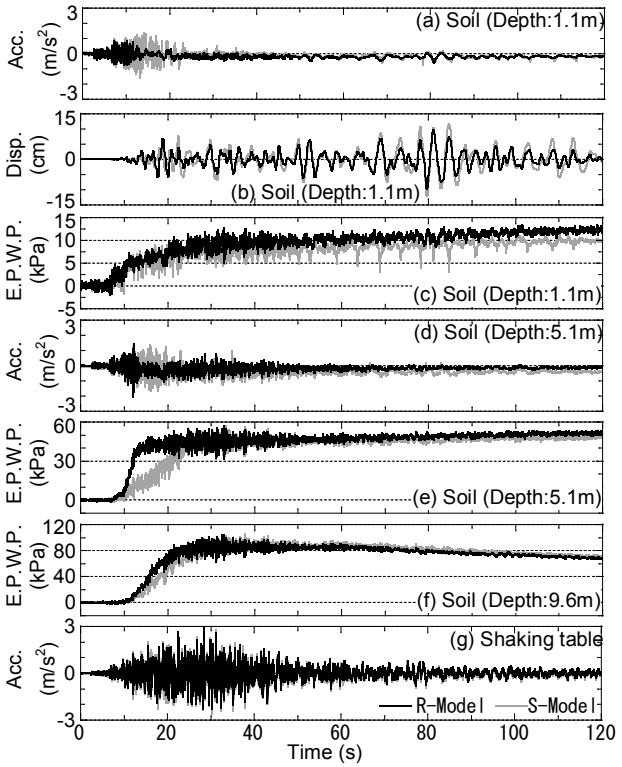

Figure 4 Time Histories of Accelerations, Displacements and Excess Pore Water Pressures of Soil

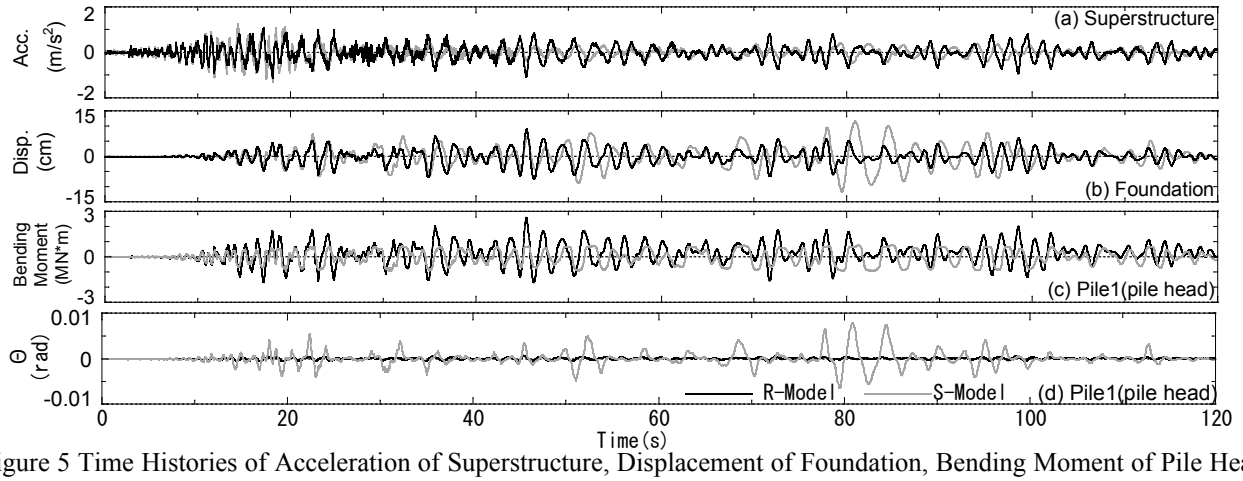

Figure 5 Time Histories of Acceleration of Superstructure, Displacement of Foundation, Bending Moment of Pile Head and Rotation Angel of Pile Head

3.3 Relationships between Bending Moments and Rotation Angles at Pile heads

Figure 6 shows the relationships between the bending moment and the rotation angle at pile head. The semi-rigid pile head connections have lower initial rigidities than the rigid pile head connections as shown in preliminary tests, and exhibit non-linear elastic behavior. And the bending moments in S-model drop steadily than those in R-model. In S-model, *Mu* varies according to the varying axial force due to overturning moment as shown Eq. (1). The moment in the pile subjected to compression is higher than the moment in the pile subjected to pullout force (Fig. (6)). And the rotation angle in the pile subjected to pullout force is larger than that in the other pile subjected to compression.

3.4 Distributions of Bending Moments along Piles

The inertia force is computed from the observed accelerations of the superstructure and the foundation. Figure 7 and 8 show the distributions of bending moments along piles at 18.0s (before liquefaction) and at 77.9s (during liquefaction). And Table 2 shows the inertia force at each second for respective models. At each second, the inertia forces of the two models are almost equal.

At 18.0s (before liquefaction), there are two peaks at pile head and at 9.4m depth in the distributions of bending moments in R-model. And the bending moments at pile heads are considerably higher than those at 9.4m depth. In the S-model that permit the rotations of pile heads, the bending moments at pile heads are lower than those occur in the soil, and those at pile head in R-model. The maximum bending moments that occur in the soil are higher in S-model than those in R-model. Moreover, the depth that the maximum bending moments occur at is shallow in S-model than that in R-model. And in the S-model, the varying axial forces due to overturning moment affect the distributions of bending moments along piles, i.e., the bending moment that occurs in the soil is larger in the pile subjected compression than that in the pile subjected to pullout force.

At 77.9s (during liquefaction), the inertia force is 40% of that at 18.0s. But, in R-model, the pile head bending moments at 77.9s are nearly the same as those at 18.0s. This is mainly because of the soil liquefaction. On the contorary, in S-model, the bending moments that occur in the soil at 77.9s are lower than those occur in the pile heads. This future of the distributions of bending moments at 77.9s is different from that at 18.0s. This is attributed to the reduction of inertia force and the soil liquefaction.

3.5 Distributions of Maximum Bending Moments along Piles

Figure 9 and 10 show the distributions of the maximum bending moments along piles before liquefaction (i.e., 0-25s) and during liquefaction (i.e., 25-120s). And Table 3 shows the maximum inertia forces for the respective periods.

Before liquefaction (i.e., 0-25s), the distributions of bending moments in R-model show two peaks at pile head and at 9.4m depth, but the bending moments at pile head are considerably higher than those at 9.4m depth. In S-model, on the other hand, the bending moments that occur in the soil are slightly higher than those at the pile

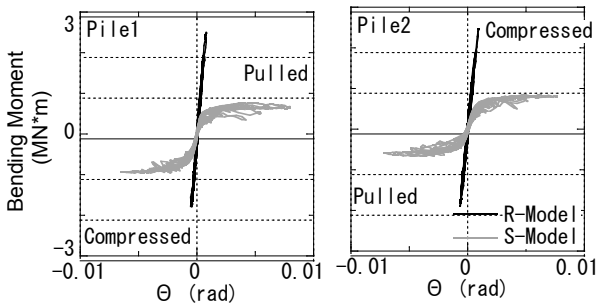

Figure 6 Relationships between Bending Moments and Roration Angles at Pile Heads

Table 2 Inertia Forces

Time	R-model	S-model
18.0s	1035kN	1072kN
77.9s	433kN	420kN

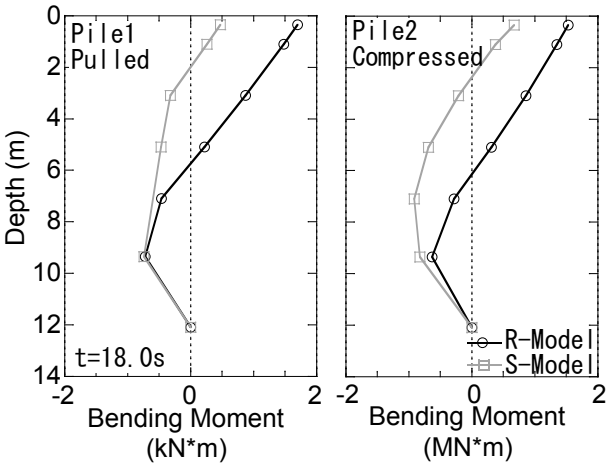

Figure 7 Distributions of Bending Moments along Piles at 18.0s

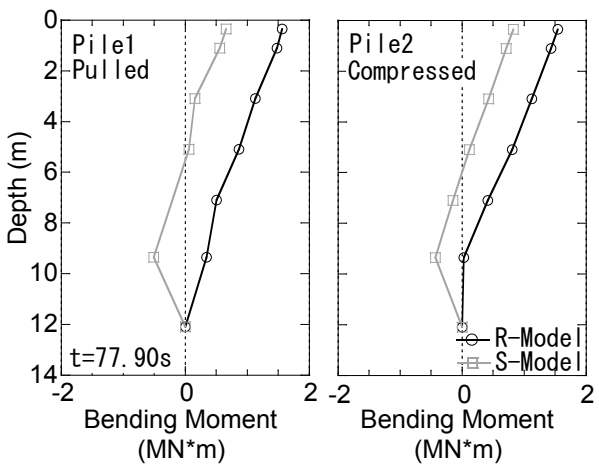

Figure 8 Distributions of Bending Moments along Piles at 77.9s

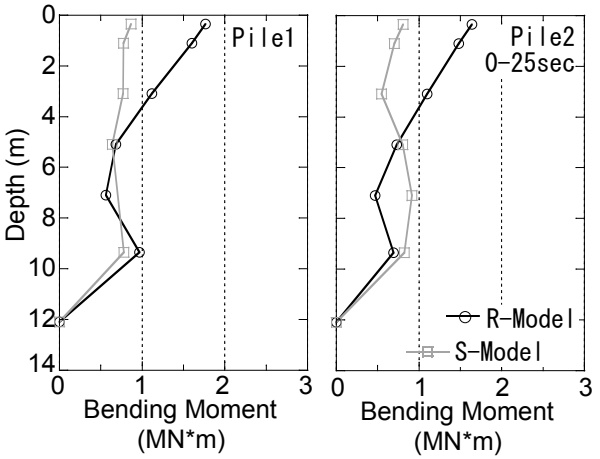

Figure 9 Distributions of Maximum Bending Moments along Piles Before Liquefaction (0-25s)

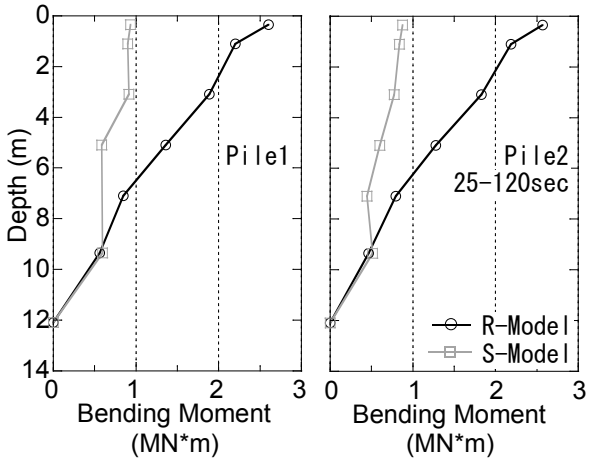

Figure 10 Distributions of Maximum Bending Moments along Piles During Liquefaction (25-120s)

heads. And the bending moments at pile heads in S-model are almost 50% of those at pile heads in R-model.

During liquefaction (i.e., 25-120s), the maximum bending moments those occur in R-model are significantly higher than those before liquefaction. This is attributed to the soil liquefaction because the inertia forces for the respective periods are the same. In S-model, in contrast, the maximum bending moments during liquefaction are lower than those before liquefaction. This is because of the reduction of inertia force and the soil liquefaction. Therefore the maximum bending moment that occurs in S-model decreases to 40% of that occurs in R-model during the whole time of shaking.

4. CONCLUSIONS

Dynamic centrifuge model tests are conducted to investigate the seismic behavior of buildings with semi-rigid pile head connections in liquefiable soil. Two soil-pile-structure models are used in the tests; the one is a building model with semi-rigid pile head connections and the other is a building model with rigid pile head connections. Following conclusions are obtained from comparisons of the two test results.

(1) The maximum acceleration of the superstructure in S-model is almost the same as that in R-model before liquefaction. During liquefaction, on the contrary, the response of the superstructure in S-model tends to decrease and delay than that in R-model.

(2) Before liquefaction, the bending moment at the pile head in S-model is about half of that in R-model. And in S-model, the maximum bending moments occurs in the soil, but is almost the same as that at pile head.

(3) During liquefaction, the maximum bending moment in R-model is higher than that before liquefaction.

Table 3 Maximum Inertia Forces

Period	R-model	S-model
0-25sec (Before Liquefaction)	1056kN	1200kN
25-120sec (During Liquefaction)	1074kN	439kN

This is because of soil liquefaction. In S-model, in contrast, the bending moment that occurs in the soil during liquefaction is lower than that occurs in the soil befofre liquefaction. This is because of the soil liquefaction and the reduction of inertia force. Therefore the maximum bending in S-model is about 40% of that in R-model during the whole time of shaking.

SEISMIC RESPONSE OF PILE FOUNDATION IN SLOPING GROUND

Akihiro Takahashi[1)] and Takaho Yamazaki[2)]

1) Associate Professor, Department of Civil Engineering, Tokyo Institute of Technology, Japan
2) Graduate Student, Department of Civil Engineering, Tokyo Institute of Technology, Japan
takihiro@cv.titech.ac.jp, yamazaki.t.ac@m.titech.ac.jp

Abstract: Seismic response of pile foundation in sloping ground was examined through a series of centrifuge model tests. This paper reports test results for the case that involves earthquake-induced large displacement of the sloping ground. Test results reveal that the loss of soil reaction due to the slip in the downslope has more impact on increase of the pile bending moment than the kimenatic load induced by soil mass movement in the upslope within the scope of the study.

1. INTRODUCTION

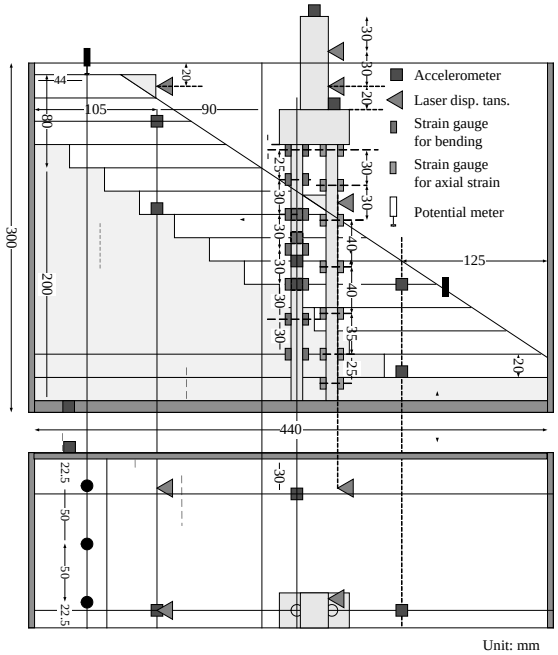
Diversification of risk is important for business continuity as well as quick disaster recovery after an earthquake. To this end, redundant transportation network is required especially for interurban roads and railways. Construction of the new Tomei Expressway and Chuo Shinkansen (new maglev line) connecting Tokyo and Nagoya in Japan are typical examples. Construction of such bypasses is typically made in mountain area and involves not only the tunnelling but also construction of many bridges. For the latter, construction of foundations in sloping ground is required.

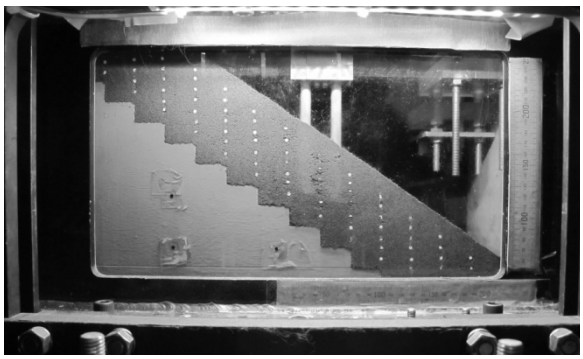
Current design specifications of bridge foundation in sloping ground require stabilization of the sloping ground prior to the bridge construction in Japan (e.g., NERI, 2010). Because of this, movement of the sloping ground is seldom considered in seismic design of the bridge foundation. However, (1) allowable slope displacement deemed to be unharmful to bridge foundations during an earthquake is unclear, (2) displacement-based seismic design is seldom applied for slopes, and (3) seismic foundation-slope interaction is little understood, although many researches have been done for problems related to liquefaction (Martin & Chen, 2005; Takahashi & Takemura, 2005 among others.)

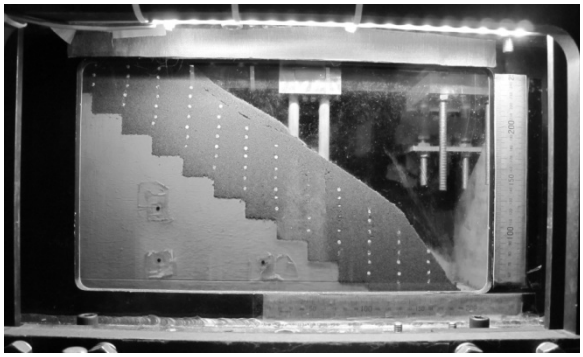
In this study, seismic response of pile foundation in sloping ground was examined through a series of centrifuge model tests. This paper reports test results for the case that involves earthquake-induced large displacement of the sloping ground.

2. TEST PROCEDURES AND CONDITIONS

The setup for centrifuge model tests is illustrated in Fig.1. In centrifuge model tests, slope is made by the Edosaki sand with 90 mm in thickness (2:25 m in prototype scale) with a slope of 1V:1.5H on the assumption that the slope is a colluvium slope or embankment over a sloping soft rock. The base soft rock is made of plates of plasticized polyvinyl chloride, considering the typical stiffness of the soft rock. At first, model piles (instrumented aluminium pipe having 10 mm diameter and 1 mm wall thickness) are installed in the prefabricated hole in the model soft rock and wet sand with a water content of 15% was placed in a model container and was compacted into a layer with 20 mm in thickness to achieve dry density ρ_d=1.4 Mg/m^3 (relative compaction of 80%). This compaction was continued up to the top of slope, while installing accelerometers as shown in Fig.1. After fixing the pile cap, structure (mass of 0.80 kg) and displacement transducers, the completed slope model (see







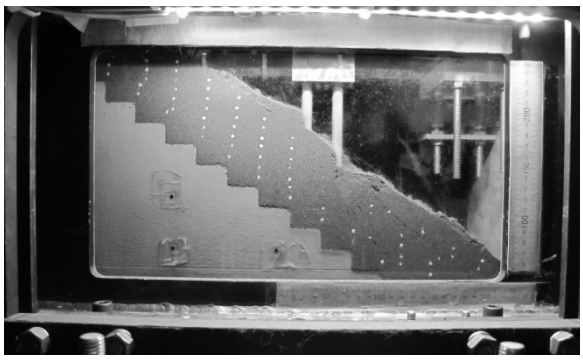


Figure 1 Model setup

(a) Before shaking

(b) Before third shaking (after second shaking with cut slope at the toe)

(c) After all the shakings

Figure 2 Side views of the model

Fig. 2(a)) was mounted on a geotechnical centrifuge, and shake table tests were conducted at 25 g field.

The target structure is a bridge pier supported by steel pipe piles arranged in 1x2 grids (2x2 for full width) with 3*D* spacing, where *D* = diameter of the pile. Weight of the structure supported by piles is determined so that the pile tip load is less than one-third of the ultimate tip resistance for the soft rock. To avoid having complicated slope—pile cap interaction problem, the stuck-out piles were employed. Natural frequency of the structure is around 30 Hz.

Figure 3 shows the typical earthquake motion applied. The earthquake motion is sinusoidal waves of 48 Hz. In total the earthquake motion was applied to the model four times. During the second shot, the surface failure occurred in the upslope of the piled structure as shown in Fig. 2(b). (Since this photo was taken after cutting the toe of the slope

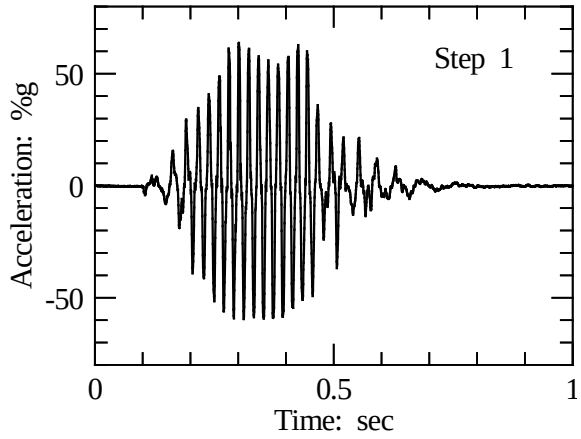

Figure 3 Typical input motion (Step 1)

as mentioned in the following section, the slope near the toe is steeper than the other location, but this portion was not steep when the two earthquake motion was applied for the first stage.) Since catastrophic failure of the slope did not occur in the first two earthquakes, the spinning of the centrifuge was stopped and toe of the slope was steeply cut to have large slope deformation in the following two earthquakes. Visual observation of the model was made from the side transparent window of the container with CCD camera.

3. TEST RESULTS AND DISCUSSIONS

3.1 Displacement of Structure and Slope

Figure 2 shows side views of the model (a) before shaking, (b) after the second shaking and (c) fourth shakings. During the second shaking the surface failure occurred in the upslope of the piled structure (Fig. 2(b)). In the following third and fourth shakings the slope near the toe also failed, resulting in relatively large deformation of the slope as shown in Fig. 2(c).

Time histories of the horizontal displacement of (a) the structure top and (c) the upslope distant from the structure are plotted in Fig. 4 for all the steps. The displacement is normalized by diameter of the model pile. Since the reading of the displacement transducer for the slope went out of range during the second shaking, the reading was reset before restarting spinning of the centrifuge for third and fourth shakings.

Horizontal displacement of the structure accumulates with shaking though its magnitude is small compared to that of the slope. The reasons for the small permanent displacement of the structure are that no plastic deformation occurred in the piles and the piles were firmly embedded in the artificial soft rock.

Unlike the slope stabilizing piles, the piles in this study support the structure, and hence response of the piles is not only affected by kinematic interaction between the slope and piles but also the inertia force of the structure. In the tests, rather smaller vibration of the structure was observed during shaking (see Fig. 4(a).) Possible explanation of the reason for this is as follows: Since the natural frequency of the slope

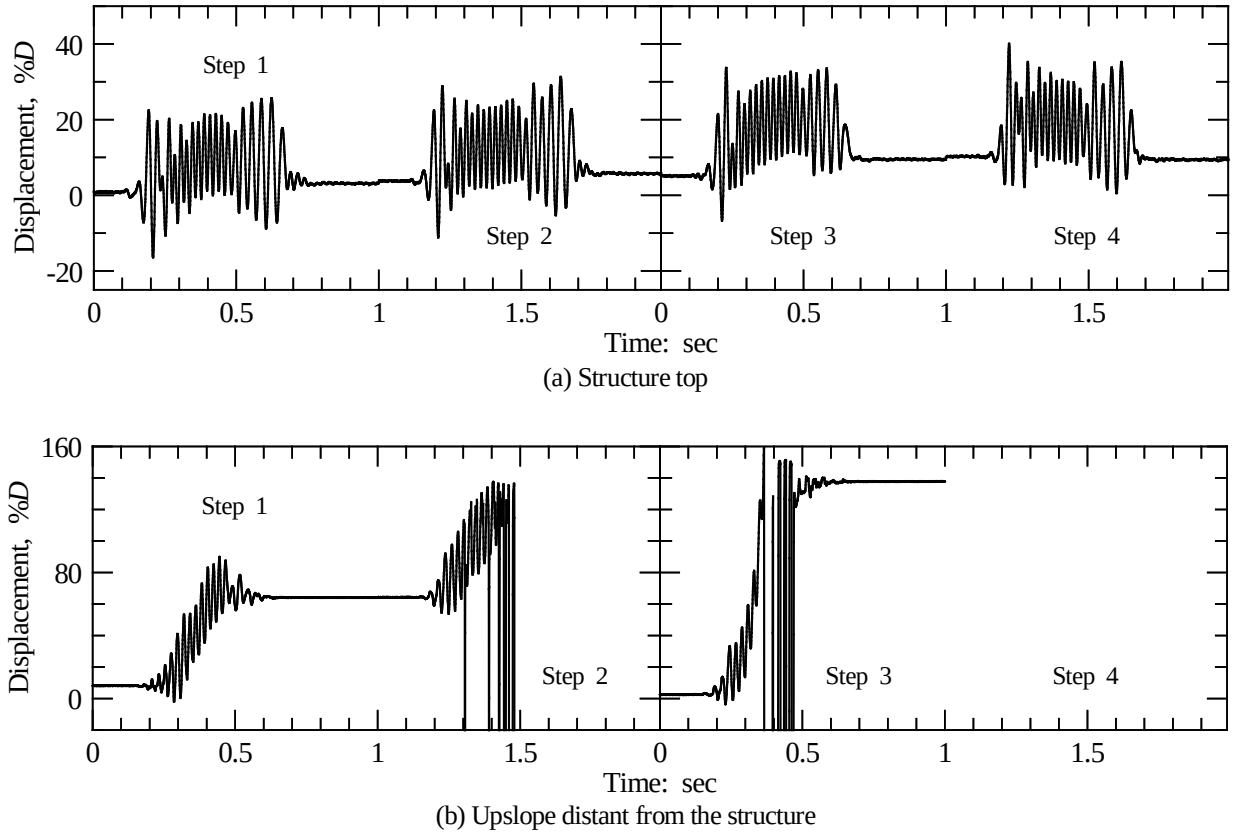

Figure 4 Time histories of the horizontal displacement of the structure and slope

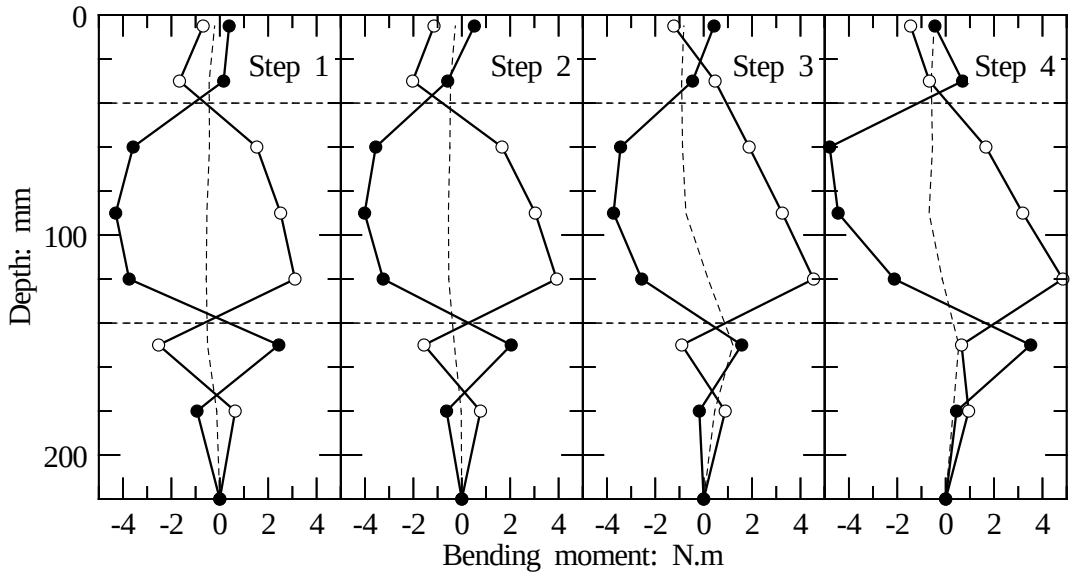

Figure 5 Bending moment profiles at the time when the maximum or minimum value is observed

(> 200 Hz) is larger than the dominant frequency of the input motion (≈ 48 Hz), the slope movement was generally in phase with the input motion, while due to the small natural frequency for the structure (≈ 30 Hz,) the movement of the structure was out of phase with that of the slope. Because of this, dynamic component of the kinematic interaction between the slope and piles acted as constraint rather than promoting vibration of the structure. The larger free vibration of the structure after shaking (see t = 0.5-0.7 or 1.5–1.7 sec in Fig. 4(a)) may support this interpretation.

3.2 Pile Response

Model piles were instrumented and strain gauges on the upslope pile allow us to calculate the bending moment distribution of the pile. The bending moment profiles at the time when the maximum or minimum value is observed are

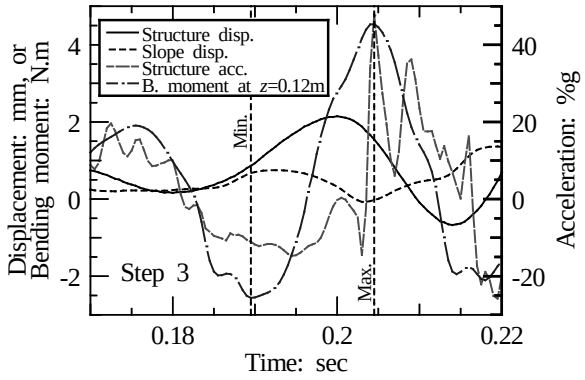

Figure 6 Time histories of displacements of structure and slope, acceleration of structure, and bending moment of pile at z = 120mm (Step 3)

illustrated in Fig. 5 for all the shaking steps. In addition, the bending moment profiles after the shaking are also plotted with the dashed lines in the figure. Irrespective to the shaking step, the maximum (plotted with open circles) or minimum (plotted with filled circles) value was observed at the very beginning of the shaking (around t = 0.2 sec. and 1.2 sec. in Fig. 4.)

In the first shaking step when the permanent displacement of the slope is not so large, the maximum and minimum bending moment profiles are more or less symmetric, while such symmetry is lost in the following shaking steps due to the relatively large permanent displacement of the slope. In the following shaking steps the maximum value increases with shaking and at the fourth shaking step about 50% increase was observed in the mobile layer, i.e., the soil above the soft rock, while such a change was about 10% for the minimum value.

Time histories of displacements of the structure top and slope (upslope distant from the structure), acceleration of the structure bottom, and bending moment of pile at z = 120mm are shown in Fig. 6 for Step 3. The time when the maximum bending moment is observed (t = 0.2045 sec for Step 3) corresponds to the time when the largest inertia force acts on the structure in the donwslope direction and the slope moves to the upslope most. At that moment, the bending moment profile is almost straight in the mobile layer. These indicate that when the maximum bending moment is observed, reaction of the soil mass in the downslope is very small, suggesting that this large bending moment is mainly attributed to the large inertia force of the structure and contribution of the soil mass movement is small.

On the other hand, the time when the minimum bending moment is observed (t = 0.1895 sec for Step 3) corresponds to the time when the structure moves in the downslope direction and the slope moves to the upslope most. This means that the bending moment at this moment is affected by the soil mass movement of the slope. Therefore the depth where the minimum value is observed changes with shaking steps, suggesting that contribution of the slope movement is relatively large.

Due to the small number of measurement points in the soft rock layer, probably the largest value in the layer could not be captured. However the increasing ratio of the peak value in the soft rock layer may be comparable to that in the soil layer above the soft rock.

4. SUMMARY

Seismic response of pile foundation in sloping ground was examined through a series of centrifuge model tests. This paper reports test results for the case that involves earthquake-induced large displacement of the sloping ground. Test results reveal the followings:

(1) Horizontal displacement of the structure accumulates with shaking though its magnitude is small compared to that of the slope.

(2) When the large bending moment is observed in the upslope pile, either (a) the largest inertia force acts on the structure in the donwslope direction and the slope moves to the upslope most, or (b) the structure moves in the downslope direction and the slope moves to the upslope most. The large bending moment is mainly attributed to the large inertia force of the structure in the former, while contribution of the soil mass movement is relatively large in the latter.

(3) The loss of soil reaction due to the slip in the downslope has more impact on increase of the pile bending moment than the kinematic load induced by soil mass movement in the upslope within the scope of the study.

AGING EFFECT ON LIQUEFACTION STRENGTH AND CONE RESISTANCE OF FINES-CONTAINING SAND INVESTIGATED IN TRIAXIAL APPARATUS

Takaji Kokusho[1)], Yohta Nagao[2)], and Fumiki Ito[2)]

1) Professor, Dept. Civil & Environmental Eng., Chuo University, Japan
2) Graduate student, Chuo University, Japan
kokusho@civil.chuo-u.ac.jp

Abstract: Innovative miniature cone penetration and subsequent liquefaction tests are carried out in a modified triaxial apparatus on sand specimens containing fines. A unique curve relating cone resistance q_t and liquefaction strength R_L is obtained for reconstituted specimens, despite the differences in relative density D_r and fines content F_c, quite contradictory to the current liquefaction potential evaluation practice. In order to examine cementation effects on the q_t~R_L, curve, a small amount of cement is added to fines in the sand specimens to simulate a long geological period in a short time, which tends to increase the liquefaction strength R_L more than the penetration resistance q_t, resulting in higher liquefaction strength under the same cone resistance with increasing F_c. Comparative tests on specimens without cement but with overconsolidation or prestraining history carried out in the same way also indicate clear increase in R_L for the same q_t, irrespective of F_c. Thus it is clarified that not the fines content itself but the aging effects such as cementation and prior stress/strain-hisories raise R_L for the same q_t, where F_c plays an important role only for the cementation.

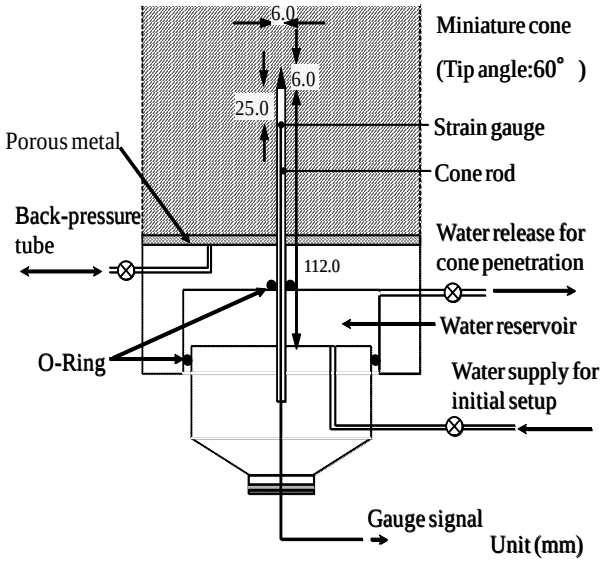
1. INTRODUCTION

Recent case studies have revealed that aging effect plays an important role in seismic liquefaction of sand deposits. Liquefaction have often occurred in backfills and reclaimed ground of young ages in contrast to natural deposits of older than thousands years being stable. The aging effect may include cementation or chemical bonding between soil particles and also mechanical particle rearrangements by prior loading due to overconsolidation, prestraining by previous earthquakes, etc. Also pointed out is that cases are increasing in which sands containing measurable amount of low-plastic fines have liquefied such as in Adapazari, during 1999 Kocaeli earthquake and in Christchurch during 2010 Darfield earthquake in New Zealand in which the aging effect may reflect.

In engineering practice, liquefaction potential is evaluated using penetration resistance in standard penetration tests (SPT) or cone penetration tests (CPT). If sands contain a measurable amount of fines, liquefaction strength is normally raised in accordance to fines content F_c in most liquefaction evaluation methods. This F_c-dependent modification of liquefaction strength may be originated from liquefaction case studies (Tokimatsu and Yoshimi 1983, Seed and De Alba 1984), in which empirical curves correlating back-calculated in situ liquefaction strengths to SPT N_1-values were found strongly dependent on fines content. More directly, Suzuki et al. (1995) carried out CPT tests and soil sampling by in situ freezing technique in the same sand deposits, showing that the higher the fines content the greater the liquefaction strength for the same q_t-value. In contrast to their finding, however, quite a few laboratory tests using reconstituted specimens, having the same relative density D_r (Kokusho 2007) or the same void ratio (Papadopoulou and Tika 2008), have shown that R_L clearly decreases with increasing fines content of low plasticity fines changing F_c=0~30%. Thus, a lack of understanding seems to remain in the current practice for liquefaction potential evaluation in the field in relation with laboratory test results for sands containing fines.

In this paper, systematic experimental studies are addressed, in which a miniature cone penetration and subsequent cyclic loading test were carried out on the same triaxial test specimens (Kokusho et al. 2005). An innovative simple mechanism introduced in a normal cyclic triaxial apparatus by Kokusho et al. (2003) was used enabling a miniature cone to penetrate into the sand specimen at a constant speed. Results from the two sequential tests on the same specimen were compared to develop direct q_t - R_L correlations for sands containing various amounts of fines. The major goal in the present paper is to investigate two types of aging effect; by cementation and by prior loading, and compare them in a series of laboratory tests. For the former aging effect, accelerated tests are carried out by adding a small quantity of cement to reconstituted specimens to simulate cementation or chemical bonding for a geological time span in a short time. For the latter, overconsolidation and prestraining are

given to specimens independently to reproduce prior loading in a long history. In both cases, penetration resistance q_t and liquefaction strength R_L are measured in the same specimens to investigate the aging effect on the q_t - R_L correlations considering fines content as a key parameter.



2. TEST APPARUTUS, SOIL MATERIAL & TEST PROCEDURES

In the triaxial apparatus used in this research, the specimen size was 100 mm in diameter and 200 mm in height. In the liquefaction tests, the soil specimen was loaded cyclically by a pneumatic actuator as a stress-controlled test. In order to carry out a cone penetration test in the same specimen prior to the liquefaction tests, a pedestal below the soil specimen was modified as shown in Fig.1, so that a miniature cone can penetrate into the specimen from below. For that goal, the pedestal consists of two parts, a fixed circular base to which the cone rod is fixed and a movable metal cap, through the center of which the cone rod penetrates in the upward direction into the overlying specimen. The annulus between the two parts is sealed by O-rings, enabling the cap to slide up and down by water pressure supplied into a water reservoir in between the two parts (Kokusho et al. 2003). During the test, the pedestal cap is initially set up at the highest level by filling water inside, and the specimen is constructed on it. By opening a valve at the start of the cone penetration, the water in the reservoir is drained by the cell pressure, resulting in the settlement of a total body of the specimen at the top of the pedestal, realizing relative penetration of the cone by 25 mm. The penetration rate is about 2mm per second, much slower than prototype CPT, and is almost constant irrespective of the difference in relative density. The miniature cone is 6 mm diameter and 60 degrees tip angle, about 1/6 smaller in dimension than the prototype cone used in the field. The strain gauges to measure the penetration resistance are glued at the inner wall of the rod tube, 25 mm lower than the foot of the cone.

Beach sand (Futtsu sand) consisting of sub-round particles of hard quality was used in this test. Fines mixed with the sand is silty and clayey soils with low plasticity index of I_p=6 sieved from decomposed granite in reclaimed ground of the Kobe city, Japan. For the test series for cementation, a prescribed quantity of Portland cement was completely mixed with the Masa fine soil to make it with different degree of chemical activity. The cement content C_c, the weight ratio of cement to soil (including fines), varied from 0 to 1.0%, and the fines content F_c including the cement changed from 0 to 30%. This means that the ratio C_c/F_c, a parameter representing chemical activity of fines, varied from 0 to 30%. Then the sand specimen with given F_c was prepared by the wet tamping method to make a given relative density D_r, which was changed in 3 steps, about D_r=30, 50 and 70%. The specimen was then completely saturated with de-aired water, and consolidated under the isotropic effective stress of 98 kPa with the back-pressure of 196 kPa. If cement is added to fines, the consolidation time was controlled exactly 24 hours after wetting, while for tests without cement it was about 2 hours.

For the test series of mechanical loading, the overconsolidation ratio, OCR=4, was applied to the specimen in one group by temporarily increasing the confining pressure up to 392 kPa for 1 hour, while non-destructive axial strain of 2×10^{-2} % in the double amplitude was given 10 thousand cycles to the specimen consolidated under 98 kPa in another group. The volume change due to cyclic straining was minimal.

Then, the specimen was fully saturated by using de-aired water in a double negative pressure method so that

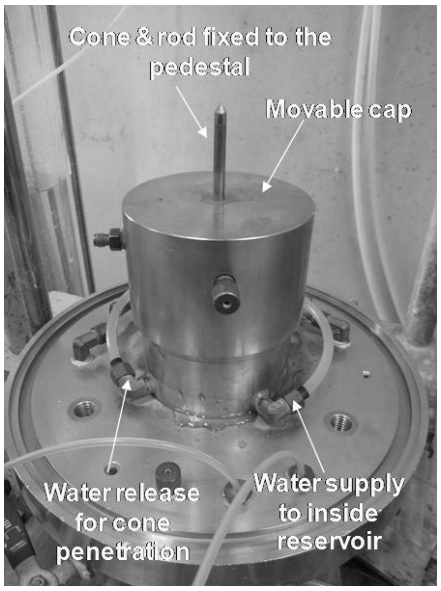


Figure 1. Cross section (right) and Photograph (left) of the modified pedestal in the lower part of triaxial apparatus

the B-value larger than 0.95 was measured, and isotropically consolidated with the effective stress of 98 kPa with the back-pressure of 196 kPa. In the test sequence, the penetration test was first carried out under undrained condition after consolidating the specimen. Then, after releasing pore pressure and reconsolidating it under the same confining pressure again, although the volume change by this procedure was almost negligible, the liquefaction test was carried out on the same specimen. The sinusoidal cyclic axial load applied with the frequency of 0.1 Hz was measured with a load cell in the pressure chamber. The cell pressure and the pore-water pressure were measured with electric piezometers and the axial deformation is measured with LVDT of 50 mm maximum capacity. It may well be suspected that, in such a test sequence, the liquefaction strength is possibly influenced by the preceding cone test and subsequent reconsolidation. However, it was already confirmed in previous research (Kokusho et al. 2005) that the cyclic stress ratio for liquefaction is almost unaffected by the cone test and reconsolidation.

3. TEST RESULTS ON CEMENTATION EFFECT

In the test, relative density D_r, fines content F_c and cement content C_c of the specimen were parametrically changed to investigate their effects on penetration resistance and undrained cyclic strength. Fig.2 shows cone resistance q_t at the top and excess pore-pressure Δu at the bottom, respectively, plotted versus the penetration length obtained in the tests for D_r≈50%, F_c=0, 5, 10, 20% and C_c=0, 0.5, 1.0%. It is clearly observed that q_t for soils without cement (C_c =0) decreases with increasing fines up to F_c =20%. For individual F_c–values, q_t tends to increase more or less with C_c changing from 0 to 1%. The excess pore pressure Δu building up almost linearly with the penetration length tends to increase with increasing F_c, though the change is not so conspicuous.

Fig.3 shows relationships between the stress ratios R_L ($\sigma_d/2\sigma'_c$: σ_d =cyclic stress amplitude, σ'_c =effective isotropic confining stress) versus the number of loading cycles N_c for the double amplitude axial strain ε_{DA}=5% obtained by undrained cyclic loading tests on sand specimens having D_r≈50%, F_c=0, 5, 10, 20%, and C_c=0, 0.5 and 1.0%. Obviously, the increase in fines content tends to reduce liquefaction strength R_L in specimens without cement as already demonstrated by previous researches (e.g. Kokusho 2007). Also indicated in the figure is that the R_L-value increases with increasing cement content for all the fines content F_c and the increment is particular large for F_c =20%.

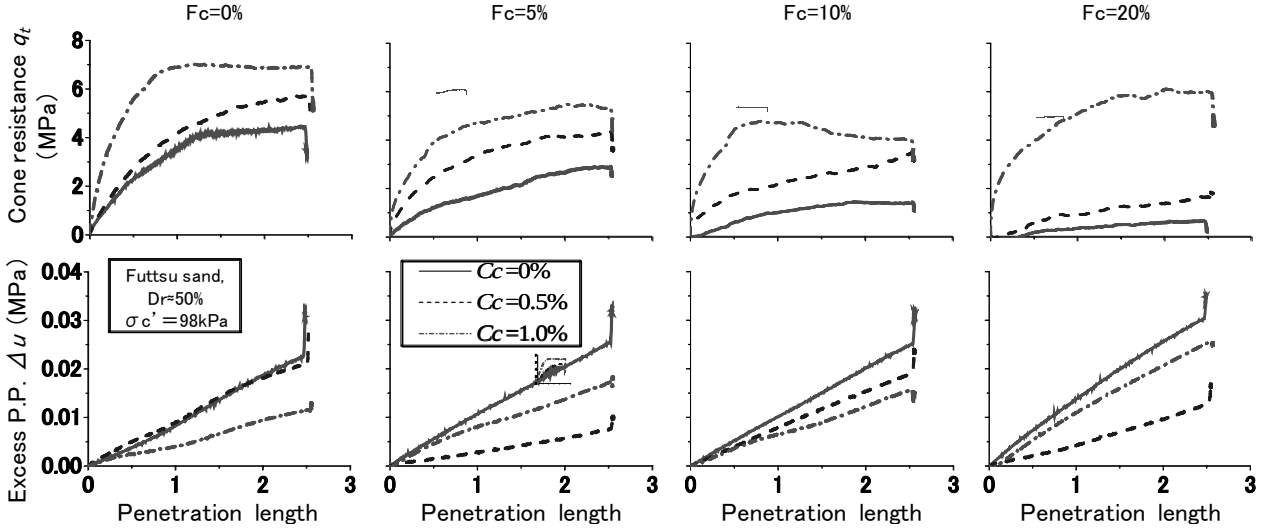

Figure 2 Cone resistance or excess pore-pressure versus penetration length for river sand specimens of D_r≈50% with different consolidation time.

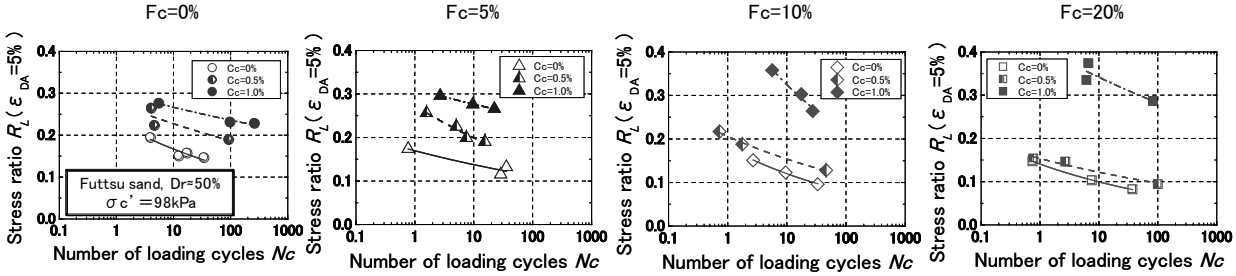

Figure 3 Stress ratios R_L versus number of loading cycles N_c

In Fig. 4, test results for different values of D_r, F_c and C_c are shown on the $R_L \sim q_t$ diagram with different symbols. The liquefaction strength R_L in the vertical axis is defined as the stress ratio $\sigma_d / 2\sigma_c'$ for ε_{DA}=5% and N_c=20 (this research) and N_c=15 (Suzuki et al.). The penetration resistance q_t in the horizontal axis is determined as the maximum value during the penetration. The open symbols (except the star symbols) corresponding to the specimens without cement are located along the thick straight line in the chart despite the wide differences in D_r (30~70%) and F_c (0~30%) as already pointed out in the previous research (Kokusho et al. 2005, 2009). This finding is inconsistent with the current liquefaction potential evaluation practice, because R_L seems to be uniquely determined from q_t irrespective of F_c.

The half-close and close symbols except the stars are all from the accelerated tests on specimens containing cement. Among them, upward triangles, for instance, represent the case F_c=5%, and they move up from the open (C_c =0) to the half-close (C_c =0.5%) further to the full-close symbols (C_c =1.0%) as C_c / F_c changes from 0 to 20% for the same value of F_c =5% as indicated by thin arrows in the diagram. In the similar manner, other symbols move up with increasing C_c or C_c / F_c for the same fines content of F_c =10%, 20% and 30%. Samples with higher value of C_c / F_c may be considered as of longer geological age because higher chemical activity is exerted in the same soil in the accelerated test. This indicates that the cementation effect tends to push up the data points on the $R_L \sim q_t$ diagram from the unique line of no cement and gives higher liquefaction strength under the same cone resistance.

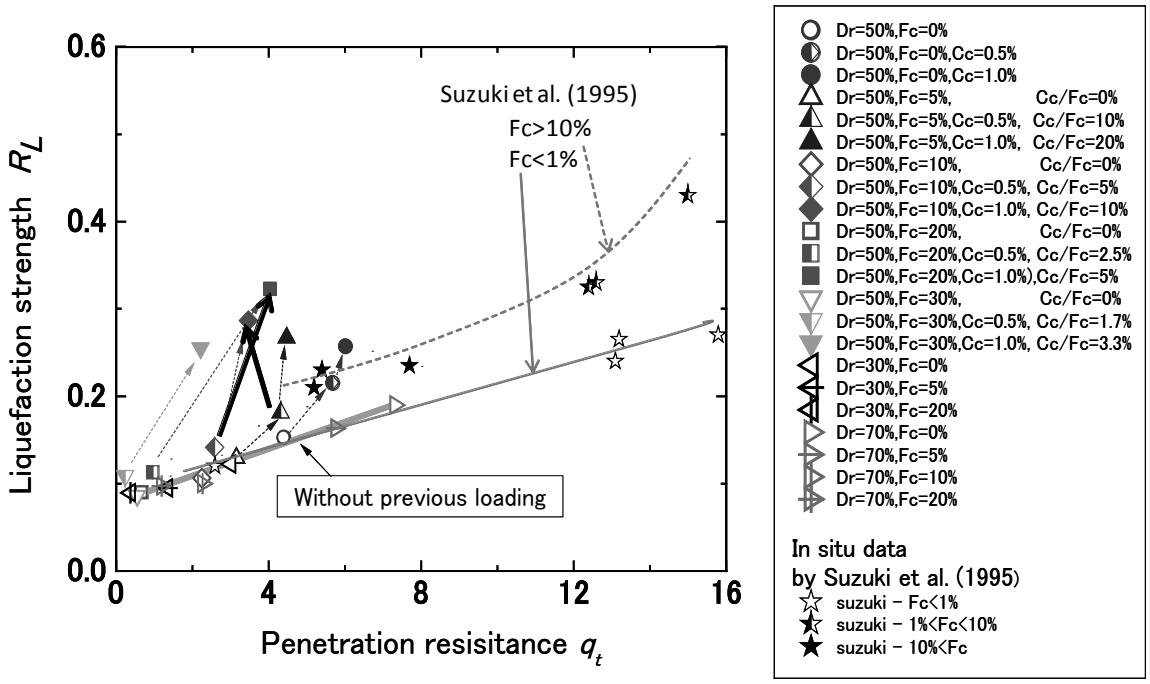

Figure 4 R_L versus q_t relationship for specimens with different cementation effect

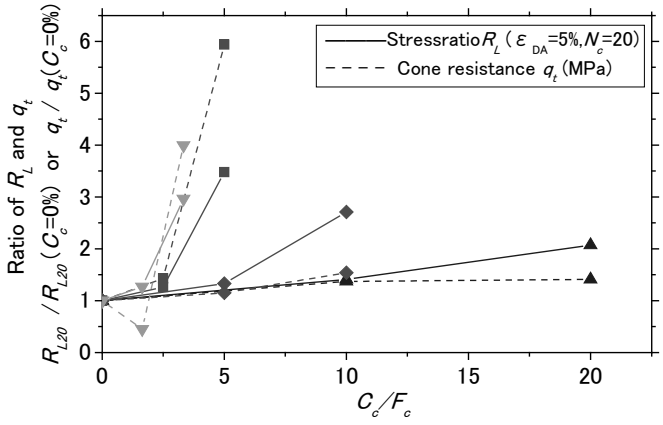

Figure 5 Rate of increase in R_L, q_t versus C_c/F_c

The star symbols in the same figure indicates the R_L~ q_t plots based on field investigations by Suzuki et al. (1995) combining prototype cone tests in situ and undrained cyclic triaxial tests on intact samples recovered from the same soil deposits by in situ freezing technique. It demonstrates a clear difference in the R_L ~ q_t relationships due to different fines contents of $\boldsymbol{F_c}$ <1.0%, $\boldsymbol{F_c}$ =1.0-10% and $\boldsymbol{F_c}$ >10%. Also noted is that the two research results are in a good coincidence not only qualitatively but also quantitatively, particularly in the case without cement, despite a large difference in the cone size and CPT test procedures.

On the other hand, data points with the same $\boldsymbol{C_c/F_c}$ –value, 5% or 10%, can be recognized to shift upward as $\boldsymbol{F_c}$ increases from the unique line of no cement as indicated by the thick arrows in the graph. This indicates that, under the same geological age, higher $\boldsymbol{F_c}$-value results in higher liquefaction strength for the same cone resistance. Thus, the present research results by the accelerated test clearly indicate that not the fines content itself but the cementation effect is responsible for the higher liquefaction strength for larger $\boldsymbol{F_c}$ under the same cone resistance.

Based on the data shown in Fig. 4, the ratio of increase in R_L or q_t is shown versus the $\boldsymbol{C_c/F_c}$ -value with the fines content F_c as a parameter in Fig. 5. With increasing chemical activity, the R_L-value increases more than the q_t-value for $F_c \leq 10\%$, but it is reverse for $F_c \geq 20\%$. Also noted in Fig. 5 is that not only the $\boldsymbol{C_c/F_c}$ -value but also the fines content $\boldsymbol{F_c}$ tends to considerably increase R_L and q_t up to F_c=20% even under the same cement content of $\boldsymbol{C_c}$ =1.0% as demonstrated by the encircled plots but the trend seems to change at F_c=30%. Thus, there seems to be a kind of transition around F_c=20%, in which the increasing trend in R_L or q_t with increasing $\boldsymbol{C_c/F_c}$ -value changes, which may possibly have something to do with soil structure change from sand grain supporting to matrix supporting.

4. TEST RESULTS ON OVERCONSOLIDATION & PRESTRAINING

Test results on reconstituted specimens of D_r≈50% , F_c =0~20%, C_c =0, which experienced either prestraining history of 10 thousand cycles of 2×10^{-2} % double amplitude axial strain or overconsolidation of OCR=4 are plotted with different symbols on the R_L~ q_t diagram in Fig. 6. The open symbols with/without bars are all for the specimens with no prior loading histories as explained before, which are almost aligned in a single unique solid line despite the wide difference in D_r and F_c. If specimens are prestrained, both R_L and q_t increase, and the data points are plotted with half-close symbols. They move upward and rightward as thin dashed arrows from the original points of no prior loading. The all half-close plots may be aligned in a straight dashed line, which tends to converge to the solid line of no prior loading at the left end. In the case of overconsolidation, both R_L and q_t increase again, moving the plots to the full-close symbols from the original open symbols as indicated with thin solid arrows. They are all located above the solid line of no prior loading and may be along a chain-dotted line almost in parallel with the solid line.

Thus, a pair of unique lines seem to exist; one corresponding to prestraining by particular stain amplitude with a given number of cycles and the other corresponding to overconsolidation of particular OCR. They tend to give higher liquefaction strength corresponding to the same penetration resistance q_t than sands without prior loading histories, although the degree of increase is certainly dependent on the specifications of loading. It is obviously seen that these lines are independent of fines content for F_c=0~20%, in a good contrast to the cases for specimens containing a small quantity of cement previously addressed.

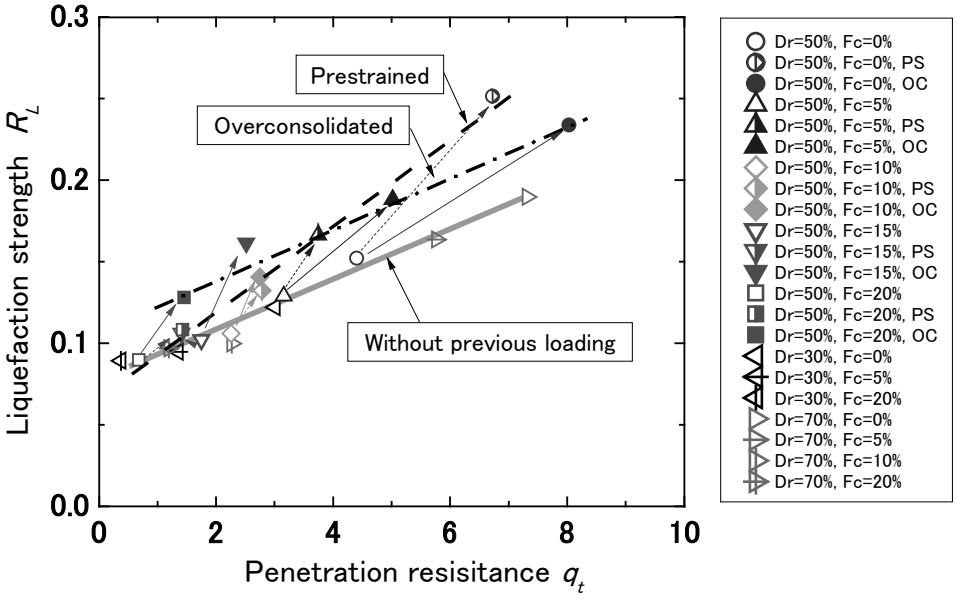

Figure 6 R_L versus q_t relationships for overconsolidated and prestrained specimens (PS: Prestrained, OC: Overconsolidated)

This observation reveals that the two types of the aging effects; by cementation and by prior loading histories such as overconsolidation and prestraining, both tend to increase liquefaction strength under the same penetration resistance on the $R_L \sim q_t$ diagram, though fines content is the major player in determining how much the increase is in the former while it has little effect in the latter. In the current liquefaction potential evaluation, fines content is dealt with as a key parameter to modify liquefaction strength by a certain amount from a standard curve of no fines. This research results indicate that the F_c-dependent modification of R_L should exclusively represent the cementation effect. No logical basis may be justified to consider the effect of prior loading by modifying liquefaction strength as a function of fines content.

5. CONCLUSIONS

A series of experimental study by miniature cone penetration tests and subsequent cyclic loading tests were carried out in the same triaxial test specimen to investigate two types of aging effect on liquefaction strength; by cementation and by prior loading, with fines content F_c as a key parameter. Accelerated tests on the cementation effect using specimens containing a small quantity of cement yielded the following major findings;

- For reconstituted soils without cement, the liquefaction strength R_L is uniquely related to the cone penetration resistance q_t, forming a single $R_L \sim q_t$ line, irrespective of relative soil density D_r and fines content F_c, quite contradictory to the current liquefaction potential evaluation practice.
- This laboratory test result coincides with in situ $R_L \sim q_t$ relation by Suzuki et al.(1995) quantitatively despite clear difference in the test procedures and cone size.
- Specimens with higher value of C_c/F_c (simulating longer geological age) results in higher liquefaction strength under the same cone resistance, indicating that the cementation effect tends to raise the $R_L \sim q_t$ line from that for soils without cement.
- For the same C_c/F_c-value (simulating the same geological age), higher fines content results in higher liquefaction strength under the same cone resistance, which is consistent with the trend found in the field investigations.
- Thus, it is revealed that the reason why higher fines content leads to higher liquefaction strength does not depend on fines content itself but cementation effect, which tends to be pronounced as fines increase.

Another series of tests on the effect of prior loading revealed;

- If specimens are prestrained with medium strain cycles, both R_L and q_t increase, and the plots on the $R_L \sim q_t$ diagram may be approximated by a straight dashed line, which tends to converge to the solid line of no prior loading at the left end. In the case of overconsolidation, both R_L and q_t increase again, and the plots may be aligned along a chain-dotted line almost in parallel with the solid line.
- Thus, the two different unique lines exist, which give higher liquefaction strength under the same penetration resistance q_t than sands of no prior loading. It is obviously seen that these lines are independent of fines content for F_c=0~20%, in a good contrast to the cases in the accelerated tests on specimens containing a small quantity of cement.

Consequently, two types of the aging effects; by cementation (chemical bonding) and by prior loading such as overconsolidation and prestraining, both tend to increase liquefaction strength under the same penetration resistance. However, fines content is the major player in determining how much the increase is in the former while it has little effect in the latter. Thus, the F_c-dependent modification of R_L should represent the cementation effect only, excluding the prior loading effects.

Abstract: Soil shear modulus non-linearity with strain is routinely measured in the laboratory, usually resulting in normalized curves of G/G_{max}. Since soil moduli at small strains (G_{max}) measured in the laboratory and in situ often differ by considerable amounts, it is customary to rely on field measurements for analysis and design. The nonlinearity is introduced by using the normalized laboratory curves together with the field estimate of G_{max}. Actual evaluation of shear modulus nonlinearity directly in the field has been rare until the recent introduction of large-scale mobile shakers which can apply higher loads and strains to the soil. The proposed method to evaluate shear modulus vs strain in situ involves applying dynamic loads on a surface foundation and measuring the dynamic response of the soil mass beneath the foundation with embedded instrumentation. Linear and nonlinear shear moduli can be estimated by analyzing phase differences of the measured velocity time histories at different locations. However, the choice in defining average strain and shear wave velocity of the wave traveling between any two measurement points will lead to different estimates of shear modulus and level of strain. This paper focuses on illustrating the consequences of these choices through simulated response.

1. INTRODUCTION

Soil shear modulus (G) nonlinearity with strain is routinely measured in the laboratory, usually resulting in normalized curves of shear modulus with its maximum value at very low strain levels. However, soil moduli at small strains (G_{max}) measured in the laboratory and in situ often differ by considerable amounts due to sample disturbance and time effects. Numerous studies have attempted to explain these differences and to provide correction factors that could be applied to the experimental data (i.e., Anderson and Woods 1975). As a result, it is common today, particularly in geotechnical earthquake engineering, to combine values of the shear modulus at low levels of strain determined in the field through geophysical methods with the normalized G/G_{max} curves from laboratory tests, or available in the literature, to obtain the variation of shear modulus with level of strain for nonlinear seismic analyses. The basic assumption is that the relative variation of the shear modulus with strain level is the same in situ and in laboratory tests. Recent studies have raised some questions as to the accuracy of this assumption and have attempted to evaluate shear modulus and its variation with strain using field data such as seismic records from arrays (Zeghal et al. 1995, Chang et al. 1996). Henke and Henke (1993, 2003) developed a torsional cylindrical impulse shear test to determine soil moduli in situ, which consists of intruding a cylinder probe into the soil and generating torsional impulses at selected levels of excitation. Roblee and Riemer (1998) proposed the Downhole Freestanding Shear Device (DFSD), which is designed to create and subsequently test a freestanding soil column at the bottom of a borehole. Safaqah and Riemer (2006) applied the DFSD to estimate nonlinear moduli in situ.

Recently, under the Network for Earthquake Engineering Simulations (NEES) program, the University of Texas at Austin developed mobile shakers (Fig. 1) that are capable of exerting sufficient strain on a larger volume of soil offering the opportunity to measure shear modulus and its variation with strain in a realistic manner (Stokoe et al. 2006, Park 2007, Park 2010). These field tests need to be interpreted carefully to ensure that

Figure 1. Large capacity vibroseis truck, T-Rex, of the University of Texas at Austin.

the desired properties are correct and no bias is introduced in the results. This paper introduces possible issues in data interpretation rising from the estimation of strains and the localized nature of the measurements.

2. FIELD TESTING SETUP

In tests performed at the Fitzpatrick Ranch in Austin Texas by Park (2010) using the dynamic testing equipment developed at The University of Texas at Austin under the auspices of NEES of the National Science Foundation, a 0.90 m circular slab was constructed on the ground and subjected to harmonic loads of different amplitudes (Figure 2). Geophones were installed in and under the footing to investigate the response of the foundation/soil system. The amplitude of the vertical force imposed on the foundation was captured through a load cell placed on the footing. Details of the experimental set up and of the measurements are provided in Park (2010).

The geophones measured particle velocities at various depths under the slab and the displacements at the geophone locations were computed by double integration. The corresponding value of the shear modulus can be determined computing first the shear wave velocity (v_s) from the time lag (Δt) between arrival times at the different depths:

$$v_s = \frac{\Delta z}{\Delta t} \qquad (1)$$

where, Δz is the distance separating two geophones, and then the modulus ($G = \rho v_s^2$) assuming a known value for the soil density ρ.

In the tests under consideration a harmonic force was applied at the top of the footing for sufficient cycles to reach steady-state. Similarly to a cyclic laboratory test, the reference shear strain associated with a shear modulus is the maximum strain in the cycles. Tests were performed at different load amplitudes to evaluate strains and shear modulus at different levels, ideally yielding a G vs γ curve. The reference shear strain can be estimated from the calculated displacements using different approaches. Two simple possible interpretations are to define the reference shear strain as (Figure 3):

$$\bar{\gamma} = \frac{\Delta u_1}{\Delta z} \qquad (2)$$

Or

$$\gamma_a = \frac{\Delta u_2}{\Delta z} \qquad (3)$$

In this paper, two approximations introduced in the estimates of the desired quantities from field data will be evaluated:

1. The determination of the reference strain from the difference between the displacements at two different depths, either at the same time or different times.
2. The determination of the shear wave velocity from the time lag between the maximum displacements.

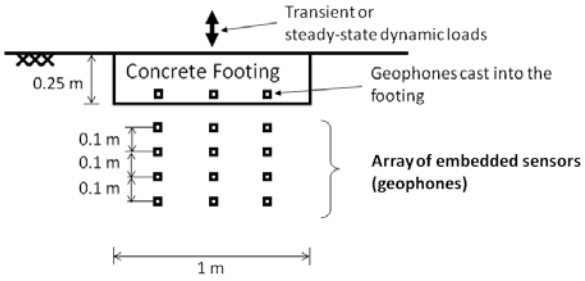

Figure 2 Schematic of the test setup at the Fitzpatrich Ranch in Austin, Texas, USA

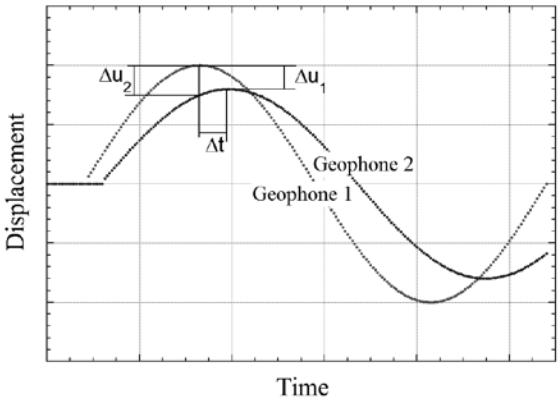

Figure 3 Definition of quantities used in equations (2) and (3).

2. FORMULATION

In this work a cone mode was used to evaluate the significance of the approximations introduced by using displacement time histories calculated from measured velocities. Meek and Veletsos (1974) pointed out that a cone could represent exactly the stiffness of a circular foundation on the surface of an elastic half space. This concept was further developed by Wolf and Deeks (2004), who presented cone solutions for a number of different excitations and layered soil profiles where the properties vary with depth.

Although a shear cone, in which only shear deformations are allowed, will provide the correct values for the horizontal stiffness of a circular mat, it will not reproduce exactly the state of strains and stresses in the soil, since in the real problem a horizontal force will produce both a

horizontal displacement and a small rotation of the foundation, with a fully three dimensional state of stresses. The study presented here, therefore, focuses on one-dimensional propagation of shear waves generated by a harmonic load applied at the surface through a circular footing. While the cone model does not reproduce the true conditions of the tests, including any effects of soil properties varying with depth, the simplifications are justified in view of the interest in evaluating the approximations in interpretation methods, which are usually based on a one-dimensional interpretation. The cone was reproduced with two different discrete models: a series of lumped masses and interconnecting springs and a finite difference using second-order central difference formulation. For the mass-spring model the total mass for each layer is (Torres 2010):

$$M = \frac{\pi}{3}\rho r_o^2 \Delta z \frac{z_i^2 + z_i z_{i-1} + z_{i-1}^2}{z_o^2} \tag{4}$$

with a corresponding spring stiffness

$$k_i = \frac{A_o G}{\Delta z}\frac{z_{i-1} z_i}{z_o^2} \tag{5}$$

with z_i and z_{i-1} the depth of the interface between layer i and i-1 from the cone vertex, z_0 is the distance of the footing from the cone vertex, $\Delta z = z_1 - z_{i-1}$, and A_0 is the area of a footing of radius r_0.

The second-order central difference discretization with mesh size Δz yields:

$$u_{i,n+1} = 2u_{i,n} - u_{i,n-1} + \frac{\Delta t^2}{\rho A_i}\left[(GA)_i \frac{u_{i+1} - 2u_i + u_{i-1}}{\Delta z^2} + \frac{(GA)_{i+1} - (GA)_{i-1}}{2\Delta z}\frac{u_{i+1} - u_{i-1}}{2\Delta z}\right]_n$$

with $u_{i,n}$ as the displacement of the i-th node at time $n\Delta t$.

For both models the bottom was placed at a sufficient distance to guarantee that reflections would not arrive back at the location of interest during the time range under consideration and the time increment Δt was taken small enough to guarantee stability of integration.

2.1 Validation of the implementation

For both approaches, mass-spring model or finite difference implementation, the solution in the linear elastic range should converge to the theoretical solution as the distance between the masses in the first case and the mesh size in the second tend to zero. The computer programs implementing the two models were validated comparing their results to the analytical predictions for the cone. In this validation case the soil deposit was characterized by a shear wave velocity of 100 m/s, a mass density of 2000 kg/m ^{3} and therefore a maximum shear modulus G_{max} of 20 MPa. A footing with a radius of 0.5 m was subjected to harmonic forces with frequencies of 10, 50 and 100 Hz.

For the mass-spring model mesh sizes of 0.05, 0.10 and 0.20 m were considered. The displacements computed at the surface are shown in Figure 4 versus Δz in comparison with the analytical solution.

Mesh sizes of 0.10, 0.05 and 0.01 m were considered for the finite difference model. In order to get accurate results the mesh size for the finite difference model needs to be much smaller than the Δz used with the lumped masses and springs. The results are also shown in Figure 4. Figure 5 shows values of the strains computed with the three models and from the analytical solution. When using a $\Delta z = 0.05$ m for the mass-spring model the strains are obtained at twice the number of points and different depths from those with $\Delta z = 0.1$ m. The results for the mass-spring model with $\Delta z = 0.05$ m and with $\Delta z = 0.01$ m for finite differences are close to the analytical curve, whereas the results with the mass-spring model with $\Delta z = 0.10$ m are slightly lower than the analytical solution.

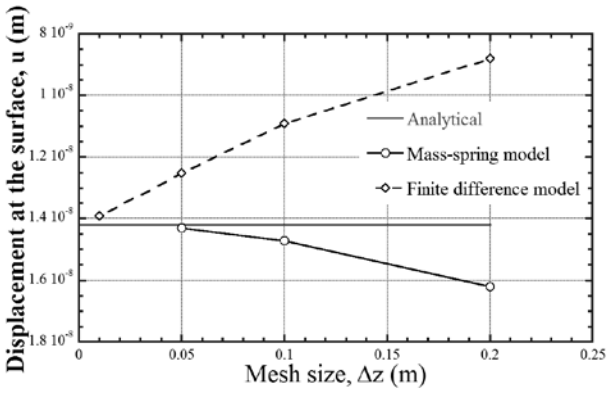

Figure 4 Comparison of displacement at the surface evaluated with the analytical solution and the mass-spring and finite difference models.

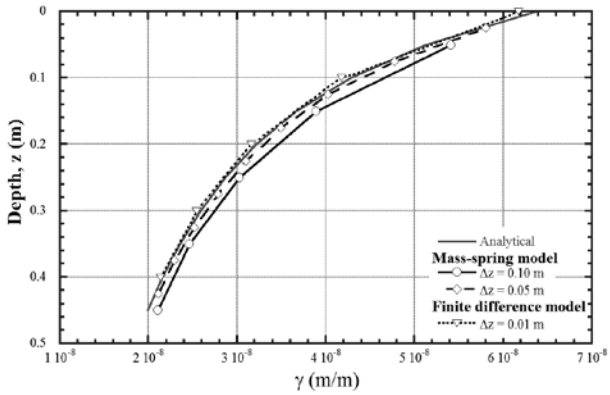

Figure 5 Comparison of strains obtained from the analytical solutions vs calculated with mass-spring and finite difference models.

3. NONLINEAR ANALYSIS

In the nonlinear analysis the soil shear stiffness varies with the level of strain according to the G/G_{max} curve illustrated in Figure 6. The variable shear modulus is implemented in the mass-spring and the finite difference models using a piecemeal linearized approach as proposed by Iwan (1967). The same problem geometry and initial properties were used for the nonlinear analysis as before for the linear analysis. The soil deposit had an initial (at low level of strains) shear wave velocity of 100 m/s, a mass density of 2000 kg/m^3 and therefore a maximum shear modulus G_{max} of 20 MPa. The footing of 0.5 m radius was subjected to harmonic forces with a frequency of 50 Hz and varying amplitudes. The harmonic force amplitudes were 100, 500, 1000, 5000, and 10,000 N for $\Delta z = 0.10$ m. Harmonic force amplitudes for $\Delta z = 0.05$ m were 100, 500, 1000, and 5000 N because for a depth of 0.025 m the strain corresponding to a force of 10,000 N exceeded the maximum strain considered in the G/G_{max} curve.

The propagation velocities were computed from the time interval between the maximum displacements at the different depths as defined in equation (1). Figure 7 shows the agreement between the values of the G/G_{max} versus γ obtained for both approaches when the shear wave velocity between two locations is evaluated for the time interval at which the maximum strain actually occurs between the two points. As expected, the agreement between the assumed material properties and those derived from the computed displacement time histories is excellent. This simply verifies that the codes reproduce correctly the variation of G with γ entered as input.

When the strain between two locations is computed from the difference between the peak displacements at the two locations ($\bar{\gamma}$), we are effectively using an averaged value for the strain that is always going to be smaller than the actual maximum. As shown in Figure 8 the values of the actual normalized shear modulus vs reference strains obtained from the difference between the peak displacements for $\Delta z = 0.1$ m and $\Delta z = 0.05$ m are always to the left of the assumed curve.

The reference strain estimated using Equation (3) is larger than $\bar{\gamma}$ and the normalized shear modulus curve is closer to the assumed values, although still to the left (Figure 9).

Figure 10 compares the assumed normalized shear modulus curve and the values of $v_s^2/\ v_s^2{}_{max}$ computed from the time interval between peak displacements, while γ is the actual maximum shear strain computed by the program. In this case the values of $v_s^2/\ v_s^2{}_{max}$ are always larger than those of the assumed G/G_{max} curve. This indicates that the shear wave velocity computed is an average velocity over time rather than the minimum velocity corresponding to γ.

If then the same values $v_s^2/\ v_s^2{}_{max}$ are plotted vs the strain computed from the difference between peak displacements ($\bar{\gamma}$), as shown in Figure 11, the agreement between estimated and computed curve improves. In this case the errors committed using $v_s^2/\ v_s^2{}_{max}$ and $\bar{\gamma}$ have opposite effect, resulting in a better match, although the estimate is still to the left of the actual values, indicating that the error committed using $\bar{\gamma}$ is larger.

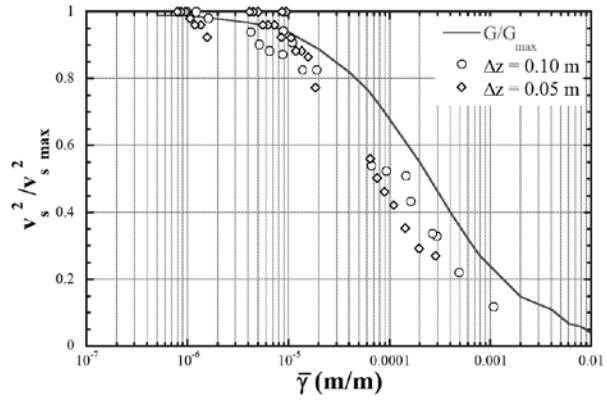

Figure 11 Shear wave velocity ratio variation with $\bar{\gamma}$.

The alternate definition of reference strain using displacements at two geophone locations at the time when the maximum is measured at the one closer to the source, yields higher values and moves the curve to the right (Figure 12), seemingly giving a better estimate of the normalized modulus curve.

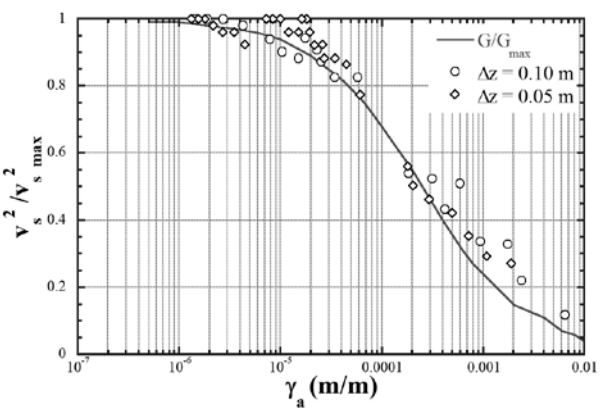

Figure 12 Shear wave ratio variation with γ_a.

3. CONCLUSIONS

The main objective of this study was to evaluate the accuracy of the procedures used in practice to determine soil properties directly from in situ measurements in order to compare them to those reported in the literature from laboratory tests.

For this purpose a shear cone that would reproduce correctly the horizontal stiffness of a circular mat foundation on the surface of an elastic, homogeneous half space, was considered. A number of cases were evaluated increasing the level of the applied harmonic force and using nonlinear springs that would reproduce a specified G/G_{max} vs. γ curve for the soil. Using a similar procedure to that used in field tests, the shear wave velocity between hypothetical receivers and the levels of strain were assessed. The results indicate that the curves obtained from the field tests need to be carefully interpreted since both the shear modulus and the reference strains estimated from field data yield averaged quantities showing a bias toward over- or under- estimation. Even in those cases where the two opposite biases may result in a better estimate, users need to be aware of the potential dangers, since there is no assurance the two errors will always be balanced equally.

Abstract: Since E-Defense opened in 2005, the first phase in the first five years was over at the end of FY 2009, and the second phase got started at the beginning of FY 2010. In the first phase, four geotechnical large-scale shaking table tests out of forty-two test projects at E-Defense were performed; i.e. two soil-pile interaction tests in liquefiable and non-liquefiable soil strata, and two liquefaction-induced lateral spreading tests. Based on these full-scale tests, better understanding on liquefaction effects on soil-pile interaction could be obtained, and potentials of E-Defense testing for geotechnical projects could be validated. In the second phase, another series of geotechnical shaking table tests will be conducted using large-scale models of underground system, such as underground highways and subway. To simulate complicated underground space under mega cities, some structure models will be placed close to others, and connected to different types of structures. This test series can provide fundamental information on seismic performance of underground system. In this paper, descriptions and some results of the tests in the first phase are briefly summarized. In addition, setup plans of the test to be performed in the second phase are available.

1. INTRODUCTION

The Kobe Earthquake, 1995 in Japan damaged a large number of structures, and gave great lessons on seismic design of the structures. The reliability of seismic resistance of the existing structures needed to be verified, and more advanced and reliable design methods needed to be established in order to reduce the risk of earthquakes coming in the near future. To achieve the above goals, one of the most powerful approaches is performance of full- or large-scale experiments.

In light of this, Science and Technology Agency (at present, the Japan Ministry of Education, Culture, Sport, Science, and Technology, MEXT) made a decision to build the research facility with large-scale three-dimensional shaking table belonging to National Research Institute for Earth Science and Disaster Prevention (NIED), Hyogo Earthquake Engineering Research Center, called E-Defense. Three great advantages of the E-Defense testing are; 1) observe "more realistic" situations and phenomena minimizing scale effect, 2) record "more detailed" behavior placing more sensors, 3) perform producing earthquake disaster which provides case histories of "artificial" disasters. Using test results, numerical analyses can be validated and improved. These innovative procedures can contribute to saving human lives and properties from large catastrophic earthquakes all over the world.

Since E-Defense opened in 2005, considerable efforts have been made by coordination and collaboration of many participants, including academic institutions, government researchers, general public, private and industrial organizations. The first five years from the start of its operation FY 2005 through FY 2009, were defined as the first phase, and forty-two shaking tests with various types of structures (Tabata and Kajiwara 2009), including four soil-structure interaction tests were successfully performed in this phase. At the beginning of FY 2010, April 2010, the second phase got started and a new geotechnical engineering research project has been carefully planned now.

In this paper, the introduction of E-Defense research facility and brief summaries of geotechnical engineering research projects performed in the first phase are presented showing some examples. Also, another series of geotechnical experiments to be conducted in the second phase is introduced.

2. SPECIFICATIONS OF TESTING COMPONENTS

First of all, specifications and characteristics of testing components belonging to E-Defense (*i.e.* the shaking table, soil containers) are introduced. These components were used for the first phase tests, and will also be used for the second phase tests.

2.1 E-Defense Shaking Table

The key element of E-Defense is a 20 m by 15 m shaking table (Photo 1). The specifications of the table shown in Table 1 gives the capability of reproducing the seismic motions recorded in the 1995 Kobe earthquake for a 12-MN model structure. Motions in horizontal and vertical directions are controlled using 10 and 14 units of hydraulic actuator, respectively. Because of noise in the hydraulic system, interaction between the shaking table and test specimens, and nonlinear behavior of test specimens, actual table motions are not always identical as target motions. Therefore, some excitations are usually inputted to the table with test specimens prior to tests to observe differences of the table motions and find correction factors at any frequency. Because of high nonlinearity of geo-materials, however, it is not reasonable to input motions to soil-structure specimens before testing, and therefore, motions with no correction are usually applied.

2.2 Soil Containers

Regarding geotechnical testing, E-Defense has two large soil containers, (a) a cylindrical laminar container, and (b) a rectangular rigid container. The former, the cylindrical laminar container has 8 m in diameter and 6.4 m in height, and is composed of 40 laminar rings that can only move horizontally. The latter, the rectangular rigid container is 16 m long, 4 m wide and 5 m high. Those containers have to be chosen with careful considerations on research purpose, target structures, and expected results.

2.3 Sand

Approximately 1000 tons of Albany silica sand is stored in the stock yard at E-Defense. The properties and indices of the sand are presented in Table 2. Details of its deformation characteristics are available in Yasuda *et al.* (2006). The grain size distribution of the sand is shown in Figure 2 with one of Toyoura sand, indicating both the sands show similar distribution. Because the Albany sand was used for tests several times, fine contents may be washed out and particles may be crushed somewhat, and therefore, its characteristics may be slightly changed. To quantify it, another series of laboratory tests (index and deformation characteristics tests) has been conducted. The results will be published in the near future.

Minimum void ratio	$e_{min} = 0.513$
Mean grain size	$D_{50} = 0.20$ mm
Uniformity coefficient	$U_c = 1.64$
Coefficient of curvature	$U'_c = 1.13$

2.4 Sensors and Data Acquisition System

As mentioned above, more than 40 full- or large-scale tests have been performed at E-Defense with various types of structures, and many kinds of measurements have been used to achieve their research goals. Therefore, various types

of sensors and tools fixing positions of these sensors are now available. In geotechnical testing programs, ground displacement, deformation of structures, accelerations in ground and structures, earth pressure acting on the structures, are usually measured, and pore water pressure is also monitored if soil liquefaction is expected. In the first phase tests at E-Defense, strain gauges, displacement transducers, earth pressure gauges, accelerometers, pore water pressure gauges, tilt-meters, and shape-tapes were applied. In addition, a unique three-dimensional displacement measuring system was employed to investigate the motions of the ground surface, the caisson, the footing and the weight of the structure (Tokuyama *et al.* 2007). In this system, displacement is determined by digital video cameras that capture reflective, spherical markers attached to an object. The advantage of the system is to acquire very large displacement that is difficult to measure by a typical displacement transducer.

The data acquisition system has approximately 900 channels. Because various behaviors of test specimens want to be measured, this number of sensors may be short. Therefore, reasonable sensoring plans with the above numbers of sensors are usually developed defining priorities of measurements.

3. PAST RESEARCH PROJECTS

In the first phase of E-Defense, there was a two-year geotechnical testing program as a part of the Special Project for Mitigation of Earthquake Disaster in Urban Areas, called Dai-Dai-Toku in Japanese. In this chapter, some examples of the large-scale tests are briefly described. More details are available elsewhere (*e.g.* Tabata *et al.* 2007).

3.1 Soil-Structure Interaction (SSI) in Level Ground

In order to obtain better understanding on soil-structure interaction and failure mechanism of pile foundations due to earthquake-induced ground motions, a series of large-scale model shaking table tests with a soil-foundation -superstructure system was performed using the E-Defense shaking table in February and August, 2006. In this paper, brief description of the test setup and some examples of the test results are presented.

The specimen for SSI test was built in the cylindrical laminar container (Figure 2). A target structure placed at the center of the container filled with a 6.4 m high non-liquefiable deposit of Albany silica sand with the relative density of 70 %. The target structure consisted of a 28-ton superstructure supported by four 30 cm high columns, a 10-ton footing, and a pile foundation composed of 9 hollow steel piles 5.7 m long, 152 mm in diameter and 2 mm thick. All the piles were fixed at the top to the footing and pinned at the bottom of the container. The four columns supporting the superstructure could be replaced in order to change natural periods of the foundation-superstructure system.

Totally 80 shaking tests were performed with different structures inputting various motions, and the test results from three cases of them are presented herein: Case 1 for the structure with a natural period shorter than the deposit's predominant period (short period structure), Case 2 for the structure with a natural period longer than the deposit's (long period structure), and Case 3 for the structure having a footing and a pile foundation without the superstructure (no superstructure). In Case 1 and 2, columns of rigid steel and vibration isolation rubbers were used in order to adjust the natural period of the structure systems respectively, and all the other specifications, such as shape and weight, were identical. In Case 3, no superstructure and column were placed on the footing. Two-dimensional horizontal motion recorded at JR Takatori Station in the 1995 Kobe earthquake (Nakamura *et al.* 1996) with the maximum acceleration adjusted to approximately 0.8 m/s^2 was applied to the shaking table.

Figure 3 presents the time histories of the table accelerations in x- and y-directions shown in Figure 2, indicating that the table motions in three test cases were almost identical. Nonlinear behaviors of the test specimens and interactions between the hydraulic system, the shaking table, and the test specimens usually affect the table motions, but their influence can be reasonably assumed to be negligible in the above three cases.

Figure 4 shows the time histories of the horizontal inertial force of the superstructure and the footing (*Fy*), and horizontal displacement of the footing in y-direction (*dy*) in Case 1 and 2. In Case 1, since time histories of *Fy* and *dy* have almost the same phase, the inertial force dominates the displacement of the footing. On the other hand, the inertial force in Case 2 has less correlation with the displacement of the footing than Case 1.

The time histories of bending strains in *y*-direction at a depth of 15 cm from the pile head along the center pile defined as B2 (Figure 2) are compared in Figure 5. The values of bending strain of the short period structure (Case 1) appear to be larger than those in the other cases especially at around 6-7 seconds, while the long period structure (Case 2) gives a similar tendency to that of the structure with no superstructure (Case 3). Figure 6 shows profiles of bending strain along Pile B2 in *y*-direction when the maximum strain appeared at 15 cm below the pile head in Case 1-3. From this figure, it is obvious that Case 2 and 3 showed similar strain distributions, while Case 1 gave quite a different profile from the others, and much larger bending strains.

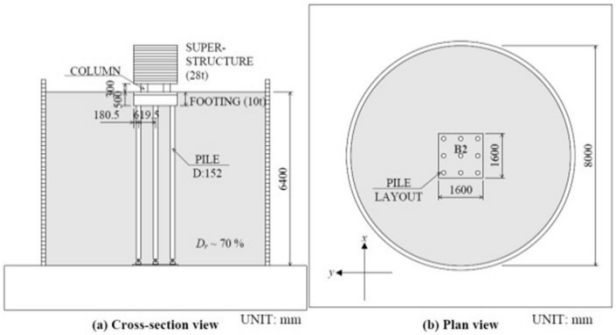

Figure 2. Specimen for SSI test and location of the pile B2

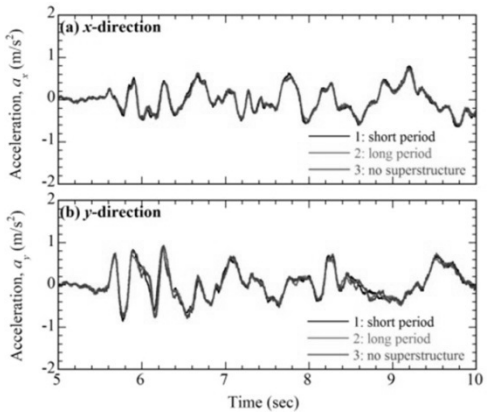

Figure 3. Comparisons of table acceleration time histories in (a) x-direction, and (b) y-direction

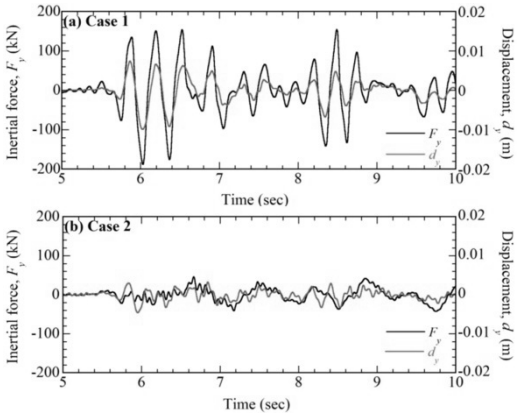

Figure 4. Time histories of horizontal inertial force induced by the superstructure and the footing (*Fy*), and horizontal displacement at the footing (*dy*)

The above comparisons show that the superstructure with long natural period (Case 2) behaved as an isolated structure, and minimized effects of inertial force of the superstructure on the piles. In addition, they indicate the inertial force of the superstructure has a great influence on the bending behavior of the piles. These facts imply that isolated superstructures can improve performance of pile foundations.

3.2 Liquefaction-induced Lateral Spreading

The other series of large-scale model shaking table tests with two different types of quay walls and a pile superstructure system right behind the walls was performed in March and December, 2006. The objectives of this testing series were to produce liquefaction and lateral spreading, and obtain better understanding on process of liquefaction generation, and failure mechanism of a quay wall and pile foundation system behind the walls. This paper briefly describes the test setup and some examples of the results from a test with a caisson type quay wall.

Figure 7 shows the test specimen built in the rectangular container. The specimen consisted of liquefiable deposit, a 2 m high caisson-type quay wall, a 40 cm thick gravel mound beneath the quay wall, and a structure supported by a pile group. The deposit was made of Albany silica sand compacted into 90 % relative density up to 75 cm from the bottom of the container, and 60 % relative density above that. The deposit was divided by the caisson into 2.5 m thick "seaside" and 4.5 m thick "landside". The level of the water table was adjusted to 0.5 m below the landside ground surface saturated with de-aired water before testing. The pile-supported structure was placed behind the caisson, consisting of six hollow steel piles, a footing and a weight representing a superstructure. The six piles were aligned with three parallels to the face line of the caisson in two rows, and fixed to the footing and pinned at the bottom of the container. The 10-ton footing was embedded into the landside deposit to a depth of 0.5 m. The 12-ton weight was placed on the footing, generating inertial force under applied motions.

The horizontal and vertical motions used for this test series were defined based on the 80 % adjusted north-south and up-down motions recorded at JR Takatori Station in the 1995 Kobe earthquake. The horizontal motion was applied in the model's long direction. The peak table accelerations were approximately 6.0 and 1.7 m/s^2 in the horizontal and vertical directions respectively, and the shaking duration was about 41 seconds. Figure 8(a) shows the acceleration time histories of the target and recorded table motions in the first 30 seconds of the shaking. Because the characteristics of the deposit were significantly changed due to liquefaction because of its high nonlinearity, the table control system could scarcely follow such change, and therefore, difference between the target and the actual table motions usually become significant. However, as shown in Figure 8, both shapes of time histories and the Fourier spectrum show reasonable agreement.

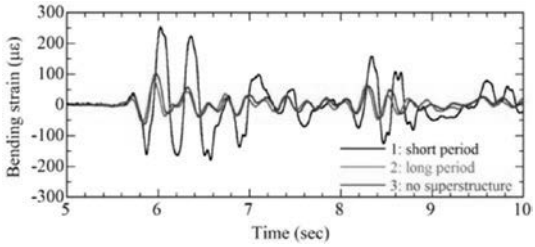

Figure 5. Bending strain time histories of the pile B2

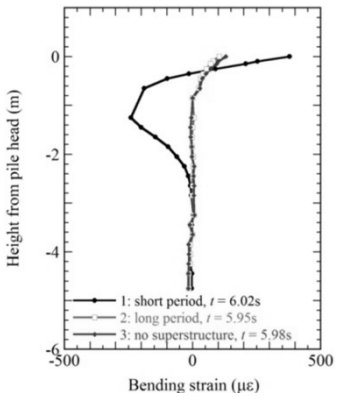

Figure 6. Bending strain distributions along the pile B2

Figure 9 illustrates permanent deformation shape of the test specimen. The caisson tilted toward the seaside at a 25-degree angle with horizontal displacement of approximately 2.0 m and 1.3 m at the top and the bottom, respectively. The mound also moved horizontally with the caisson. Three seaside piles significantly bent at almost the same elevation of the seabed as shown in Photo 3. Figure 9 also shows permanent displacement of the landside ground surface decreased with the distance from the caisson. This trend is similar to some cases observed in the 1995 Kobe earthquake (Ishihara *et al.* 1996). The above observation indicates the test was able to simulate a lateral spreading phenomenon of the liquefied deposit observed in actual damaged sites. The liquefaction and induced lateral spreading also generated approximately 20 cm settlement in the landside deposit, while relatively small settlement was observed at the seaside deposit.

Figure 10 shows the changes of excess pore water pressure, Δu, at four different depths (0.6, 1.7, 2.9 and 3.7 m from the landside ground surface) under the measurement point F indicated in Figure 7. As shown in Figure 10, Δu began to increase at all the depths when the shaking started, and then reached their overburden pressure in about 7 seconds. It shows all the depths of the deposit were fully liquefied. Following this Δu built-up process, Δu dissipation started from the bottom layer to the surface, indicating the liquefied deposit settled from the bottom to the surface. In addition, the Δu dissipation process at any depth provided identical paths from 40 to 100 seconds. This fact indicates the Δu of upper layers began to dissipate when its pressure level reached that of the lower layers.

Figure 11 shows the horizontal displacements of the caisson, the weight and the footing of the pile-supported structure, and their surrounding deposit represented by the measurement point D. Note that the point D was located on the ground surface between the caisson and the footing of the structure (Figure 7). This figure indicates the caisson significantly moved toward the seaside at 10.5 seconds. It is consistent with significant drop of the pore water pressure Δu observed at this time in Figure 10 because the pore water was released from the confinement due to the movement of the caisson. Until the caisson tilted, horizontal displacement toward the seaside at the point D was always smaller than that of the caisson, and those of the weight and the footing were smaller than those of the caisson and the point D. Also, the horizontal displacement changed with nearly the same phase. Just after the caisson significantly tilted at 10.5 seconds, the horizontal displacements of the weight and the footing became the same as one of the point D, and kept increasing together. This observation implies that a major trigger of inclination of the pile-supported structure was tilting of the caisson. Moreover, the horizontal displacement of the weight was identical to that of the footing before 12.5 seconds, and data of the footing was lost at 12.5 seconds because the marker sunk into the water. Considering on the pore water pressure drop at this time in Figure 10, it can be guessed the inclination of the structure toward the waterside started at this point.

3.3 Summaries

Through the Dai-Dai-Toku two-year projects, the following capabilities of the E-Defense testing facility could be validated:

- Reproduction of ground motion records on the table
- Simulation of liquefaction and liquefaction-induced phenomena such as lateral spreading
- Simulation of failure mechanisms on structures (e.g. piles and caissons)
- Preparation and installation of soil, structure models and sensors

Using the above capabilities, another series of large-scale model geotechnical shaking table tests has currently been conducted from FY 2010 through FY 2015. This current research project is briefly introduced in the next chapter.

4. CURRENT RESEARCH PROJECT

In the second phase of E-Defense starting at the beginning of April in 2010, another series of geotechnical engineering large-scale tests will be performed. According to goals of E-Defense, achieving resilient cities, the subject chosen for the second phase tests is “underground transportation system in mega cities”. This chapter presents fundamental descriptions about the project. More details will be published soon.

4.1 Abstract

In mega cities, many types of underground structures, such as underground road networks, subway systems, underground streets and underground parking lots, have been built. Therefore, underground structures beneath mega cities often show very complicated distribution. Subway systems in Tokyo, Osaka, New York and San Francisco Bay Area are great examples. As another example, a part of the road network around Financial District in Boston was buried into the ground to use space on the ground more effectively (Boston Big Dig Project). In addition, there are great projects of building an express railway network in some countries including the United States, and the network may be under ground in existing city areas because of the limit of space above the ground surface. Burying public city functions may be promoted more in the near future for more effective land usage and preservation of the landscape.

Regarding underground structures in mega cities, there are still some uncertainties of their seismic behavior, such as effect of neighboring structures and behavior of connections between different types of structures. In the current design practice, for instance, the effect of neighboring structures needs to be considered only for appropriate choice of construction method (e.g. prevention of unacceptable deformation of existing structures induced by construction of new structures close to the existing ones), not for estimation of their seismic performance. Such uncertainties need to be clarified in order to achieve great resiliency of urban areas against earthquake disasters by controlling risk of losing lives and properties.

In light of this, a large-scale model shaking table test of underground structures will be performed at E-Defense in FY 2011. Because large-scale test specimens can be shaken on the E-Defense large shaking table, scale effect can be relatively eliminated compared with the past experiments with smaller specimens. In addition, more detailed information will be available through the data acquired by large amounts of sensors placed on the large test specimen. As a result, more reasonable understanding on seismic behavior of underground structures, soil-structure and structure-structure interactions can be obtained analyzing the results of this “artificial case history”.

Because E-Defense shaking table tests take lots of time and cost, the best test plan must be built in order to gain more useful results, and therefore, an effective project network needs to be established. Figure 12 shows the current research network for this project, including three important components; i.e. an E-Defense large-scale model test, a small scale model test, and a numerical simulation analysis. Prior to the large-scale test, the numerical analysis, the small-scale 1-g and the centrifuge shaking table tests are conducted in order to gain fundamental information and improve plans of the large-scale tests. After the large-scale test, the small-scale test and the numerical analysis will be

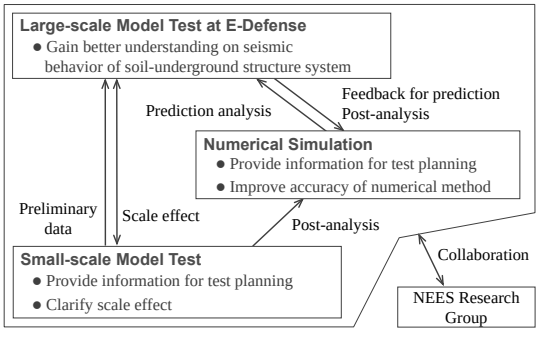

Figure 12. Project network including three important components and research collaboration with NEES

validated comparing results from all the tests and numerical simulation approaches.

In addition to the above important components, representatives of Network for Earthquake Engineering Simulation (NEES) will be involved into this research project. Current collaboration activities and possible future research collaboration are described below.

4.2 Draft of Test Plan

As mentioned above, there are still numbers of uncertainties in seismic behavior of underground structures. However, it is very difficult to perform large-scale tests in many times to reveal all the uncertainties, and therefore, the following three uncertainties are focused in the first large-scale test:

- Damage development at joints between different components such as tunnels, subway stations, vertical shafts and ventilation towers: Because of significant difference of seismic responses among these components, it is expected that damage can be localized at these joints. There are several options on types of joints, such as rigid connection, flexible connection, and connection with no fixity in an axial direction of horizontal components and fixed in the other directions (representing typical shield-shaft connections). Connections to be tested will be determined with careful consideration on types of actual structures, and reliability of data obtained. One of possible options is to use rigid connection in the first test providing results which are easy to analyze, and more complicated connections later.
- Effect of neighboring structures on seismic behavior of underground structures: Since underground space in mega cities has been highly developed, newly constructing structures often have to be designed with very small distance from existing structures. The distance between these structures is one of the significant factors affecting their seismic behaviors. This project will focus on the relationship between the distance of underground structures and magnitude of the effect of these neighboring structures. Distribution of structure specimens will be designed based on results of preliminary tests and simple pre-numerical analyses.
- Seismic behavior of vertical underground structures: Vertical underground structures are generally built through several different types of soil strata. This complexity of soils may significantly affect seismic behavior of the structures. To evaluate effect of ground composing of different types of soil strata on structural response, a vertical structure embedded into a hard soil (*e.g.* cement-mixed soil) stratum underlying a relatively soft cohesionless soil stratum is considered.

Based on these three target uncertainties defined above, one of possible setup plans for the large-scale model test and its dimensions are shown in Figure 13 and 14, respectively. The scale of this test setup is 1/30. It is noticeable that this plan is tentative, and the detailed test plans will be made based on discussion about the results to be obtained in the preliminary small-scale model shaking table test and the following simulation analyses performed prior to the large-scale test.

Materials (*e.g.* stiffness and ductility) and specifications (*e.g.* shape, dimensions, and distribution) of structure models shall be carefully chosen in order to represent typical structures and observe expected phenomenon. Materials which can give fundamental information to be used for quantitative assessment of design code and numerical analyses in small and middle levels of motions, and provide mechanism of failure development in large level of motions are ideal, but the former has higher priority if both are incompatible. Mortal with short fibers, acryl, aluminum, and steel are possible materials.

Sensoring plans shall be designed based on preliminary simulation analyses in order to obtain useful records. Accelerometers, earth pressure gauges, strain gages, shape-tape, tilt-meters and displacement transducers will be used as usual. In addition, applications of fiber optic sensors giving deformation of structures and ground, and tactile sensors showing two-dimensional earth pressure distribution at the surface of the underground structures are under examination.

Two or three levels of motions, such as small-, middle-, and large-levels, will be applied to the test specimen.

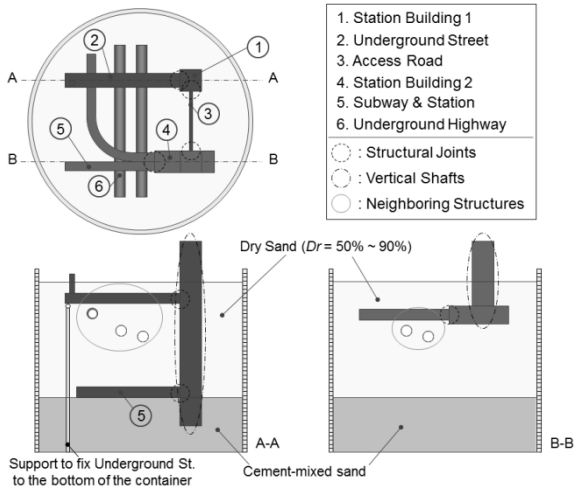

Figure 13. An example of possible test setup

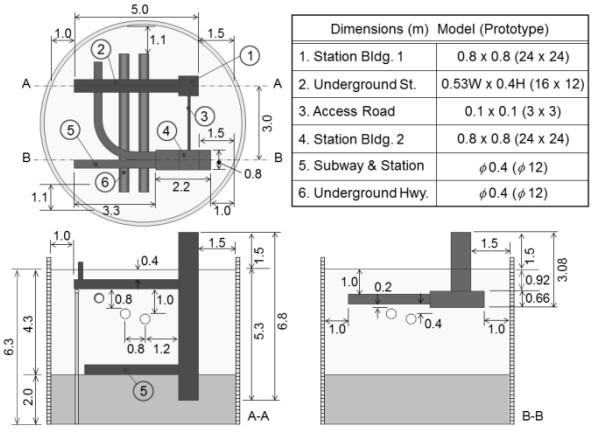

Figure 14. Dimensions of the possible test specimen

Because the height of the specimen is only about 6 m, it is difficult to simulate propagation and amplification processes of motions from the bottom to the top. Therefore, motions recorded at the ground surface in actual earthquake events will be used as large-level motions. To assess dynamic characteristics of the specimen, small-level of white noise or sweep will also be applied. Because three-dimensional behaviors of model structures are expected, especially around connections, various shaking directions will be tested by rotating directions in order to find the most critical direction giving the maximum responses of the structures.

4.3 Collaboration Works with NEES

In July 2005, NIED and NEES concluded Memorandums of Understandings (MOU) covering collaboration activities through 2010. According to the MOU, E-Defense and NEES have held 8 joint meetings as of January 2011, and some collaboration research activities. In 2010, there were three meetings in which the current geotechnical project was discussed; the 9th National and the 10th Canadian Conference on Earthquake Engineering in Toronto, the 8th NEES/E-Defense joint meeting in Miki, and 2010 Quake Summit in San Francisco. In the meetings, Japanese and U.S. geotechnical researchers exchanged opinions about the project, and determined to look for how the both will work together. Currently, a competition of preliminary simulation analysis is considered as one of possible options.

4.4 Test Schedule

This project has been performed for six successive fiscal years, 2010 through 2015. A long term schedule including contents for each fiscal year is shown in Table 3. Details of the second half of this project (FY 2013~ FY 2015) will be made based on the results in the first half (FY 2010 ~ FY 2012).

Also, details of the schedule for the first and second fiscal years are presented in Table 4. The first large-scale model test will be performed in February, 2012. Note that the test setup of the first test shall be finalized by the end of May, 2011 in the current schedule as of January 15, 2011.

Table 3. Project schedule (long term)

Fiscal Year	Contents
2010	Preliminary test for the entire soil-structure system test: - Centrifuge shaking test (scale: 1/50) - Small-scale shaking table test - Laboratory tests of geo-material to be used - Post-simulation analyses of preliminary tests - Planning the large-scale system test to be performed in FY 2011
2011	Entire soil-structure system test: - Pre-simulation analyses - Large-scale model shaking table test at E-Defense (scale: 1/30)
2012	Evaluation of the results from the system test - Post-simulation analyses - Planning the preliminary test for the other large-scale model shaking table test and the prediction analyses
2013 ~ 2015	Small-scale model preliminary shaking table test and large-scale model shaking table test (component test or another system test) Pre- and post-simulation analyses Evaluation of results from the component test Summary of the whole project

Table 4. Project schedule (short term)

Research works	Research meetings in Japan and U.S.
Fiscal Year 2010 (2010/4 ~2011/3) October, 2010 ~ February, 2011: Perform the preliminary tests (Centrifuge, small-scale shaking table tests, and laboratory tests of soil to be used) February, 2011 ~ May, 2011: Make a detailed plan of the system test	July 26-29: 9th National and 10th Canadian Conf. on Eq. Engr. (Toronto) September 17, 18: E-Defense/NEES Planning Meeting (Miki) October 7, 8: NEES Annual Meeting (San Francisco)
Fiscal Year 2011 (2011/4 ~2012/3) June, 2011 ~ January, 2012: Pre-simulation of the large-scale system test November, 2011 ~ February, 2012: Make a test specimen of the entire soil-structure system February, 2012: Perform the large-scale system test at E-Defense	(Undecided) June 9-11: 2011 NEES & MCEER Annual Meeting (Buffalo)

5. CONCLUSIONS

Since E-Defense started its operation, approximately six years have passed. Nowadays, testing knowledge and technique with the E-Defense shaking table have been developed, great connections with international research groups have been established, and various kinds of tools and sensors become available. Using the above advantages, E-Defense will keep distributing more effective and useful data to academic societies.

Abstract: A series of centrifuge model tests are conducted under the scheme of the modeling of models technique to find issues on the generalized scaling law for dynamic centrifuge tests (Iai et al., 2005). In a series of dynamic tests on a flat, saturated sand layer of 1/100 scale, four different centrifugal accelerations from 5 g to 70 g are employed on the scaled models for which the prototype is uniquely given. The models are exposed to sinusoidal input accelerations with 0.65 Hz and amplitudes of 2.5 m/s^2 and 3.1 m/s^2 in prototype scale. For response during shaking, nearly identical accelerations and excess pore-water pressure buildups are recorded for all the cases in the prototype scale. Discrepancies are found on surface settlements and duration time for dissipation of excess pore-water pressure. The major causes of the discrepancy may be (1) the duration time for the initial consolidation, (2) small value of the shear modulus due to low confining stress in model ground under low centrifugal acceleration, and (3) reduced permeability due to adsorption of viscous fluids on sand particles.

1. INTRODUCTION

Application of the geotechnical centrifuge modeling to design practice was considered in the past (e.g., Craig, 1984); however, with increasing demands on performance-based design of large structures, physical model testing seems to be facing limitations due to modeling techniques and equipment. This is where the breakthrough for physical modeling can be addressed as to directly apply test results of large prototypes to performance-based design practice. This may be one of the challenging topics for the geotechnical centrifuge community to be linked with industry (Terashi et al., 2004; Gaudin et al., 2010).

One of the great advantages of numerical analyses is that response of full-scale structures can be readily simulated, and parametric studies can be conducted just by changing numbers in input files. However, numerical methods are solely validated through results of physical model tests or real-scale behavior of geotechnical structures. Despite the fact that results of numerical analyses are merely an approximation, they have often been used for quantitative evaluation of structural behaviors without comparing results of computation with other numerical or physical models.

Use of a geotechnical centrifuge has an advantage in accurately simulating real-scale behavior in a scaled model by applying the same confining stresses to the model ground as prototypes. In the centrifuge model testing, although structural models have to be small and simplified, the prototype behavior is approximated in accordance with scaling laws (e.g., Garnier et al., 2007), and it qualitatively represents prototype behavior. One of the major obstacles for application of physical modeling results to performance-based design practice is that a specific prototype cannot be tested due to restrictions associated with experimental conditions, such as the size of the model container and scaling effects on materials. For 1-g model testing, to overcome these restrictions, the size of the experimental facility has become larger and larger so that real-scale models can be tested [e.g., E-defense (Tokimatsu et al., 2007), U.C. San Diego (Einde et al., 2004)]. However, for geotechnical structures, development of a larger research facility may still have limitations because, even with such a large facility, physical modeling with foundations and surrounding ground has to be reduced due to factors inherent in a large facility, such as the capacity of the shake table, budget, etc.

Demands for the testing of large prototypes are increasing under the restrictions mentioned above. To resolve such demands and restrictions, Iai et al. (2005) proposed the scaling law by combining the scaling law for centrifuge testing with the one for 1-g dynamic-model testing. They call it the “generalized scaling law” in dynamic centrifuge modeling. The objective of the present study is to investigate and point out issues on the applicability of the scaling law through the technique of “modeling of models” for dynamic behavior of flat, saturated sand deposits.

1.1 Brief review of the generalized scaling law

Scaling factors for physical model tests can be introduced in general forms by choosing a set of basic

physical properties to be independent and deriving the scaling factors for other properties via governing equations of the analyzed system. These primitive forms of scaling factors are listed in row (4) in Table 1. In the concept of the generalized scaling law, a model on a shaking table in a geotechnical centrifuge is considered to be a small-scale representation of a 1-g shaking-table test. Figure 1 visualizes this concept by introducing a virtual 1-g model to which the prototype is scaled down via a similitude for 1-g shaking-table tests (Iai, 1989). The virtual 1-g model is subsequently scaled down by applying a similitude for centrifuge tests to the actual physical model. In this way, the geometric scaling factors applied in 1-g tests (μ) [row (1) of Table 1] can be multiplied with those for centrifuge tests (η) [row (2) of Table 1], resulting in much larger overall scaling factors $\lambda=\mu\eta$ [row (1) of Table 1].

Table 1. Scaling factors (= Prototype/Model) in physical model tests

	(1) scaling factor for 1g test	(2) scaling factor for centrifuge test	(3) partitioned scaling factor	(4) generalized scaling factors
Length	μ	η	$\mu\eta$	λ
Density	1	1	1	1

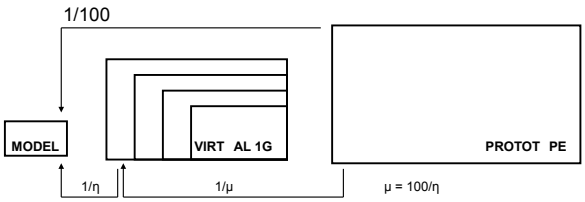

Figure 1. Concept of "modeling of models" applied to the generalized scaling.

2. DYNAMIC CENTRIFUGE TESTS ON FLAT, LOOSE, SATURATED SAND DEPOSIT

To investigate the applicability of the generalized scaling relations described above, a series of dynamic tests was conducted following the principle of "modeling of models." This technique was introduced by Schofield (1980) to assess the behavior of a prototype through repetition of the test at different scales and comparison of the results in prototype scale. In the present study, without changing the actual size of the physical model but varying the virtual 1-g dimension, the overall scaling factor ($\lambda=\mu\eta$) is kept constant (Fig. 1). Here, it is set to a fixed value comprising different combinations of the scaling factors for 1-g model testing, μ, and centrifuge testing, η. Table 2 lists the applied geometric scaling factors as well as frequencies and amplitudes of the input motions employed in the study. In what follows, units are in prototype unless otherwise specified.

2.1 Test cases

Test cases are summarized in Table 3. In the test series referred to Case A, centrifuge tests under 5, 10, 50, and 70 g were employed with the target amplitude of the input acceleration of 2.5 m/s^2. In the tests referred to Case B, centrifugal accelerations of 5, 10, and 50 g are carried out with the target amplitude of the input acceleration of 3.1 m/s^2.

Input waves are sinusoidal, and their frequency is fixed at 0.65 Hz, and duration is 35 s. Note, for example, that a case specified by "50B89" in Table 3 indicates that the centrifuge test was conducted in 50 g with 8.9 min of consolidation time in model scale in Case B. Here, the time for consolidation is the duration time given to the model to have a normally consolidated condition under specified centrifugal acceleration before shaking.

2.2 Test setup and experimental facilities

The tests were conducted in the geotechnical centrifuge of the Disaster Prevention Research Institute, Kyoto University, Japan, which has an arm length of 2.5 m and is equipped with a shaking table that allows us to expose the models to dynamic excitation in the tangential direction of flight. The instrumentation of the model is shown in Fig. 2. The strong box with inner dimensions of 45 cm by 15 cm (model scale) in width was filled up to an intended height of

Table 3. Test cases with scaling factors, properties of input motion, measured relative density and time for consolidation before shaking

Case	Scaling factors			Target input motion		Initial relative density	Time for consolidation
	1g test	Centrifuge test	Overall	Acceleration	Frequency		
	μ	η	λ=μη	(m/s^2)	(Hz)	(%)

25 cm (model scale) corresponding to a 25-m-deep sand deposit in prototype scale.

Acceleration was measured at six different depths of the model (Fig. 2). Also, with depth, five excess pore-water pressure transducers and two earth pressure transducers were installed at the locations specified in Fig. 2. Surface settlements were continuously measured with three laser-displacement transducers attached above the ground surface (Fig. 2). Reflection plates as targets of the laser-displacement transducers were hand-made with the density of the plate adjusted to slightly heavier than that of the mixture of viscous fluid so that it followed the surface settlements (Fig. 2). The height of the ground surface was also manually measured at 18 points before and after shaking.

The temperature of the model ground was monitored by digital thermometers to have the specific viscosity of the pore fluid [Metolose (Shin-Etsu Chemical Co., 1997)], which is known to be highly temperature-dependent.

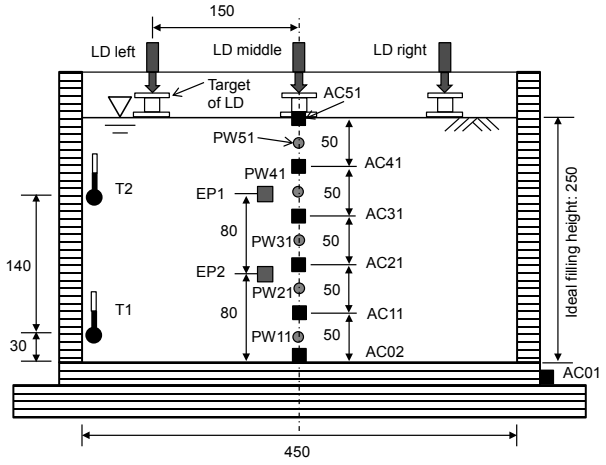

Figure 2. Test setup. LD: Laser displacement transducers. AC: Accelerometers. PW: Pore-water pressure transducers. EP: Earth pressure transducers. T: Thermometers.

2.3 Material of the model ground

The model ground was prepared with the method of water pluviation. Dry silica sand No. 7 was sprinkled slowly into high viscous water from approximately 10 cm (model scale) above water level. The relative density in the models varied between 24% and 33% in Case A, and 44% and 47% in Case B. Although the total weight of sand in the box was kept constant, a slight difference in achieved height of the model ground caused variation of the relative density.

According to the scaling factors in Table 1, the viscosity of the pore fluid has to be scaled with a factor, $\mu^{0.75}\eta$, relative to water. This leads to the use of higher viscous water in all tests than that of usual centrifuge model tests. To produce water with the specific viscosity for each test, the methylcellulose solution (Metolose, SM-100) is employed. The usability of the Metolose to produce high viscous water without changing other significant fluid parameters such as density or surface tension was tested and verified up to 100 mPa s (Dewoolkar et al., 1999; Stewart et al., 1998). As the viscosity of the Metolose solution is highly dependent on the water temperature, it was measured and adjusted by adding water or denser solution before pouring it into the strong box.

3. RESPONSE OF THE MODEL GROUND

3.1 Input and ground acceleration

To fulfill the purpose of the experiments, it is important to give the identical input motions in prototype scale for all of the test cases. Following the scaling relations of acceleration and frequency shown in Table 2, the input amplitude and time scale of acceleration for each test in model scale are determined (Table 3).

At the bottom row of Fig. 3(a), plotted are time histories of input accelerations in model scale. By applying the generalized scaling factors of acceleration and time to those time histories, they are converted into the ones shown in the bottom row of Figure 3(b). As shown in these figures, although amplitudes and durations of shaking of the input acceleration in model scale are different, in prototype scale fairly similar input accelerations are obtained for all of the tests in both cases. This guarantees that nearly identical input

acceleration was given to each model. Note that in the test 10A50 by mistake the frequency of the input motion was a little smaller than the aimed value (34.57 Hz instead of 36.55 Hz). Judging from the figures, the influence should be minor.

In the same way as the input motion mentioned above, time histories of accelerations in the model ground are plotted in Fig. 3 for Cases A. In both cases, accelerations near the ground surface in prototype scale [Figs. 3(b)] show reduction of the amplitude due to liquefaction. The envelope of the time histories in prototype scale are satisfactorily similar to one another, despite the small variation in the relative density of the model ground (Table 3).

3.2 Excess pore-water pressure

Time histories of excess pore-water pressures are compared in Figs. 4 and 5 for Cases A and B, respectively. Figures 4(a) to 4(e) show excess pore-water pressure buildup during shaking, and Figs. 4(f) to 4(j) show those until full dissipation. As shown in Figs. 4(a) to 4(e), agreements are significant for all of the cases, except for case 70A50. In 70A50, by considering that the input and ground accelerations are very similar to the others [Fig. 3(b)], pore-water pressure transducers might be malfunctioning, and possibly they were not perfectly saturated. For Case B in Figs. 5(a) to 5(e), agreements are significant, except for the tests 5B50 and 10B50, in which ceramic filters (5.0 mm thick) whose opening is much smaller than metal mesh (55-μm opening) was attached on the pore-water pressure

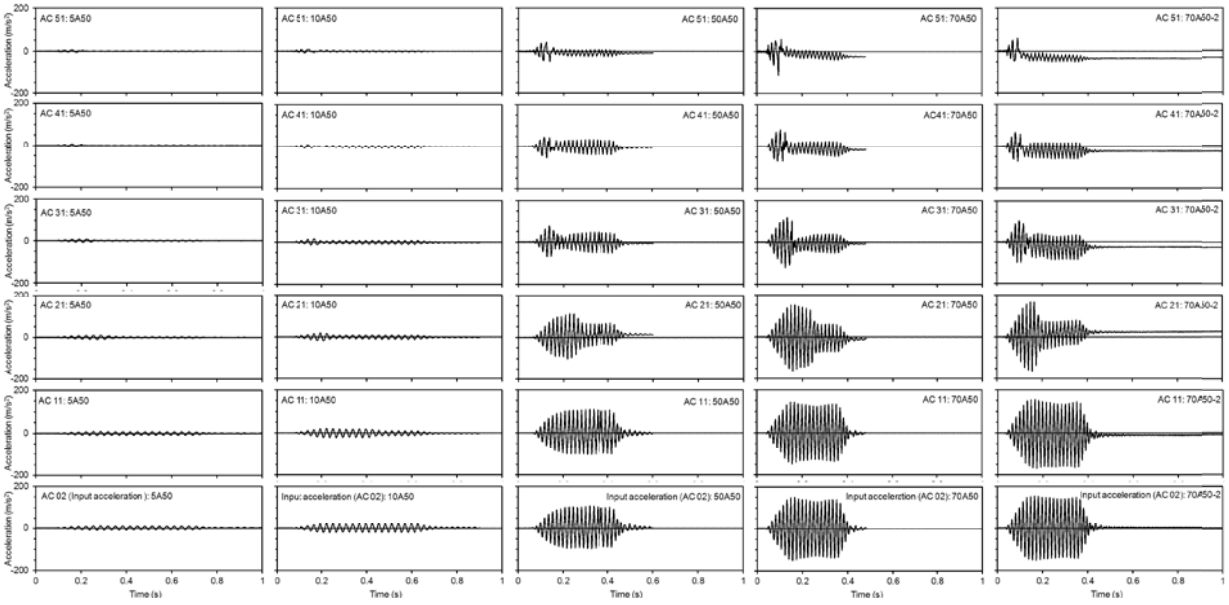

Figure 3(a). Measured time histories of acceleration in model scale for Case A.

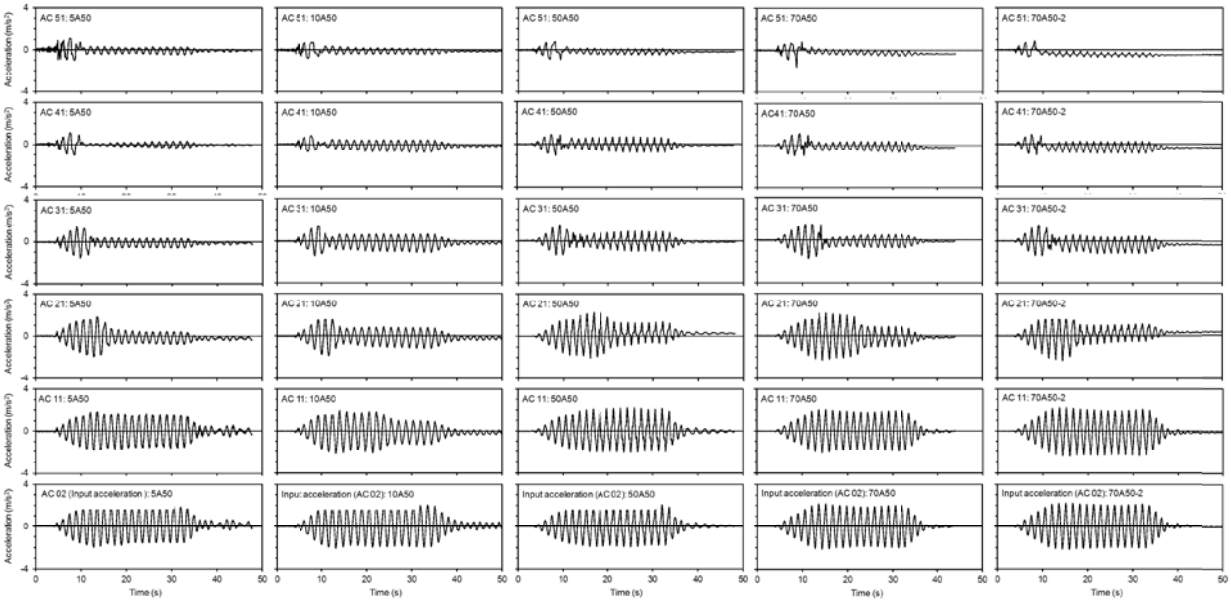

Figure 3(b). Measured time histories of acceleration in prototype scale for Case A.

transducers. Therefore, sensitivity was lost.

As shown in Figs. 4(f) and 4(g) for tests 5A50 and 10A50, the time required for full dissipation is much longer than in the other cases. The same may be said for test 5B50 and 10B50 in Case B, shown in Figs. 5(f) to 5(j), compared with the one shown in Fig. 5(j) for test 50B50. The cause of this will be investigated later.

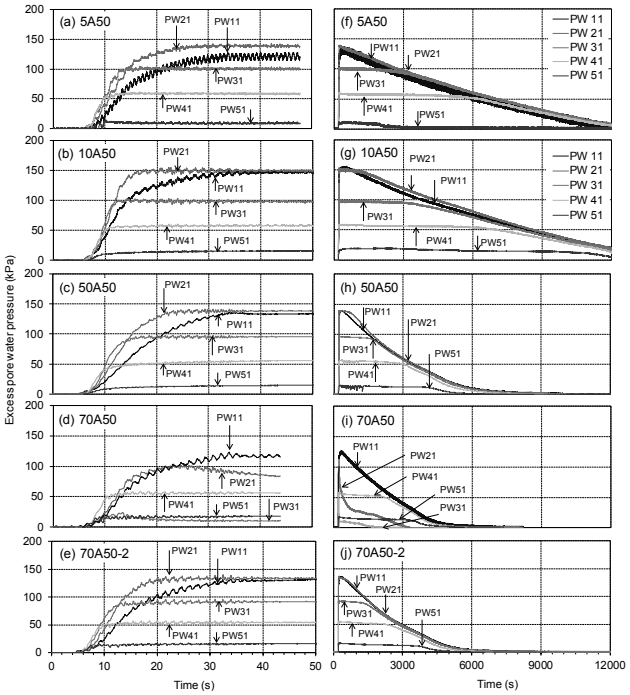

Figure 4. Measured time histories of excess pore-water pressure in prototype scale for Case A: (a) to (e) in the phase of pressure buildup (0–50 s), and (f) to (j) in the phase of dissipation (entire record).

3.3 Ground settlements

For the time range in dynamic excitation, the generalized scaling law can be verified for all reported aspects of soil behavior except for the ground settlements measured with laser displacement transducers which showed a big scatter among the models. Figure 6 shows those for Case A. In these figures, (a) to (c) are the ground settlements during shaking, and figures (d) to (f) are those until nearly complete dissipation of the excess pore-water pressure. The variations seem to be completely random. The variation observed in the ground settlements may be attributed to the device used in the tests and/or large scaling factors for displacement. The target plate of the laser displacement transducer might be influenced by the shaking because of its height, which is 3 cm in model scale (Fig. 2). Another cause may be that the scaling factor of displacement in the generalized scaling law is much larger, i.e., sensitive, compared with other scaling factors (Table 2). Therefore, special care had to be taken in the measurements of ground settlements [e.g., particle image velocimetry (PIV) (White et al., 2003)]. As shown in Fig. 6, the duration of settlements after shaking for tests 5A50 and 10A50 in Case A is much longer than the other cases with higher centrifugal accelerations. A similar trend can be seen in tests 5B50 and 10B50 in Case B—i.e., saturating the model ground with lower centrifugal acceleration tends to take more time for full settlements and give larger residual settlements.

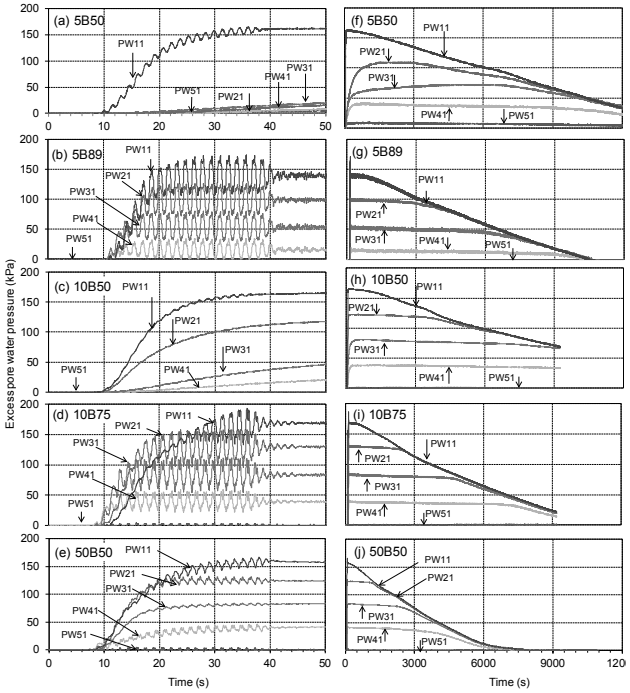

Figure 5. Measured time histories of excess pore-water pressure in prototype scale for Case B: (a) to (e) in the phase of pressure buildup (0–50 s), and (f) to (j) in the phase of dissipation (entire record).

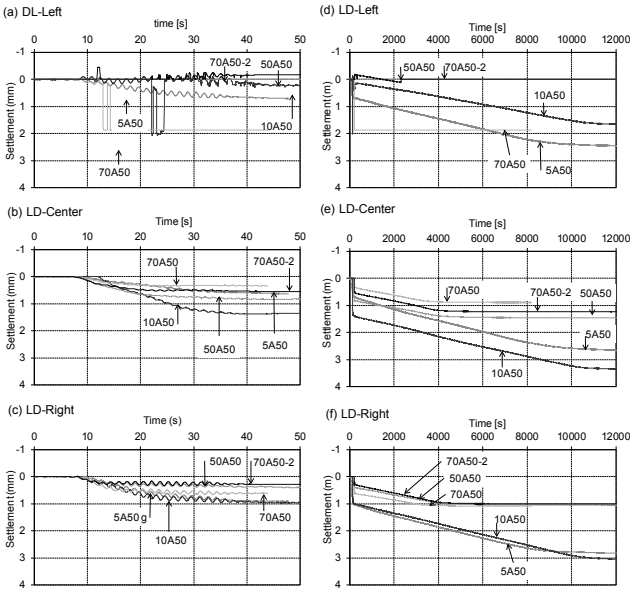

Figure 6. Measured time histories of ground settlements in prototype scale for Case A: (a) to (c) in the phase of shaking (0–50 s), and (d) to (f) in the phase of dissipation (entire record).

4. CAUSES OF DISCREPANCY AT LOW CENTRIFUGAL ACCELERATION

The two cases that were run at 5 g and 10 g showed much larger settlements and a longer duration time for pore-water dissipation in prototype scale than the others with higher centrifugal accelerations. In what follows, investigations are carried out to seek causes of the low rate of dissipation of excess pore-water pressure. Here, the following causes are assumed and examined in detail: (1) effects of duration time for consolidation before shaking, (2) effect of low effective confining stress on the scaling law, and (3) possible change of permeability of the model ground due to adsorption of the Metolose polymers on sand particles.

4.1 Effects of duration time for consolidation before shaking

In the centrifuge experiments, to have a normally consolidated ground under the given centrifugal acceleration, the model ground is consolidated about 5 min before shaking. This 5 min is arbitrarily taken because consolidation of sandy ground is assumed to be quickly achieved. However, with viscous fluid, this assumption may be a mistake. In tests 5B50 and 10B50, fluid viscosities are, respectively, 47.3 mPa s and 56.2 mPa s, and the duration times of consolidation are converted, respectively, to 281 min and 237 min in prototype scale, which is much shorter than that of 50B50—421 min.

In Case B, tests 5B89 and 10B75 are the cases in which the duration time of consolidation is adjusted so that the same duration time with test 50B50 is applied in prototype scale. In tests 5B89 and 10B75, duration times for consolidation were, respectively, 8.9 min and 7.5 min in model scale. As shown in Fig. 5(g) for 5B89 and Fig. 5(i) for 10B75, dissipation of excess pore-water pressure becomes quicker than in the cases of 5B50 and 10B50 and approaches the ones of 50 g's [Fig. 5(j)]. Although the duration time of consolidation is adjusted, a perfect match is not achieved, indicating the existence of other causes on the discrepancy.

4.2 Effect of low effective confining stress on the scaling law

The curves in Figs. 4(f) to 4(j) and Figs. 5(f) to 5(j) indicate that time required for excess pore-water dissipation becomes systematically shorter as the centrifugal acceleration increases. Model behavior in dissipation phase can be explained by the consolidation theory from which the following formula for time for consolidation is derived:

$$t = \frac{T_v d^2 m_v \gamma_w}{k} = \frac{T_v d^2 \gamma_w}{Mk} \tag{1}$$

where T_v: time factor, d: length of longest drainage pass, m_v: volume compressibility (= 1/M), M: constrained modulus of elasticity ($= 2G(1-\nu)/(1-2\nu)$), G: shear modulus, ν : Poisson ratio, γ_w: unit weight of water, and k: permeability. In the experiments under low centrifugal accelerations, the effective confining stress in model scale is low in the dissipation phase, and this may lead to a smaller stiffness of the model ground. From Eq. (1), small elastic stiffness leads to a long period of time for consolidation. Thus, scaling of stiffness might have an influence on the time of the pore-water dissipation.

In what follows, to investigate the scaling of stiffness under low effective confining stress, a scaling factor of strain in the 1-g model test is derived by fitting with experimental results.

The scaling relation of time in general form is expressed from row (4) in Table 1:

$$\lambda_t = \left(\lambda \lambda_\varepsilon / \lambda_g\right)^{0.5} \tag{2}$$

where λ , λ_ε, and λ_g are, respectively, the scaling factor of length, strain, and acceleration. In 1-g model tests, $\lambda_g = 1$, and if the scaling factor of strain is assumed to be $\lambda_\varepsilon = \lambda^{0.5}$ (Iai, 1989), then the scaling factor of time is derived from Eq. (2) as

$$\lambda_t = \lambda^{0.75} \tag{3}$$

For the scaling of centrifuge tests, $\lambda_g = 1/\lambda$, and $\lambda_\varepsilon = 1$, and therefore the scaling of time is derived again from Eq. (2) to be

$$\lambda_t = \lambda \tag{4}$$

When the scaling factor of a 1-g test is μ, and that of a centrifuge test is η, the generalized scaling factor of time is given as a combination of the above two factors (Iai et al., 2005):

$$\lambda_t = \mu^{0.75} \eta \tag{5}$$

In addition to the assumption made for the scaling factor of strains, Iai (1989) showed that when the shear-wave velocity is known, λ_ε can be determined more accurately with the following form:

$$\lambda_\varepsilon = \frac{\lambda}{\left[\left(V_s\right)_p / \left(V_s\right)_m\right]^2} \tag{6}$$

where $(V_s)_p$ and $(V_s)_m$ are, respectively, the shear-wave velocity of the prototype and the model. From Eq. (6), it is evident that the scaling of stain is closely related to shear-wave velocity, which can be readily converted to the shear modulus of the ground.

Now, let us assume that the scaling factor of strain can be expressed with α as

$$\lambda_\varepsilon = \lambda^\alpha \tag{7}$$

Then, from Eq. (2), scaling of time becomes

$$\lambda_t = \lambda^{0.5(1+\alpha)} \tag{8}$$

Scaling of time for the generalized scaling relation is expressed as

$$t_p = \mu^{0.5(1+\alpha)} \eta t_m \tag{9}$$

where t_p and t_m are, respectively, time in the prototype and the model.

Table 4. Parameters for correction of time scaling in the phase of excess pore-pressure dissipation

	Sacling factor of length						Scaling factors			
	1 G	Centrifuge					Time	Displacement		
	μ	η	t_1	t_2	Δt_m	α	$\mu^{\alpha}\eta$	$\mu^{\alpha+1}\eta$	$(V_s)_p/(V_s)_m$	G_p/G_m
5A50	20	5.0	50.0	261.6	211.6	-0.08	20.0	79.8	5.00	2.24
10A50	10	10	44.7	242.8	198.2	-0.39	20.2	40.7	4.96	2.23
50A50	2.0	50	19.5	81.8	62.3	-0.16	66.8	89.2	1.50	1.22
70A50-2	1.4	70	12.1	63.3	51.2	0.50	91.5	119.5	1.09	1.05
5B50	20	5.0	151.5	402.2	250.8	-0.20	16.5	54.3	6.07	2.46
5B89	20	5.0	107.7	216.5	108.7	0.43	42.5	362.0	2.35	1.53
10B50	10	10	139.0	302.8	163.8	-0.19	25.3	63.9	3.96	1.99
10B75	10	10	82.4	194.4	112.0	0.20	39.6	157.1	2.52	1.59
50B50	2.0	50	30.6	82.5	51.9	0.92	97.2	188.8	1.01	1.01

Next, parameter α is fitted with experimental results. Here, the duration time for the excess pore-water dissipation measured at PW31 of test 70A50-2, Δt_p^{70}, in prototype scale, is taken as a reference value to be fitted. Then, by assuming that the duration times for dissipation at PW31 of other tests, Δt_p, in prototype scale, are equal to Δt_p^{70}:

$$\Delta t_p = \Delta t_p^{70} \tag{10}$$

Rewriting Eq. (10) with the generalized scaling factors given in Eq. (9), with time in model scale, Δt_m and Δt_m^{70},

$$\mu^{0.5(1+\alpha)} \times \eta \times \Delta t_m = \mu_{70}^{0.5(1+\alpha)} \times \eta_{70} \times \Delta t_m^{70} \tag{11}$$

where $\mu_{70} = 1.4$ and $\eta_{70} = 70$ are scaling factors, respectively, in the virtual 1-g and 70-g centrifuge model tests. Here, the duration time for dissipation in model scale is defined as,

$$\Delta t_m = t_2 - t_1 \tag{12}$$

where t_1 corresponds to the time when the excess pore-water pressure at PW31 starts to decrease [Figs. 7(a)–(d)] and t_2 is defined at the time when the excess pore-water pressure becomes 5% of the one at time t_1. Solving Eq. (11) for α yields

$$\alpha = 2\left(\log\frac{\eta_{70}\Delta t_m^{70}}{\eta\Delta t_m}\right)\left(\log\frac{\mu}{\mu_{70}}\right)^{-1} - 1 \tag{13}$$

Table 4 shows the computed value of α by substituting Δt_m and Δt_m^{70} into Eq. (13).

In Table 4, the shear-wave ratio is computed by

$$(V_s)_p / (V_s)_m = \mu^{(1-\alpha)/2} \tag{14}$$

and the ratio of shear modulus G_p/G_m is computed by taking the square root of Eq. (14), where G_p and G_m are, respectively, the shear modulus in prototype and model scale.

Figures 7 (a) to 7 (d) show time histories of excess pore-water pressure in model scale. In these figures, duration time for dissipation is indicated by dotted vertical lines. Figures 7(e) to 7(h) are the converted time histories in prototype scale with fitted scaling factors of time listed in Table 4. Here, the scaling for stress—i.e., the magnitude of excess pore-water pressure—is not affected by the fitting procedure.

Ratios of the shear modulus computed with the fitted parameter α in Table 4 show that if the 1-g scaling factor of strain is given as $\lambda_\varepsilon = \mu^{0.5}$ —i.e., $\alpha = 0.5$, then the ratio is assumed to be $G_p/G_m = 0.96$. In this case (70A50-2), it is recognized that the stiffness of the model and the prototype are nearly equal.

For tests with low centrifugal accelerations, 5A50 and 10A50, the values of α are negative, and the ratios are computed to be G_p/G_m(5 g) = 2.24 and G_p/G_m(10 g) = 2.23, which is about two times the one obtained from test 70A50-2, G_p/G_m(70 g) = 1.05 (Table 4). From this computation, if we demand that the shear modulus in prototype scale is constant regardless of the level of centrifugal acceleration, then the shear modulus under low centrifugal acceleration has to be about half of that under high centrifugal acceleration [e.g., G_m(70 g) = 2.1G_m(5 g)]. Thus, in the experiments conducted under low centrifugal acceleration, shear modulus or elastic modulus of the model ground in model scale has to be adjusted smaller than that in high centrifugal accelerations so that an identical duration time of excess pore-water pressure dissipation is achieved in prototype scale.

The fitting for Case B is done by the same procedure by taking the same value of the test 70A50-2 as a reference. In Table 4, the values of parameter α for tests 5B89 and 10B75 are, respectively, 0.43 and 0.20, and the shear modulus ratios are, respectively, G_p/G_m(5 g) = 1.53 and G_p/G_m(10 g) = 1.59, which are smaller than those obtained from tests 5A50 and 10A50 and close to the one in 70A50-2 [G_p/G_m(70 g) = 1.05]. Again, if we demand that shear modulus in prototype scale is identical, we obtain G_m(70 g) = 1.4G_m(5 g) and G_m(70 g) = 1.5G_m(10 g). Thus, to achieve identical duration time for dissipation of excess pore-water pressure with the one under high centrifugal acceleration, the shear modulus in model scale under low centrifugal acceleration has to be larger than that in prototype scale. The discrepancy investigated in this section may be due to the small value of the shear modulus caused by the low confining stress in the model ground under low centrifugal acceleration.

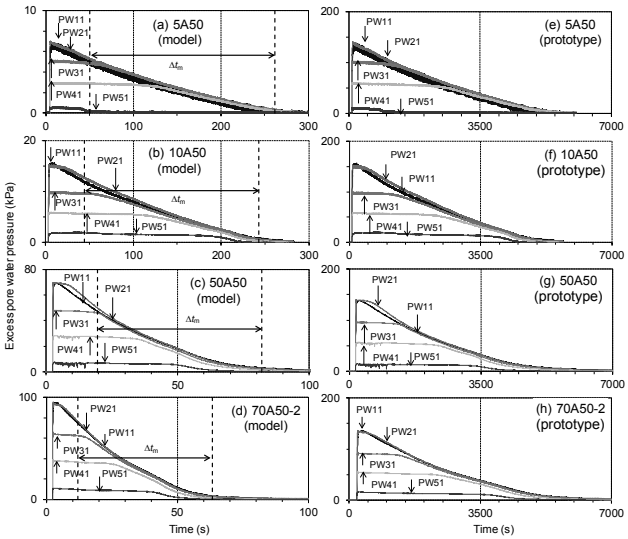

Figure 7. Time histories of excess pore-water pressure build-up for Case A: (a) to (d) model scale, (e) to (h) fitted curves in prototype scale. (h) is shown in Fig. 5(j).

4.3 Possible change of permeability of the model ground due to absorption of the Metolose on sand particles

In the experiment, the Metolose (methylcellulose) was used as a substitute for pore fluid so that scaling for excess pore-water pressure dissipation is satisfied with dynamic conditions (Ko, 1994; Stewart et al., 1998; Dewoolkar et al., 1999). It is known that the viscosity of the methylcellulose is exerted by long chains of micro-fibers (polymers) constituted of cellulose (Stewart et al., 1998). Because of the form of micro-fibers, absorption of the Metolose on sand particles might occur. To investigate the possibility, falling head permeability tests for silica sand No. 7 with a relative density of 40% with water, Metolose solution, and silicone oil were conducted. To conduct the tests, the procedure specified by JIS A 1218:2009 was followed. A metal-mesh net with a 75-μm opening was used as a filter instead of using filter paper in order to prevent clogging of molecular cellulose. Metolose of 2% solution was prepared and adjusted to specific viscosity by adding water. Details of tests can be found elsewhere (Tobita and Iai, 2010, under preparation).

Test results are summarized in Fig. 8. As shown in Fig. 8(a), the permeability of water is kept constant at about 1.0×10^{-2} cm/s. The reduction of permeability after the 11th measurements with water is -4.7%, which can be regarded as no reduction. Meanwhile, as shown in Figs. 8(b) and 8(c), the permeability with the Metolose is consistently decreasing with the number of measurements. For example, the permeability of viscous fluid of 15 mPa s is decreased 44% from 1.46×10^{-3} cm/s to 8.13×10^{-4} cm/s after the 11th measurements. In Fig. 8(d), although the permeability of silicone oil is fluctuating, the permeability is nearly constant for each viscosity.

The reduction in permeability that may be achieved with an increase in pore-fluid viscosity is mostly smaller than the expected values. For example, a reduction in permeability by a factor of 2.4 was recorded for an increase in viscosity of 5 times. This trend has been reported in other research papers (Stewart et al., 1998; Dewoolkar et al., 1999). Stewart et al. (1998) gave possible explanation for this discrepancy that both the Metolose solution and silicone oil may exhibit non-Newtonian behavior, where viscosity is not constant with varying velocity gradients. If this is the case, the reduction ratio of permeability would be different than that of the inverse viscosity ratio.

Based on the permeability test data, the permeability of the model ground during the centrifuge experiments might be slightly decreasing as excess pore-water pressure dissipates with the flow of the viscous fluid. However, no clear trend is found on the permeability change with the magnitude of viscosity. Further investigation is necessary to identify the effect of the absorption on the reduction of permeability.

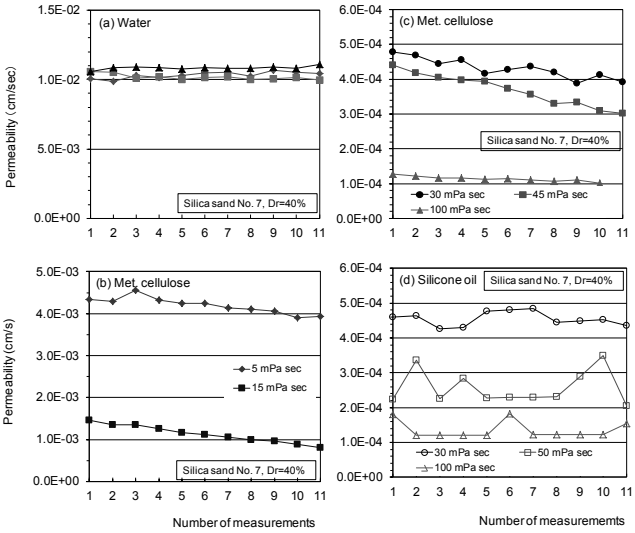

Figure 8. Variation of permeability with the number of measurements: (a) water, (b) methylcellulose of 5 and 15 mPa s, and (c) methylcellulose of 30, 45, and 100 mPa s, and silicone oil of 30, 50, 100 mPa s.

5. CONCLUSIONS

To investigate the applicability of the generalized scaling law in dynamic centrifuge tests on a flat, saturated sand deposit, the modeling-of-models technique was implemented in centrifugal accelerations ranging from 5 to 70 g, and the results were compared in prototype scale. In the tested range of an overall scaling factor of 1/100, the applicability of the generalized scaling law was confirmed for the time range during dynamic excitation. Only the ground settlement in this time range varied among the cases with different centrifugal accelerations. One of the causes might be the target device for the laser displacement transducers, which might not be stable under shaking conditions. Additional care has to be given to measurements of displacement because in the generalized scaling law the scaling factor of displacement tends to be very large, and in turn very sensitive to the measurements.

In the time histories of pore-water dissipation and surface settlements, two cases below 10 g showed much larger duration time for excess pore-water pressure dissipation. Investigations are carried out for (1) the effect of duration time for consolidation before shaking, (2) the effect of low effective confining stress on the scaling law, and (3) possible change of permeability of the model ground due to absorption of methylcellulose polymer on sand particles. A major cause of the discrepancy might be the small value of elastic stiffness due to low confining stress in the model ground under low centrifugal experiments. From results of the permeability tests, use of the Metolose to simulated dissipation behavior is questioned because of the possibility of the absorption on sand particles.

Abstract: Liquefaction is a critical seismic design issue for geotechnical engineers who are concerned with minimizing damage to lifelines and to maintain performance during and immediately following an earthquake. One developing research tool that may give more insight into liquefaction behavior of soils and structures is through the use of controlled blasting. Initially used as a ground improvement technique, controlled blasting has expanded its applicability to full-scale in-situ liquefaction experiments. In order to promote interest in the emerging topic, this paper aims to provide background into the use of blasting, the mechanics behind the method, existing empirical models to predict soil response, and a presentation on a newly developed empirical model that can be used for blasting studies utilizing multiple blasts.

1. INTRODUCTION

The framework for the understanding of liquefaction began with post-earthquake investigations and laboratory testing. Based upon these observations and results, empirical models were developed that integrate in-situ testing measurements, such as the standard penetration test (SPT), cone penetration test (CPT) or shear-wave velocity measurements, into the liquefaction assessment. Although these models have shown to be applicable for "textbook" liquefiable soils (i.e. loose, saturated clean sands to silty sands), there are some recognized limitations to these methods.

One critical limitation is that these models can become unreliable for gravels, clays, and silts that can be susceptible to strength loss following an earthquake (Bray and Sancio, 2006). Secondly, the laboratory tests that helped form the models may have included uncertainties such as sample disturbance, sample size, misrepresentation of existing conditions of the site, and human error. Therefore, to minimize some of the uncertainties and limitations in performing liquefaction assessments, in-situ testing has been proposed as the supplemental but refining step in the efforts to understand liquefaction, including soil susceptibility and behavior. Testing soil in its in-situ state is highly advantageous as it can minimize effects due to sample disturbance and can account for existing stress conditions.

Current methods emerging as in-situ testing tools include vibroseis and controlled blasting. Vibroseis utilizes a large vibrator applied at the ground surface to induce shear strains at a constant rate to create pore pressure buildup within the soil (Chang et al. 2007). Controlled blasting utilizes detonation of buried explosives, and can generate excess porewater pressures as the shock wave passes through the soil.

2. CONTROLLED BLASTING

2.1 History

Controlled blasting began as a ground improvement to densify loose soils such as embankments and mine tailings (Narin van Court and Mitchell 1994). Prompted by military interest, controlled blasting studies were performed to determine the radius of liquefaction for various types of explosives (Charlie et al. 1988). Recently, blasting has been integrated into seismic studies to initiate liquefaction for several different projects, including a pile behavior (Ashford et al. 2004) and performance of lifelines (Sugano et al. 2002, PARI 2009). Rollins et al. (2004) and Gohl et al (2001) discuss the use of blasting to perform in-situ liquefaction evaluations as a supplement to existing methods.

2.2 Mechanics of Blasting

The effectiveness of blasting is highly influenced on the site conditions, such as soil and rock properties and groundwater conditions, and blasting parameters, including charge weight per unit volume of soil, placement, delay time, and sequence (Charlie 1988). Generally, denser soils require more explosive energy (i.e. charge weight) as they exhibit greater shear strength than looser soils. Also, more explosive energy is required as the distance between the explosive and intended liquefaction area is increased due to attenuation. During blasting, shock waves travel radially from the source throughout the soil as a compression wave. When interfaces are encountered, such as rock-soil boundaries, water table, or ground surface, shear waves and surface waves can be

generated, imparting energy into the blast area. An example of generalized wave paths is shown on Figure 1. A point of interest, as shown in Figure 1, will feel the compression waves first as they travel faster than shear waves. The controlling wave is determined by the distance between the energy source and the point of interest. The compression waves "subject the soil to large and abrupt, albeit short-lived, pressure and strain pulse" (Dowding and Hryciw 1986), but they attenuate much quicker than shear waves. This is observed in earthquakes where the source is tens to hundreds of kilometers away, causing the controlling wave to be shear waves. However, in blasting, the compression waves are the controlling wave due to the short distances separating source to point of interest.

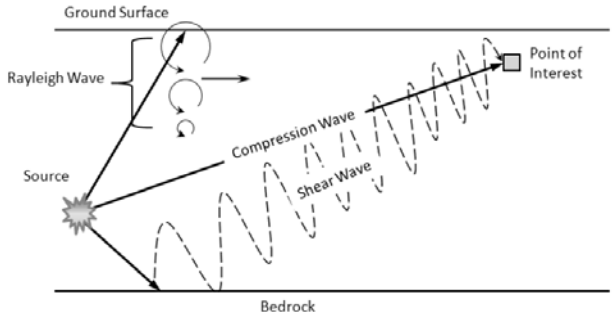

Figure 1 Generalized Wave Paths from an Explosion

Initially, large single explosions were used to liquefy soil. However, it was found that this was ineffective, particularly for ground improvement methods, as it caused cracking in overlying soils and substantial heat loss (Narin van Court and Mitchell 1994). Time-delayed multiple blasts have been used to cyclically load the soil, inducing shear strains in the soil. If the strains are large enough to weaken the soil structure, excess pore pressures can be generated. During undrained conditions, the excess pore pressures lead to a reduction in the effective stress of the soil, leading to a complete loss of shear strength when the excess pore pressure is equal to the initial effective stress. At this state, liquefaction has occurred.

During blasting, a soil will experience three distinct pore pressure response stages: (1) peak, or transient, pore pressure that is attributed to the compression wave, (2) excess (residual) pore pressure, and (3) dissipation of pore pressure. These stages are illustrated in generalized example shown in Figure 2, which show three blasts detonated at time intervals of 1.0 second. The peak pore pressures can exceed the liquefaction level of Ru = 1.0, but they are short-lived. As the excess pore pressures dissipate, the soil transition from their suspended state due to liquefaction and settle, generally rearranging themselves into a denser state than pre-blasting conditions.

2.3 Predicting Pore Pressure Response

Several studies have been conducted to predict pore pressure response with blasting. The general method is to relate excess pore pressure represented by the residual pore pressure ratio, Ru, to the scaled distance, $R/W^{0.33}$, where W is the TNT-equivalent charge size in kilograms, and R is the radial distance between the point of interest and the explosive charge in meters. The inverse of the scaled distance is also used, and is referred to as the Hopkinson's Number (Narin van Court and Mitchell 1994). Other methods predict pore pressure response by peak particle velocity or compressive strain (Charlie 1988, Al-Qasimi et al. 2005).

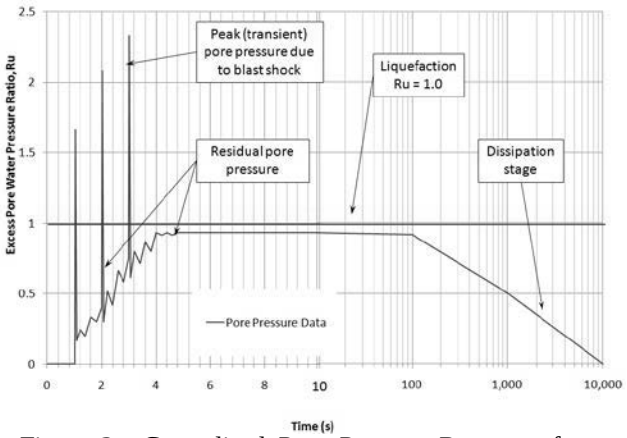

Figure 2 Generalized Pore Pressure Response from an Explosion

Much of the past research in estimating excess pore pressures was centered in saturated sandy soils using single blasts. The first such study observed that liquefaction typically occurred between $R/W^{0.33}$ values of 6 to 8 for a sandy soil with a relative density of 30 to 40% (Ivanov 1967). The most commonly referenced empirical method is the Studer and Kok (1980) relationship developed from a blasting study in Amsterdam Harbor using single blasts. Their method, based on scaled distance, is represented by the following equation and Figure 3:

$$Ru = 1.65 + 0.64 \ln \frac{W^{0.33}}{R} \qquad (1)$$

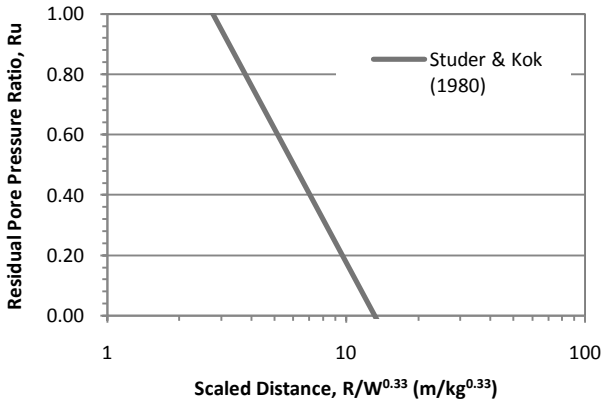

Figure 3 Studer & Kok (1980) Empirical Model predicting residual pore pressure with blasting

2.4 Motivation for Research

In evaluating the current methods used to relate pore pressure buildup with blasting, there are 2 significant limitations associated with these models, particularly the main referenced model by Studer and Kok (1980). The first limitation is that the empirical model does not consider soil conditions when predicting pore pressure response, as it is solely based on charge weight and distance between explosive and point of interest. Generally, denser soils would require more energy to cause contraction and resulting excess pore pressure than loose soils but this is not accounted for or consider with the models.

Secondly, current practice today uses multiple blasts to induce liquefaction rather than the large single blasting program used to develop these models. To induce pore pressure generation within a soil, more energy is required to do it in one blast (i.e. 1 cycle) than in multiple blasts due to cyclic loading. Therefore, an empirical model for single blasts would not be applicable to using multiple blasts for it may underestimate the scaled distance (i.e. representing more energy) for a specific *Ru* value. Therefore, it was deemed that it would be beneficial for the future development of blasting for liquefaction studies to refine the methods used previously to account for multiple blasting and in-situ soil conditions.

3. Development of a Refined Empirical Model

3.1 Accounting for Multiple Blasts

Generally, most of the empirical models relate *Ru* with the scaled distance, $R/W^{0.33}$. The scaled distance is easily calculated for single blasts, but it became unclear how to account for multiple blasts where the distances, weights, and time delays all affect development of *Ru*. Therefore, the following assumptions were made prior to conducting the research:

- The magnitude of pore pressure generated from each sequential blast is influenced by the previous blast and resulting *Ru*. A blast of the same scaled distance will have a different effect on the soil when $Ru = 0$ versus when $Ru = 0.5$.
- Time delays between blast are short enough to minimize significant pore pressure dissipation
- Blasting pattern was not a significant factor in pore pressure generation.

Therefore, from these assumptions, a general method to account for pore pressure generation with multiple blasts was established, and is represented by the following equation:

$$R/W^{0.33} = \frac{\overline{R}}{\Sigma W^{0.33}} = \frac{\left(\frac{R_1+R_2+\ldots R_i}{N_i}\right)}{\Sigma(W_1+W_2+\ldots W_i)^{0.33}} \qquad (2)$$

Where *R* is the radius in meters, *W* is the equivalent charge weight to TNT in kilograms, *N* is the number of blasts, and *1,2,* and *i* denote the associated distance and weight of the charge number.

3.2 Case Histories

After establishing a method to account for multiple blasts, several case histories were selected to development a potential empirical model.

Table 1 – Blast-Induced Liquefaction Case Histories

Test Location/Year	Purpose of Study	Principal References
Ishikari, Hokkaido Island, Japan (2007)	Observe resiliency of airport infrastructure subjected to liquefaction	PARI (2009)
Vancouver, British Columbia., Canada (2004)	Evaluate performance of vertical earthquake drains to mitigate liquefaction	Rollins (2004) Strand (2008)
Maui, Hawaii, USA (2004)	Assess in-situ liquefaction potential of coralline sands	Rollins et al (2004)
Tokachi, Hokkaido Island, Japan (2002)	Performance of piles, pipelines, and quay walls against lateral spreading	Ashford & Juirnarongrit (2004)
Delta, British Columbia., Canada (2004)	In-situ liquefaction evaluation to supplement other data	Gohl et al. (2001)
Treasure Island, San Francisco, California, USA (1998)	Determine lateral load-displacement relationships for piles subjected to liquefaction	Ashford & Rollins (2002) Ashford et al. (2004)
Fort McMurray, Alberta, Canada (1997)	Investigating the potential for blasting as a liquefaction assessment technique	Pathirage (2000)

From the references presented in Table 1, in-situ soil conditions, blasting layout, and pore pressure results were collected. There are several other case histories performed in the past three decades, but these were deemed as being the most useful towards the research due to the available data. Based upon the pore pressure results and blasting layout, and utilizing Eq. (2), *Ru* was plotted against $R/W^{0.33}$ for each case history. The results are shown in Figure 4.

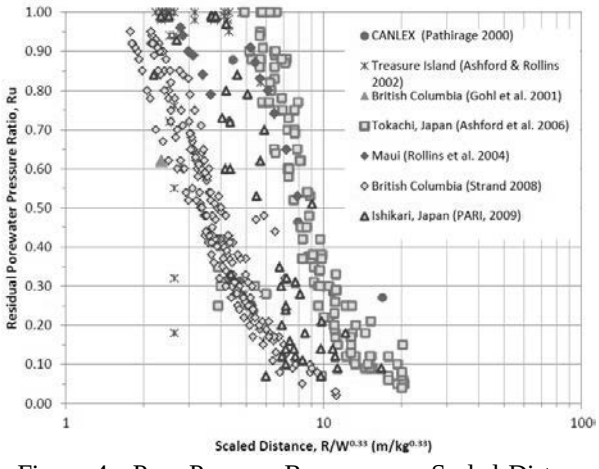

Figure 4 Pore Pressure Response vs. Scaled Distance for Multiple Blasts

Of the case histories analyzed, no two were alike. The tests varied in soil type, density, overlying soils, aging effects, blasting layout, time delays, and many others. However, the goal of the research was to develop an empirical model that could better predict pore pressure generation from blasting.

From Figure 4, it is observed that the pore pressure results all follow a trend of increasing *Ru* with decreasing scaled distance. However, the range of scaled distance for a given *Ru* value, such as 1.0, varies from 2.1 to approximately 7 m/kg$^{0.33}$. In a different view, at a scaled distance of 7 m/kg$^{0.33}$, *Ru* values range from 0.07 to 1.0. This shows that using scaled distance alone to relate to *Ru* is not sufficient. It may be better to account for soil conditions which can affect pore pressure development.

3.3 Regression Analysis

To identify the influence of in-situ soil conditions on predicting blast-induced pore pressure development, several multiple regression analyses were performed. The soil parameters used in the analyses included corrected SPT $(N_1)_{60}$ values, initial relative densities (D_r), corrected shear wave velocities (v_{s1}) initial effective overburden pressure (σ'_{vo}) and the cyclic resistance ratio (*CRR*) as determined from the Youd et al. (2001) method. The scaled distance $R/W^{0.33}$ was used to represent blasting conditions. The results from the analysis, represented by the adjusted correlation scoefficient R^2, are shown below in Table 2. The adjusted correlation coefficient R^2, describes the variability of the predicted data (i.e. *Ru*) as explained by the predictors (i.e. scaled distance, in-situ conditions), and forecasts how well future events are able to be predicted by the model by describing the linear association of the dependent factor to the regressors. A R^2 value of ±1.0 indicates a good fit of the model to the data.

Table 2 – Results from Multiple Regression Analyses

	Blasting Parameters		In-situ Soil Parameters					
Test	Ru	R/W$^{0.33}$ m/kg$^{0.33}$	Relative Density, Dr %	Effective Overburden Stress, σ'v kPa	SPT N-value $(N_1)_{60}$	Cyclic Resistance Ratio, CRR	Shear Wave Velocity, v_{s1} m/s	Adjusted Correlation Coefficient, R^2
1	X	X						0.43
2	X	X	X					0.49
3	X	X		X				0.52
4	X	X			X			0.57
5	X	X				X		0.53
6	X	X					X	0.56
7	X	X		X	X			0.64
8	X	X		X	X	X		0.60
9	X	X		X	X		X	0.62
10	X	X	X	X	X	X	X	0.64
11	X	X			X	X	X	0.62

The regression results shown in Table 2 provide many helpful insights into understanding what has a significant role in predicting blast-induced pore pressure response. When looking at the first test that only considered blasting parameters, the R^2 value of 0.43 confirms that this parameter alone is not a sufficient parameter to estimate blast-induced pore pressure. Test #7, which included SPT $(N_1)_{60}$ values and initial effective overburden pressure (σ'_{vo}) in the analysis, provided the better and most practical model with a R^2 value of 0.64. This is considered the most practical of the models as SPT blowcounts are typically performed in the field prior to testing.

The equation for the empirical model from test #7 provides a logarithmic fit that is consistent with previous models. The equation is as follows:

$$Ru_{multiple-log} = 1.747 - 0.512 \ln\left({}^{R}/_{W^{0.33}}\right) - 0.032(N_1)_{60} - 0.002\sigma'_{v0}\,(kPa) \quad (3)$$

A p-value test was performed to evaluate the reasonableness of including a parameter in the regression analysis. The p-value test indicated that both the SPT $(N_1)_{60}$ value and initial effective overburden pressure (σ'_{vo}) are valid predictors in the analysis. As shown by the equation, the *Ru* value is decreased by increasing SPT $(N_1)_{60}$ values and initial effective overburden pressure (σ'_{vo}). This coincides with the fundamental understanding of inducing pore pressure: denser soils require more energy than looser soils. An example of the model with SPT $(N_1)_{60}$ of 5 and σ'_{vo} of 50 kPa is plotted in Figure 5.

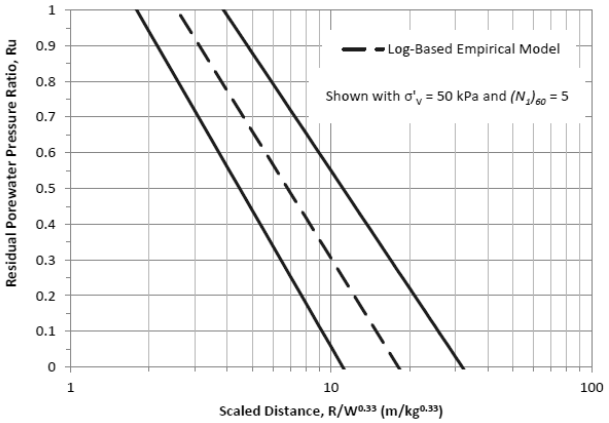

Figure 5 Empirical Model developed for Multiple Blasts (shown with 95% confidence limits)

Although this model can be compared to previous blasting tests, the best and most scrutinizing test would to perform a field blasting experiment. Some uncertainties and limitations that may exist include:

- Consideration of blasting layout. It was observed that simpler layouts (with less than 30 blasts) were better represented by the model than larger, more complex layouts.
- Time delays between blasts may be a factor if significant drainage is occurring within the soil.
- The model was developed for a bounded range of vertical effective overburden stress from 14 to 136 kPa, and SPT $(N_1)_{60}$ values from 1 to 16 blows per 30 cm.

4. CONCLUSIONS

Once used as a ground improvement technique, controlled blasting is developing into a useful research tool to induce excess pore pressures for in-situ liquefaction research. Currently, there are several empirical models to blast-induced pore pressure but to the authors' understanding, they typically do not consider in-situ soil conditions but are solely based on blasting parameters as represented by the scaled distance. Through the use of several controlled blasting case histories, a statistical analysis was performed to identify whether residual pore pressure could be predicted based upon the blasting layout and in-situ soil conditions for multiple blasts.

An empirical model that factors in soil density as represented by SPT $(N_1)_{60}$ values and initial effective overburden pressure (σ'_{vo}) with scaled distance, $R/W^{0.33}$ was developed with a R^2 value of 0.64. This R^2 value indicates that the model does not consider all factors affecting pore pressure development during blasting. However, it is anticipated that the model will provide a better fit than previous models, and is more versatile in that it can be applied to multiple blasts rather than a single blast, and for a variety of soil types.

The true validity test is to perform blasting experiments and compare field measurements to predicted results. If the model is validated, this information can be used in future blasting studies to serve as a tool in developing blasting layout as a function of soil conditions.

Abstract: Three dynamic centrifuge model tests were conducted to simulate the seismic responses of sandy soil deposits with a silt seam embedded at various depths. The model sand beds had the same relative density and were saturated with the same viscous pore fluid and then were subjected to the same magnitude of base acceleration. The aim of this study is to investigate the effect of existence of low-permeability silt seam embedded at the different depths for a level ground on the generation and dissipation of excess pore water pressure, the surface settlements and the related liquefaction mechanism in a loose sand deposit. The test results show that (1) the silt seam in the sand deposit can reduce the extent of liquefaction and surface settlement; (3) the magnitude of surface settlement is proportion to the values of the proposed area ratio; (2) liquefaction occurs only beneath the silt layers on the sand bed with a shallow silt seam. However, for the deeper silt intra-layer, liquefaction occurs not only in the sand beneath the thin silt layers but also in the sand near the ground surface.

1. INTRODUCTION

Soil liquefaction or partial loss of soil strength during earthquakes causes severe damage to geotechnical structure systems (e.g., settlement of buildings, pile damage due to lateral spreading of liquefied soils). Natural soil deposit normally consists of sublayers with different permeability, i.e., thin silt or clay layer. In some cases, the thin silt or clay sublayer may not be indentified by a normal geotechnical exploration procedure. If a silt or clay seam is sandwiched in the sand deposit, an upward flow of excess pore water pressure will form a water film beneath the silt seam (Kokusho 1999). Kokusho (2000) also used a simple consolidation theory to simulate the process of water film growth and decay beneath a thin silt seam. This zero strength of thin water film might result that a lateral spread or slope failure in a liquefied ground took place even after ending of shaking. Malvick et al. (2003) performed a centrifuge shake table test to demonstrate formation of water films and void redistribution. The effect of silt seam on the emergency of water film is the major consequence in lateral spreading. In this paper, a series of 1-D centrifuge shaking table tests was performed to investigate the seismic response, pore water pressure generation and post-liquefaction behavior for a sand deposit intra-layered a silt seam at different depths. Two arrays of accelerometers and pore water pressure transducers were used to monitor the time histories of acceleration and the excess pore water pressure along the depths for loose sand subjected to 1-D shaking.

2. GEOTECHNICAL CENTRIFUGE MODELING AND TESTING PROCEDURES

2.1 Testing Equipments

This experimental work was undertaken in the Centrifuge at the National Central University (NCU), Taiwan. The NCU Centrifuge has a nominal radius of 3 m and equips a 1-D servo-hydraulically controlled shaker integrated into a swing basket. The shaker has maximum nominal shaking force 53.4 kN with maximum table displacement of ±6.4 mm and operates at up to 80 g centrifugal acceleration. The nominal operating frequency range is 0 - 250 Hz. The table payload mounting area is 1000 mm x 546 mm x 500mm. A laminar container with inside dimensions of 711 mm x 356 mm x 353 mm is constructed from 38 light-weight aluminum alloy rings arranged in a stack. Each ring is 8.9 mm in height and is separated from those adjacent to it by roller bearings, specially designed to permit translation in the longitudinal direction with minimal frictional resistance. The laminar container is designed for dry or saturated soil models and permits development of stresses and strains associated with one dimensional wave propagation.

2.2 Tested Sand and Preparation of Sand Bed

A fine quartz sand and a silt were used to prepare the sand deposit. The characteristics of the quartz sand and silt are summarized in Table 1. The permeabilities of quartz and silt are 6.8×10^{-5} and 7.4×10^{-6} (m/sec), respectively. The quartz sand was pluviated with a regular path into the container from a hopper at various falling heights and at a constant flow rate for preparing fairly uniform sand deposits

having various relative densities. The pluviation process was interrupted as needed for embedding the transducers at specified elevations. Before placing thin silt layer at the predetermined elevation the prepared sand bed was saturated with a water-metulos solution (MCE) with a viscosity of 70 times the viscosity of water in advance. The surface of pore fluid rose to 10 mm above the prepared sand surface and then the silt was pluviated with a funnel through the pore fluid into the sand surface. The thickness of silt layer was 10 mm. After leveling the silt surface the quartz sand was pluviated as described before until reaching the predetermined thickness of sand bed. Finally the saturation process was conducted again.

An acrylic plate was used to tightly cover the container for the saturation process of sand. Air was then simultaneously and continuously vacuumed out from both the inside of container and the outside of container and at the same time a water-metulos solution was carefully dripped into the container to saturate the sand bed until the water level rose to 2 mm above the sand surface. Multiple saturation processes for the preparation of sand deposit with a thin layer of silt was required to ensure the test model being fully saturated. Then the centrifuge was accelerated at a 10 g per step until it reached the acceleration of 80 g. In each step the model was maintained and lasted for 5 minutes at this g level to ensure the sand bed reaching full consolidation at the current overburden stress. Finally the model was excited with a one-dimensional sinusoid acceleration consisting of 16 cycles having maximum amplitude of 0.1 g and a frequency of 1 Hz in prototype units. Acceleration, pore water pressure and displacement time histories were recorded simultaneously.

Table 1. Characteristics of fine quartz sand and silt.

	G_s	D_{50} in (mm)	D_{10} in (mm)	ρ_{max} (g/cm^3)	ρ_{min} (g/cm^3)	Prototype permeability (m/sec)
Quartz sand	2.65	0.193	0.147	1.66	1.44	6.8×10^{-5}
Silt	2.65	0.025	0.002	1.53	1.29	7.4×10^{-6}

[1]The maximum and minimum densities of the sand were measured in the dry state, according to the method (JSF T 161-1990) specified by the Japanese Geotechnical Society.

2.3 Testing Setup and Testing Conditions

Figure1 presents a sketch of laminar container to show the dimensions of the tested sand bed, the position of silt layer, and the types and the positions of instrumentation used in the models. Figure 2 shows the test package rested on the shaker. The thickness of model sand bed is 30 cm, simulating a 24 m thick and a 56.8 m long sand deposit at a centrifuge acceleration of 80 g. The sand bed is instrumented with seven vertical spaced accelerometers (A#) to record the shear wave propagating from the base to the ground surface as shown in Figure 1. At the same elevations close to the accelerometers six pore water pressure transducers (P#) were instrumented as well. The accelerometers and the pore water pressure transducers were particularly instrumented at the elevations above and beneath the silt layer for examining the changes in the pore water pressure generation and accelerations. Two LVDTs were installed at the top of surface to measure the time history of surface settlement. An attempt was made to locate transducers in similar locations in each test. This comprehensive instrumentation and detailed measurements are necessary to understand the seismic response of the sand deposit with an intra-silt layer and the associated excess pore water pressure generation at various elevations during 1-D shaking. A total of three centrifuge tests were conducted; the test conditions in prototype for each model are listed in Table 2. Model Test1 was the uniform sand deposit, whereas Model Test2 and Model Test3 were the composite deposits with an intra-silt layer emerging at the depths of 4.8-5.7 m and of 9.6-10.4 m, respectively. The test conditions described in Table2 were used to study the major factors contributing to the liquefaction susceptibility of sand deposit with an intra-silt layer at various depths.

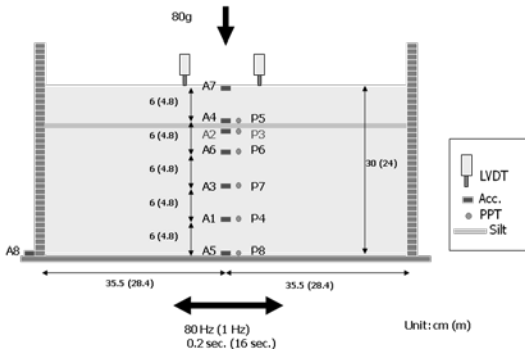

Figure 1 Sketch of laminar container, soil profile and instrumentations used in the models (Test2)

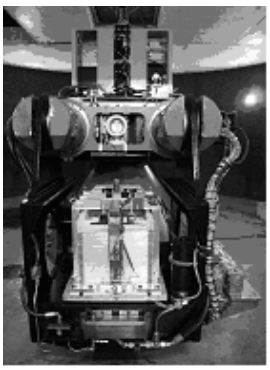

Figure 2 Test package and instrumentations on the shaker

3. TEST RESULTS AND INTERPRETATIONS

3.1 Accelerations on Sand Deposit During Shaking

Figure 3 gives the typical input acceleration time history used in these three tests, in which the maximum input acceleration is around 0.1 g. Figures 4 and 5 presents the comparison of the acceleration time histories measured at different depths for Test1 and Test2 and for Test1 and

Test3, respectively. The long horizontal red bars as shown in Figures 4 and 5 indicate the location of silt layer for Test2 and Test3. The accelerometers of A4 and A2 were located at above and below the silt layer. The attenuation of the acceleration measured at the levels above the depth of 14.4 m is very obvious for Test1. In the case of the silt layer at the depth of 4.8 m (Test2) the high frequency acceleration spikes appear, whereas in the case of the silt layer at the depth of 9.6 m no acceleration spike is observed. The existence of intra-silt layer would greatly modify the seismic responses of the sand deposit above and just beneath the silt layer after comparison of Figures 4 and 5. In addition the embedded depth of silt layer is another factor to influence the seismic response of sand deposit.

Table 2 Summary of testing conditions

Model No.	Dr (%)	Peak input Acc. (g)	Depth of silt layer (m)
Test1	39	0.1	-
Test2	36	0.1	4.8-5.6
Test3	41	0.1	9.6-10.4

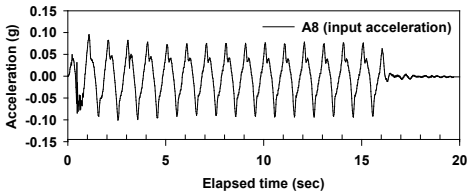

Figure 3 Typical input base acceleration

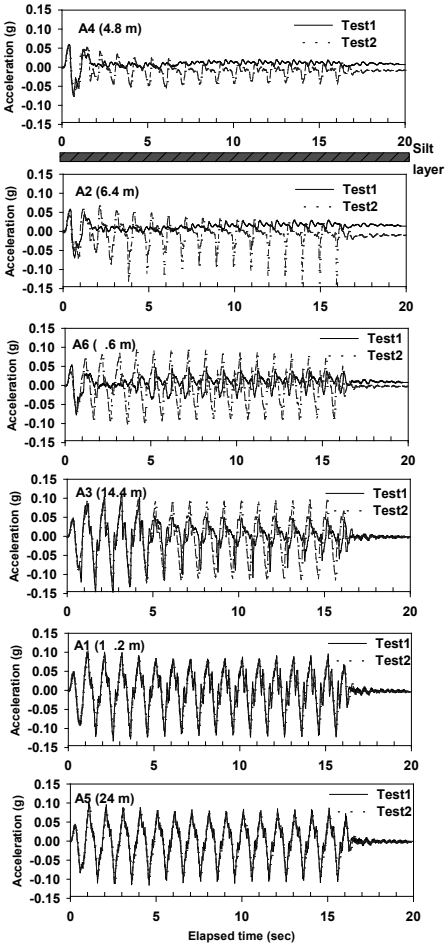

Figure 4 Comparison of acceleration time histories measured at various depths for Test1 and Test2

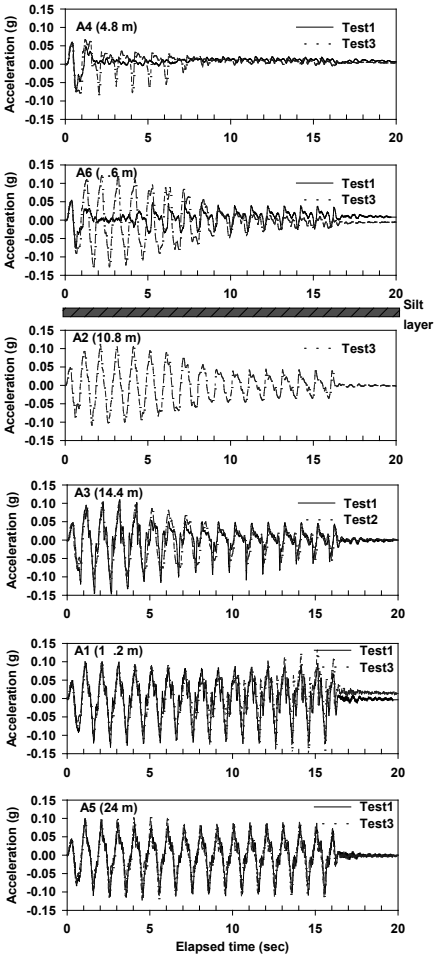

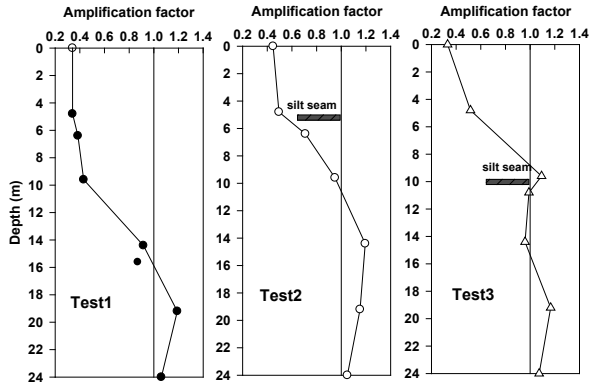

Figure 5 Comparison of acceleration time histories measured at various depths for Test1 and Test3

A single parameter that includes the effects of the amplitude and frequency content of the acceleration time history is the root mean square acceleration (RMS acceleration, a_{rms}), defined as

$$a_{rms} = \sqrt{\frac{1}{T_d}\int_0^{T_d}[a(t)]^2\,dt} \qquad (1)$$

where T_d is the duration of the acceleration and dt is the time interval of the acceleration time history. The larger the RMS acceleration value the higher the energy input to the sand deposit. An acceleration amplification factor is defined as the ratio of the RMS acceleration value measured at different depths to the base RMS acceleration value. Figure

6 presents the RMS acceleration amplification factors, those which were calculated from Test1, Test2, and Test3. The level of the silt seam is also point out with the long red bar in these figures. The amplification factors above the depths of 16 m on the sand deposit without the silt seam (Test1) become less than 1 because of the excess pore water pressure generation. In the deposits sandwiched with the silt seam (Test2 and Test3) the depths at which the amplification factors less than 1 become shallower. The deeper the silt seam embeds the smaller the amplification factor on the ground surface and the less energy input to the ground surface.

(a) (b) (c)

Figure 6 Amplification factors along depths; (a)Test1; (b)Test2; (c)Test3

3.2 Time Histories of Excess Pore Water Pressure in Sand Deposit During And After Shaking

Figures 7, 8 and 9 display the time histories (log scale) of excess pore water pressure ratio, r_u , along the depths for Test1, Test2, and Test3. The excess pore water pressure ratio is defined as the measured excess pore water pressure (Δu) divided by the corresponding effective overburden pressure ($\sigma_v^{'}$).That is:

$$r_u = \frac{\Delta u}{\sigma_v^{'}} \qquad (2)$$

These three figures demonstrate that the patterns of the excess pore water pressure generation and dissipation are quiet different on the sand deposits without and with the silt seam sandwiched at various depths, respectively. For uniform sand deposit the thickness of liquefaction extended from the depth of about 15 m to the surface and liquefaction occurred very early (the 2nd sec) and liquefying lasted for about the 100 seconds (Figure 7). For the sand deposit sandwiched with the shallow silt seam, in contrast, liquefaction only took place beneath the silt seam layer (between 6m to 10 m) and liquefying emerged in the later shaking periods and lasted for the 400 seconds (Figure 8). For the sand deposit sandwiched with the deeper silt seam liquefaction also occurred very early (the 2nd sec) in the top layer but liquefying only lasted for 40 seconds. The liquefaction also appeared beneath the silt seam in the later shaking periods and liquefying lasted for about 100 seconds on the deposit just beneath the silt seam as shown in Figure 9. The time required for the excess pore water fully dissipation on these three sand deposits are different. The required dissipation time is longest for the sand deposit sandwiched with the deeper silt seam and shortest for the sand deposit without silt seam, and in between for sand deposit sandwiched with the shallow silt seam. The existence of the silt seam would lengthen the time of dissipation on the excess pore water pressure.

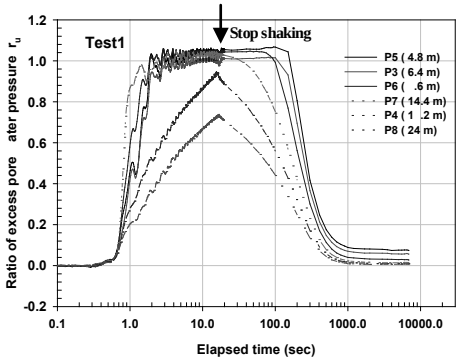

Figure 7 Time histories of r_u at various depths for Test1

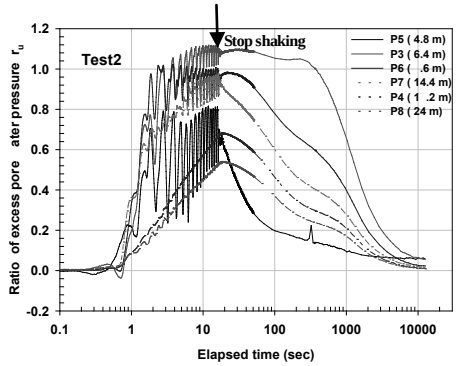

Figure 8 Time histories of r_u at various depths for Test2

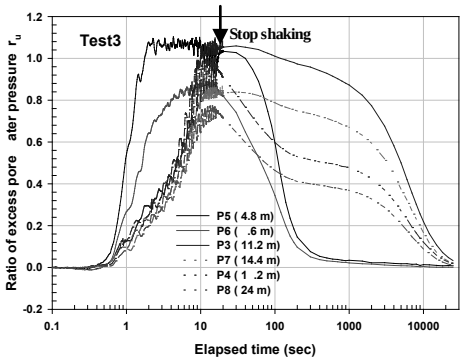

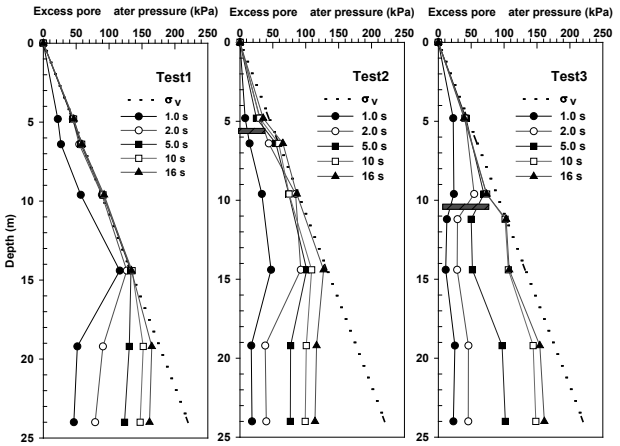

Figure 9 Time histories of r_u at various depths for Test3

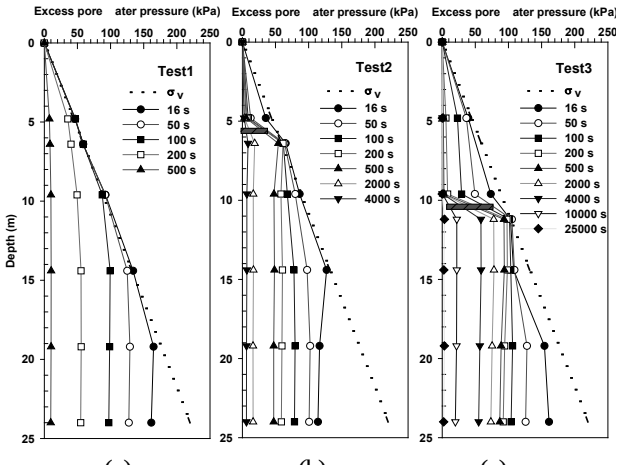
Figure 10 demonstrates the excess pore water pressure distribution along the depths at various elapsed times during shaking period for Test1, Test2, and Test3. The horizontal red bars as shown in Figures10 indicate the locations of silt layer for Test2 and Test3. In the case of the uniform sand deposit the largest excess pore water pressure first emerged at the depth of around 15 m in the beginning of shaking and

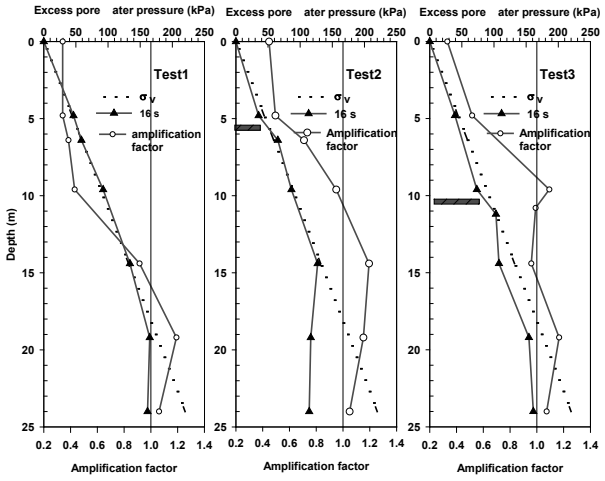


then the excess pore water pressure increased from this elevation both toward the top and the bottom layers. Finally the layer of the top 15 m fully liquefied at the end of shaking. In contrast, in the cases of sand deposit with the silt seam, the excess pore water pressure generation occurred concurrently, both in the upper layer and lower layer. The excess pore water pressure on the top of silt seam was smaller than that below the silt seam for the deposit with the shallow seam, while it was larger in the beginning of shaking for the deposit with deeper silt seam until after 5 seconds.

Figure 11 demonstrates the processes of excess pore water pressure dissipation along the depths at various elapsed times after shaking period for Test1, Test2, and Test3. The elevations of the silt seam on the Test2 and Test4 are also shown in the figure. In the uniform sand deposit the pore water pressure dissipates from the bottom layer to the surface (Figure 11(a)). In contrast, the sand deposits with silt seam, the excess pore water pressure dissipate

(a) (b) (c)

Figure 10 Distribution of excess pore water pressure along depths at various elapsed times during shaking period: (a) Test1; (b) Test2; (c) Test3



(a) (b) (c)

Figure 11 Distribution of excess pore water pressure along depths at various elapsed times after shaking period: (a) Test1; (b) Test2; (c) Test3

simultaneously, both in the upper and lower layers. The gaps of elevations of silt seam are very obvious and implies that the the excess pore water pressure distribution at the silt seam would experience the seepage flow from the lower layer through the silt seam to the top layer with the higher hydraulic gradient during dissipation period. In addition, the accumulated the excess pore water pressure equal to the effective stress beneath the silt seam lasts for almost 500 seconds. The water film as described by Kokusho (2000) is expected to form beneath the silt seam and lasted for considerable time after shaking.

Figure 12 demonstrates the distribution of excess pore water pressure at the instant of stopping shaking and the amplification factor profiles along the depths for Test1, Test2, and Test3. The greatest amplification factor occurs approximately at the elevation where the effective stress is approximately equal to 0 as shown in Figure 12(a) and 12(b). In the case of sand deposit with deeper silt seam the patterns of excess pore water pressure distribution and of the amplification factor profile in the upper layer are similar to those appeared in lower layer for Test1 and Test2.

(a) (b) (c)

Figure 12 Distribution of excess pore water pressure at stopping shaking and the amplification factor profiles along the depths: (a) Test1; (b) Test2; (c) Test3

3.3 Surface Settlement and Excess Pore Water Pressure in Sand Deposit During And After Shaking

Figure 13 displays the time histories of surface settlement for Test1, Test2, and Test3. There was the largest surface settlement in the uniform sand deposit (Test1) after the excess pore water pressure fully dissipated and the second largest surface settlement in the sand deposit with deeper silt seam (Test3), and the smallest settlement in the sand deposit with the shallower seam in between (Test2). The existence of the silt seam can reduce the extent of liquefaction as shown in figure 10 in the sand deposit and decreases the surface settlement. A concept that the magnitude of surface settlement is proportion to the area ratio, which is defined as the confined area by the excess

pore water pressure profile along the depths divided by the area confined by the effective overburden stress as shown in Figure 10, at the instant of stopping shaking is proposed to evaluate the maximum surface settlement. Figure 14 illustrates the confined area by the excess pore water pressure profile as shown in Figure 10 divided by the area confined by the effective overburden stress. The larger area ratio represents the more great extent of liquefaction in the sand deposit and would cause the larger surface settlement.

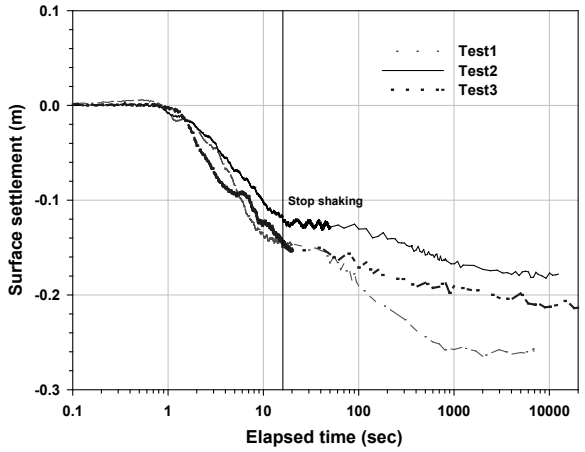


Figure 13 Time histories of ground settlement for Test1, Test2, and Test3

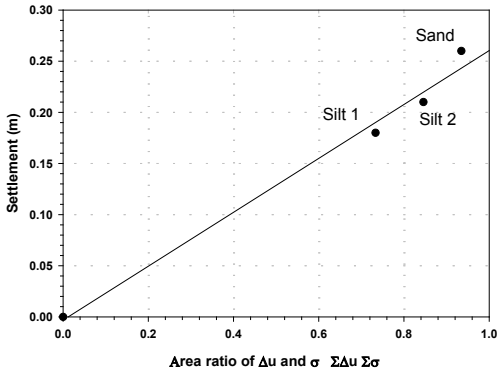

Figure 14 Area ratios of the excess pore water pressure and the effective overburden pressure at the instant of stopping shaking

4. SUMMARY AND CONCLUSIONS

Three dynamic centrifuge model tests were conducted to simulate the seismic responses of sandy soil deposits with the silt seam embedded at various depths. The model sand beds had the same relative density and were saturated with the same viscous pore fluid and then were subjected to the same magnitude of base acceleration. The effect of existence of low-permeability silt seam at the different depths on the generation and dissipation of excess pore water pressure, the surface settlements and the related liquefaction mechanism in a loose sand deposit are investigated in detail. The test results show that (1) the sand deposit without silt seam experienced the largest surface settlement and the silt seam in the sand deposit can reduce the extent of liquefaction and the surface settlement; (2) the concept of area ratio is proposed to evaluate the magnitude of surface settlement; (3) liquefaction occurs only in the sand beneath the thin silt layers for the sand deposit with the shallow silt seam. However, for the deeper thin silt intra-layer, liquefaction occurs not only in the sand beneath the thin silt layers but also in the sand near the surface. (4) the water films are formed beneath the silt seam and would last for amount of time after shaking.

kramer@u.washington.edu, niner@gis.tw

Abstract: Advances in the development of performance-based earthquake engineering offer important opportunities for more rational, objective, and consistent evaluation of liquefaction hazards. Performance-based procedures for evaluation of liquefaction potential have been shown to provide more consistent and accurate indications of the actual likelihood of liquefaction in areas of different seismicity than conventional procedures. These procedures can be extended to include effects of liquefaction such as lateral spreading and post-liquefaction settlement. This paper describes a recently developed framework for performance-based liquefaction hazard evaluation. The integration of procedures for estimation of liquefaction susceptibility, potential, and effects are described. The procedures are illustrated with an example of the evaluation of post-liquefaction settlement hazards..

1. INTRODUCTION

Liquefaction hazards are generally assessed by evaluating (a) the susceptibility of a soil deposit to liquefaction, (b) the potential for initiation of liquefaction under some anticipated loading, and (c) the effects of liquefaction. The level of loading considered in the assessment is usually expressed in terms of a ground motion intensity measure at a single return period. In practice, liquefaction susceptibility, potential, and effects are usually evaluated deterministically.

The development of performance-based earthquake engineering concepts allow probabilistic evaluations of susceptibility, initiation, and effects to be combined with a probabilistic evaluation of ground motion hazards to produce more rational and consistent estimates of liquefaction hazards. The purpose of this paper is to show how performance-based concepts can allow uncertainties in susceptibility, initiation, and effects to be incorporated into post-liquefaction settlement hazard assessments.

2. CONVENTIONAL PROCEDURES FOR ASSESSMENT OF LIQUEFACTION HAZARDS

The assessment of liquefaction hazards can be broken down into three primary components (Kramer, 1995) – evaluation of liquefaction susceptibility, evaluation of the potential for initiation of liquefaction, and evaluation of the effects of liquefaction.

2.1 Liquefaction Susceptibility

The primary difficulty in evaluating liquefaction susceptibility at this time lies in the susceptibility of fine-grained soils of marginal plasticity and coarse-grained soils with high fines contents. Following recent observations of liquefaction in fine-grained soils, extensive research on the liquefaction susceptibility of fine-grained soils was undertaken. At this stage, two major studies have proposed criteria for evaluating the liquefaction susceptibility of fine-grained soils. These criteria are consistent for many conditions but differ for others. Both were developed using the results of field observations and laboratory tests by well-respected leaders of the geotechnical engineering profession.

Boulanger and Idriss

Boulanger and Idriss (2005) reviewed case histories and laboratory tests involving cyclic loading of different fine-grained soils. Boulanger and Idriss identified two types of behavior that they described as “sand-like” and “clay-like” on the basis of stress normalization and stress-strain behavior. Soils exhibiting sand-like behavior were considered susceptible to liquefaction and soils exhibiting clay-like behavior were not. Boulanger and Idriss found that soil plasticity characteristics determined whether an individual soil was likely to exhibit sand-like or clay-like behavior, and proposed that the distinction could be made based on plasticity index, *PI*.

To quantify the transitional nature of observed sand-like to clay-like behavior, a numerical relationship can be established. The *PI* transition from clay-like to sand-like behavior from Boulanger and Idriss (2005) can be described using a susceptibility index, defined as

$$S_{BI} = \left[1 + \left(\ln PI / 1.843\right)^{11.483}\right]^{-2.0} \quad (1)$$

which has a value of 0.0 for clay-like (non-susceptible) behavior and 1.0 for sand-like (susceptible) behavior, and varies in a manner consistent with that shown graphically by Boulanger and Idriss (2005).

Bray and Sancio (2006)

Bray and Sancio (2006) investigated fine-grained soils that liquefied during 1994 Northridge, 1999 Kocaeli, and 1999 Chi-Chi earthquakes and proposed new compositional criteria for liquefaction susceptibility evaluation. In addition to plasticity index, Bray and Sancio found the ratio of water content to liquid limit (w_c/LL) to also influence liquefaction susceptibility.

A function similar to that used to approximate the Boulanger and Idriss criterion can be developed to quantify Bray and Sancio's susceptibility criteria. The equation is simply the product of two terms which have same general form as Equation 1, i.e.,

$$S_{BS} = \left[1 + \left(\ln PI / 2.778\right)^{33.077}\right]^{-2.0} \left[1 + \left(4.401 / \ln(w_c / LL)\right)^{360.471}\right]^{-2.0} \quad (2)$$

These equations were determined by assuming the boundary between susceptibility and non-susceptibility to be uniformly distributed within the 'moderately susceptible' zone of Bray and Sancio, and fitting a function that would have the same mean and variance with respect to both *PI* and w_c/LL. As in Equation 1, a value of 0.0 indicates non-susceptibility and 1.0 indicates susceptibility.

2.2 Initiation of Liquefaction

Liquefaction potential is generally evaluated by comparing consistent measures of earthquake loading and liquefaction resistance. It has become common to base the comparison on cyclic shear stress amplitude, usually normalized by initial vertical effective stress and expressed in the form of a cyclic stress ratio, *CSR*, for loading and a cyclic resistance ratio, *CRR*, for resistance. The potential for liquefaction is then described in terms of a factor of safety against liquefaction,

$$FS_L = CRR/CSR \quad (3)$$

Characterization of Earthquake Loading

The cyclic stress ratio is most commonly evaluated using the "simplified method" first described by Seed and Idriss (1971), which can be expressed as

$$CSR = 0.65 \frac{a_{\max}}{g} \cdot \frac{\sigma_{vo}}{\sigma'_{vo}} \cdot \frac{r_d}{MSF} \quad (4)$$

where a_{max} = peak ground surface acceleration, g = acceleration of gravity (in same units as a_{max}), σ_{vo} = initial vertical total stress, σ'_{vo} = initial vertical effective stress, r_d = depth reduction factor, and *MSF* = magnitude scaling factor, which is a function of earthquake magnitude. It should be noted that two pieces of ground motion information, a_{max} and magnitude, are required for estimation of the cyclic stress ratio.

Characterization of Liquefaction Resistance

The cyclic resistance ratio is generally obtained by correlation to insitu test results, principally from standard penetration (SPT), cone penetration (CPT), or shear wave velocity (V_s) tests. Of these, the SPT has been most commonly used and will be used in the remainder of this paper. A number of SPT-based procedures for deterministic (Seed and Idriss, 1971; Seed et al., 1985; Youd et al., 2001, Idriss and Boulanger, 2004) and probabilistic (Liao et al., 1988; Cetin et al., 2004) estimation of liquefaction resistance have been proposed.

3. POST-LIQUEFACTION SETTLEMENT

Damage to structures underlain by liquefiable soils is often affected by settlement of the liquefied soil. The most common form of liquefaction-induced settlement is that which results from the volumetric compression that occurs when excess porewater pressures dissipate under level-ground conditions (i.e., when shearing deformations are insignificant). The contractive nature of sands subjected to vibratory loading has been recognized for many years.

Tokimatsu and Seed (1987) reviewed previous laboratory test data, which showed post-liquefaction volumetric strain to be related to relative density and peak shear strain. They then related relative density to SPT resistance and peak shear strain to cyclic stress ratio to develop curves relating volumetric strain to $(N_1)_{60}$ and *CSR* (Figure 1a). The curves in Figure 1(a) show that post-liquefaction volumetric strain increases with increasing loading and decreasing SPT resistance and suggest that volumetric strains can be as large as 10 percent in extremely loose sands. They also show that, for strong levels of shaking, the soil reaches a limiting volumetric strain. The Tokimatsu and Seed procedure computes ground surface settlement by integrating volumetric strain over the depth of the liquefiable layer, i.e., as

$$\Delta H = \int \varepsilon_v dz \quad (5)$$

Other investigators (Ishihara and Yoshimine, 1992; Shamoto et al., 1998; Wu and Seed, 2004) have proposed similar relationships; that of Wu and Seed (2004) is shown in Figure 1(b). This relationship, like several others, does not suggest the existence of a limiting volumetric strain for moderately dense soils (corrected SPT resistances above about 10).

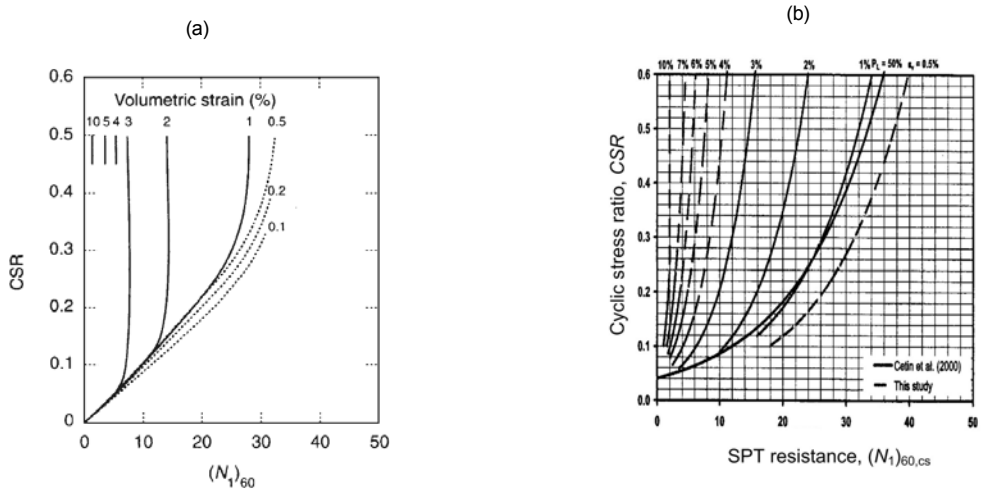

Figure 1 Variation of volumetric strain with corrected SPT resistance and cyclic stress ratio (a) Tokimatsu and Seed (1987), and (b) Wu and Seed (2004).

4. PERFORMANCE-BASED LIQUEFACTION HAZARD ASSESSMENT

Performance-Based Earthquake Engineering (PBEE) is generally formulated in a probabilistic framework to evaluate the risk associated with earthquake shaking at a particular site. The risk can be expressed in terms of economic loss, fatalities, or other measures. Pacific Earthquake Engineering Research (PEER) Center has developed a probabilistic framework for PBEE (Cornell and Krawinkler, 2000; Krawinkler, 2002).

The PEER PBEE framework computes risk as a function of ground shaking through the use of several intermediate variables. The ground motion is characterized by an *Intensity Measure, IM*, which could be any of a number of ground motion parameters. The effects of the *IM* on a system of interest are expressed in terms used primarily by engineers in the form of *Engineering Demand Parameters*, or *EDP*s. For a liquefiable site, the geotechnical engineer's initial contribution to this process for evaluating liquefaction hazards comes primarily in the evaluation of the conditional probability distribution of *EDP* given *IM*. In the PEER framework, the mean annual rate of exceeding some *EDP = edp* is given by

$$\lambda_{EDP}(edp) = \sum_{i=1}^{N_{IM}} P[EDP > edp \mid IM = im_i]\Delta\lambda_{IM}(im_i) \qquad (6)$$

Within the context of the previously described susceptibility/initiation/effects evaluations for liquefaction hazard assessment, the effects of liquefaction (e.g., settlement) would be taken as the *EDP*, and the susceptibility and initiation considerations would need to be addressed as intermediate steps in the evaluation of liquefaction effects. The evaluation of the conditional probability of *EDP* given *IM* would then take the following form

$$P[EDP > edp \mid IM] = P[EDP > edp \mid IM, initiation] \times P[initiation \mid IM, susceptibility]P[susceptbility] \qquad (7)$$

The evaluation of this conditional distribution therefore requires evaluation of the probability that a given element of soil is susceptible to liquefaction, the probability that liquefaction will be triggered by ground motions of various intensities, and the probability that some level of effects will be reached given the intensity level and the fact that liquefaction has been initiated.

4.1 Susceptibility

The susceptibility indices given by Equations 1 and 2 can be interpreted in different ways. Neither were developed in a sufficiently formal manner as to represent probabilities of liquefaction susceptibility. However, they could be interpreted as degrees of belief, or subjective probabilities, that a soil would be susceptible to liquefaction in that they have values of zero for conditions in which Boulanger and Idriss (2005) and Bray and Sancio (2006) indicate non-susceptibility and value of 1.0 where they indicate susceptibility. Differences between the two approaches could be treated as epistemic uncertainty using a logic tree.

4.2 Initiation

As indicated previously, a number of probabilistic liquefaction initiation models have been proposed over the past 20 years. The model of Cetin et al. (2004) provides a good example of such methods. For a soil of a given density, the Cetin et al. (2004) model allows computation of a probability of liquefaction initiation for a liquefaction-susceptible soil as

$$P[initiation|\ IM, susceptbilty] = \Phi\left[-\frac{(N_1)_{60}(1+\theta_1 FC) - \theta_2 \ln CSR_{eq} - \theta_3 \ln M_w - \theta_4 \ln\left(\sigma'_{vo}/p_a\right) + \theta_5 FC + \theta_6}{\sigma_\varepsilon}\right] \quad (8)$$

where Φ is the standard normal cumulative distribution function, $(N_1)_{60}$ = corrected SPT resistance, *FC* = fines content (in percent), CSR_{eq} = cyclic stress ratio (Equation 4 without *MSF*, which serves as the *IM* in this case), M_w = moment magnitude, σ'_{vo} = initial vertical effective stress, p_a is atmospheric pressure (in same units as σ'_{vo}), σ_ε is a measure of the estimated model and parameter uncertainty, and θ_1-θ_6 are model coefficients obtained by regression. In this form, *CSR* and M_w form a vector *IM*.

4.3 Effects

Huang (2008) developed a probabilistic post-liquefaction settlement model based on interpretation of previous laboratory test results presented by Tokimatsu and Seed (1987), Ishihara and Yoshimine (1992), Shamoto et al., (1998), and Wu and Seed (2004). Huang (2008) developed an expression for the median volumetric strain in a liquefiable soils as given by Wu and Seed (2004) as a function of *CSR* and $(N_1)_{60}$. Assuming lognormality, the vertical strain fragility relationship can be expressed as

$$P[\varepsilon_v > \varepsilon_v^* | CSR\ , N] = \Phi\left[\frac{\mu_{\ln \varepsilon v} - \ln \varepsilon_v^*}{\sigma_{\ln \varepsilon_v}}\right] \quad (10)$$

where $\Phi(\cdot)$ is the standard normal cumulative distribution function.

The fact that the Wu and Seed (2004) curves do not become vertical at high *CSR* levels implies that volumetric strain continues to increase without bound with increasing *CSR*. However, considerable experimental evidence suggests that the continued vibration of soil leads to densification only to some limiting void ratio or density. Therefore, there must exist some limiting volumetric strain for a soil of a given initial density. Because the performance-based approach integrates response over all levels of ground motion hazard (Equation 6), extrapolating the Wu and Seed (2004) curves to the very high *CSR* values that can exist in areas of high seismicity can lead to unrealistically high volumetric strain levels. Huang (2008) reviewed data from compaction, minimum void ratio, drained cyclic tests, and consolidation tests following cyclic loading to suggest a tentative relationship between maximum volumetric strain and SPT resistance. The relationship can be approximated by

$$\bar{\varepsilon}_{v,\max}(\%) = 9.765 - 2.427 \ln[(N_1)_{60,cs}] \quad (11)$$

Recognizing the approximate nature of this relationship, Huang (2008) assumed that $\varepsilon_{v,\max}$ was uniformly distributed over a range of 0.5 $\bar{\varepsilon}_{v,\max}$ to 1.5 $\bar{\varepsilon}_{v,\max}$.

Example

To illustrate the performance-based settlement evaluation procedure, a simple, hypothetical site in Seattle, Washington (Figure 2) is assumed. The site consists of 6 m of loose, silty sand with a groundwater level 1 m below the surface. The sand has a corrected clean sand SPT resistance, $(N_1)_{60,cs}$ = 15 and PI = 5.

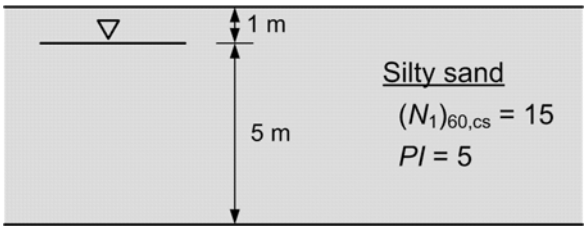

Figure 2. Hypothetical soil profile in Seattle, Washington.

To illustrate the roles of susceptibility, initiation, and maximum volumetric strain, the post-liquefaction settlement hazard for the site is computed for four different cases. Case 1 assumes that P[*susceptibility*] = 1.0, P[*initiation*] = 1.0, and that no maximum volumetric strain exists. For this case, the curves of Wu and Seed (2004) are extrapolated to large *CSR* values. Case 2 is identical to Case 1, except that the distribution of maximum volumetric strain is taken into account. Case 3 is the same as Case 2, except that the probability of initiation of liquefaction is also computed and accounted for. Finally, Case 4 accounts for the probability of liquefaction susceptibility, the probability of initiation, and the existence of a maximum volumetric strain.

The computed settlement hazard curves for all four cases are shown in Figure 3. For Case 1, the settlement hazard curve shows steadily increasing settlement with increasing return period (decreasing mean annual rate of exceedance). At long return periods, the unbounded settlement relationship implies settlement of over 0.5 m, which would correspond to average volumetric strains (over the 5 m saturated thickness) in excess of 10%. This volumetric strain would exceed that which has been observed in laboratory tests. The mean value of $\varepsilon_{v,\max}$ predicted by Equation 11 for such a soil would be approximately 3.2%, so the upper limit according to Huang (2008) would be less than 5%.

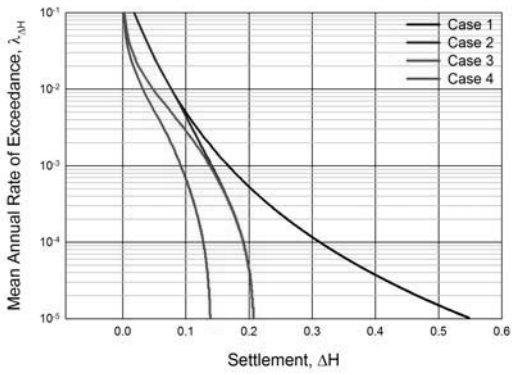

Figure 3. Post-liquefaction settlement hazard curves.

For Case 2, in which the existence of a maximum volumetric strain was considered, the settlement hazard curve matches the Case 1 curve at short return periods where volumetric strains do not approach the maximum value. At return periods beyond about 250 yrs, however, the shaking becomes strong enough that the maximum volumetric strain begins to affect the settlement hazard. At longer return periods, the Case 2 settlement hazard curve drops below the Case 1 curve and eventually becomes asymptotic to a maximum settlement slightly greater than 0.2 m. This settlement would correspond to an average maximum volumetric strain of about 4% under the strongest possible shaking, a value that is consistent with the results of laboratory tests.

The Case 2 curve assumes that liquefaction is initiated at all return periods. For the relatively weak shaking at short return periods, however, the probability of liquefaction may be less than 1.0. The Case 3 curve accounts for the probability of liquefaction initiation, and therefore drops below the Case 2 curve at short return periods. For return periods longer than about 1,000 years, the Case 3 curve converges to the Case 2 curve, as expected.

Finally, the settlement hazard curves for the first three cases all assume that the *PI* = 5 soil is susceptible to liquefaction. This *PI* level, however, would be in the transitional zone identified by Boulanger and Idriss (2005) and would be assigned a value of S_{BI} = 0.68 according to Equation 1. Taking S_{BI} as a subjective probability of susceptibility, the expected value of settlement drops to the Case 4 curve shown in Figure 3.

5. SUMMARY AND CONCLUSIONS

Performance-based concepts can allow objective and consistent evaluation of liquefaction hazards. By properly combining uncertainties in ground motions with uncertainties in liquefaction susceptibility, initiation, and effects, the actual return period for a given level of effects can be computed. The application of these concepts to the problem of post-liquefaction settlement prediction is illustrated in the paper.

The fact that performance-based settlement estimates are based on all levels of ground motion, including very strong levels that may only occur very rarely, requires the consideration of bounding values on volumetric strain. An approximate model for maximum volumetric strain was developed and implemented, and found to have a significant effect on post-liquefaction settlement at long return periods. The implementation of this probabilistic settlement model into a performance-based framework that allows probabilistic characterization of liquefaction susceptibility and the potential for initiation of liquefaction allows the most consistent and objective estimates of post-liquefaction settlement hazards to be evaluated.

Abstract: The 4 September 2010 earthquake in the Canterbury region, New Zealand caused widespread damage to residential buildings and lifeline facilities due to soil liquefaction and the associated ground deformations. Liquefaction occurred in areas which are known to have high potential to liquefaction - former river channels, abandoned meanders, wetlands, and ponds. These areas are characterized by the presence of loose saturated sandy deposits. This paper discusses the results of the post-earthquake damage investigation conducted in the area after the earthquake, with emphasis on liquefaction-induced damage.

1. INTRODUCTION

An earthquake of magnitude (M_w) 7.1 occurred at 4:35am on 4 September 2010 with an epicentre located at Darfield, a town about 40 km west of the city of Christchurch. The earthquake has a focal depth of 10 km and the maximum intensity felt was 8 based on MMI scale (GNS, 2010). Fortunately, the earthquake resulted in no casualties, which is a sort of a miracle considering the magnitude of the earthquake.

According to GNS Science (2010), the earthquake happened in an area that has previously had few earthquakes compared to other parts of the South Island. There are some mapped faults in the region, but the fault rupture occurred along a previously unknown east-west faultline. It is buried under the gravels that were deposited on the plains at the end of the last glaciation, about 16,000 years ago. As the gravels previously showed no sign of having been disturbed, it is likely that the fault that caused the Darfield Earthquake had not moved for at least 16,000 years.

Although damage to buildings due to ground shaking is extensive, especially in the central business district of Christchurch, severe liquefaction has been observed in many areas, notably in Kaiapoi and some of Christchurch's eastern suburbs. Liquefaction caused ground subsidence, tilting and settlement of residential houses while lateral spreading induced cracking of roads, footpaths, grounds and residential buildings. Water and sewer pipes buried underground broke and water from the cracked mains flooded many streets. Sands were ejected under house foundations' ground cracks, covering the houses with thick layers of fine sands and silts. A more comprehensive report of the damage is provided by the NZ-GEER team (2010).

2. GEOLOGICAL AND TECTONIC SETTING

The Canterbury Plains, about 180 km long and of varying width, are New Zealand's largest areas of flat land. They have been formed by the overlapping fans of glacier-fed rivers issuing from the Southern Alps, the mountain range of the South Island. The plains are often described as fertile, but the soils are variable. Most are derived from the greywacke of the mountains or from loess (fine sediment blown from riverbeds). In addition, clay and volcanic rock are present near Christchurch from the Port Hills slopes of Banks Peninsula.

The city of Christchurch is located at the coast of the Canterbury Plains adjacent to an extinct volcanic complex forming Banks Peninsula. Most of the city was mainly swamp, behind beach dune sand, and estuaries and lagoons, which have now been drained (Brown et al., 1995). The landforms in Christchurch and the environs are shown in Figure 1.

Canterbury has abundant water, in the rivers which carry mountain rainfall to the coast, and in aquifers. Beneath the plains, layers of porous gravels are interspersed with impermeable finer sediments. Near Ashburton, bedrock is at a depth of 1,600 metres (Wilson, 2009). Unlike most urban water supplies, Christchurch's water comes from aquifers beneath the city. The aquifers are recharged by rainfall and by river seepage. They have been tapped to irrigate farmland and for town water supplies.

The two main rivers, Avon and Heathcote, which originate from springs in western Christchurch, meander through the city and act as main drainage system. The Waimakariri River with its catchment in the Southern Alps, regularly flooded Christchurch prior to stopbank

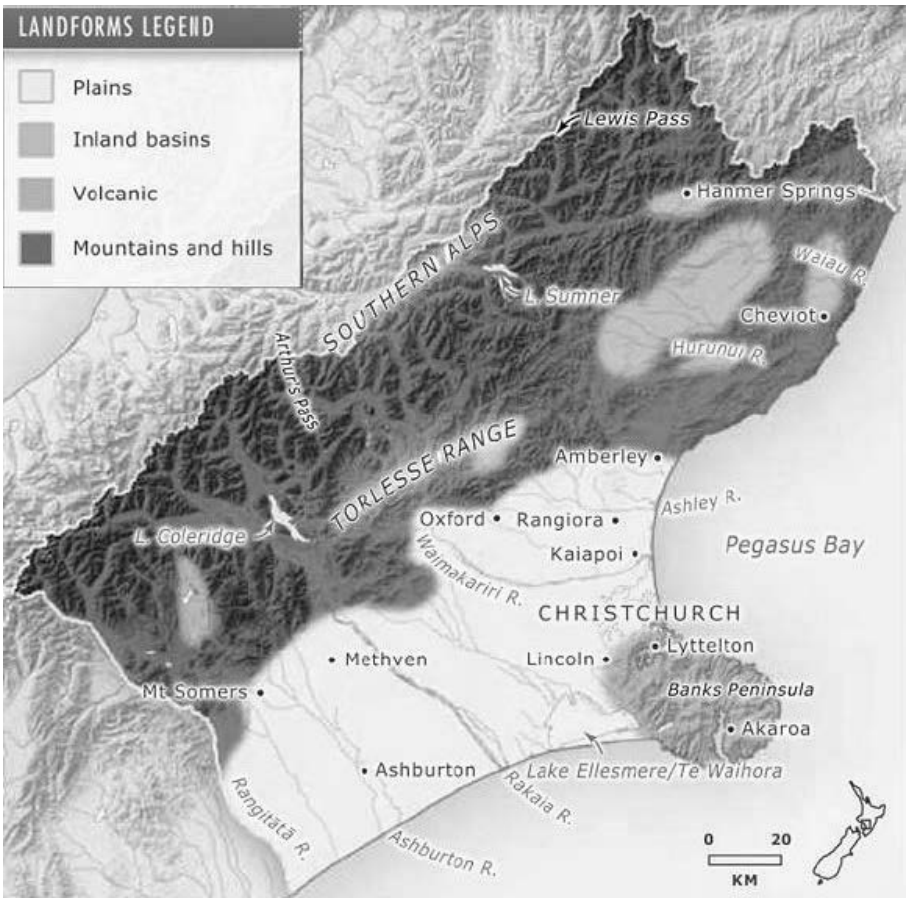

Figure 1. Landforms in and around Canterbury Plains (Source: http://www.teara.govt.nz)

construction and river realignment, which began shortly after the city was established in 1850. Variable foundation conditions as a consequence of a high water table and lateral changes from river floodplain, swamp, and estuarine-lagoonal environments, impose constraints on building design and construction (Brown et al., 1995).

According to studies by Brown et al. (1995), the geology, tectonic setting, and active seismicity of the Christchurch area indicate that future large earthquakes will occur which will have major impact on the city. Based on historical records, the north Canterbury Earthquake of 1888, centred on Amuri, damaged many buildings and caused the top of the spire on Christchurch Cathedral to collapse. In addition, the 1901 earthquake centred near Cheviot caused minor damage in the city while the Arthur's Pass earthquake of 1929 caused significant rockslides in the mountains.

3. STRONG MOTION RECORDS

The New Zealand Earthquake Commission (EQC) has provided funding for the country's real-time seismic hazard monitoring and data collection through GeoNet. The system consists of over 250 strong motion recorders to monitor how structures perform during earthquakes, 46 seismographs to measure accurately the magnitude, location and other characteristics of the earthquakes and another 40 accelerographs in the central south Island operated by the Canterbury strong ground motion network (CanNet) in anticipation of a M8+ rupture of the Alpine fault.

During the 2010 Darfield earthquake, a series of strong motion accelerographs was triggered and motions recorded at several stations. The distribution of maximum horizontal accelerations is shown in Figure 2. Although it can be seen that the maximum recorded acceleration was in the order of 1.25g near the earthquake epicentre, no serious damage was reported in the area. In the city of Christchurch, the recorded accelerations were in the order of 0.2-0.3g. Closer inspection of the ground motion records indicated that the duration of significant shaking was in the order of about 30 sec.

4. LIQUEFACTION-INDUCED DAMAGE

As mentioned above, extensive liquefaction was observed in the town of Kaiapoi and in the eastern suburbs of Christchurch, such as in Dallington and Bexley. In the next sections, typical types of damage observed due to liquefaction are presented based on post-earthquake investigations performed on September 8 and September 10-14. The regions visited are shown in Figure 3. Note that the occurrence of liquefaction was also reported in other areas, aside from those mentioned in this paper; however, these are not discussed herein because of space limitations.

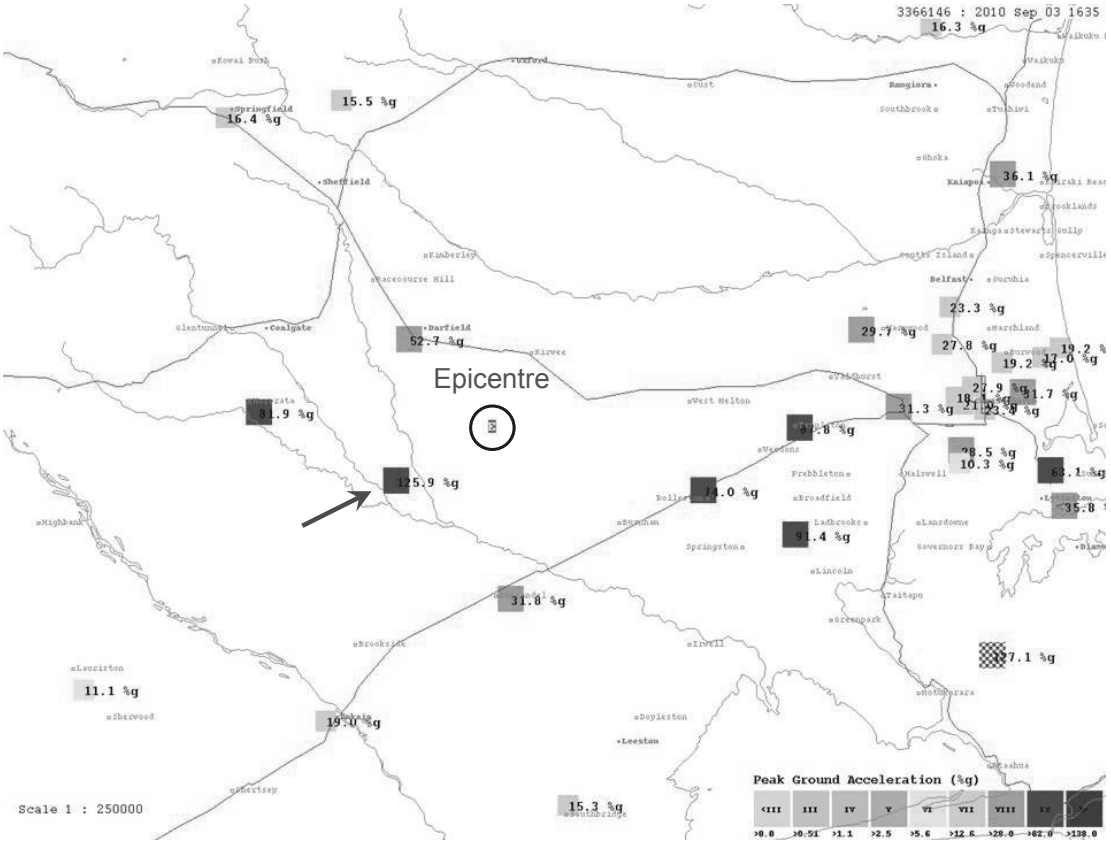

Figure 2. Distribution of maximum horizontal acceleration recorded during the earthquake. E indicates the location of the epicentre (Source: GNS Science website).

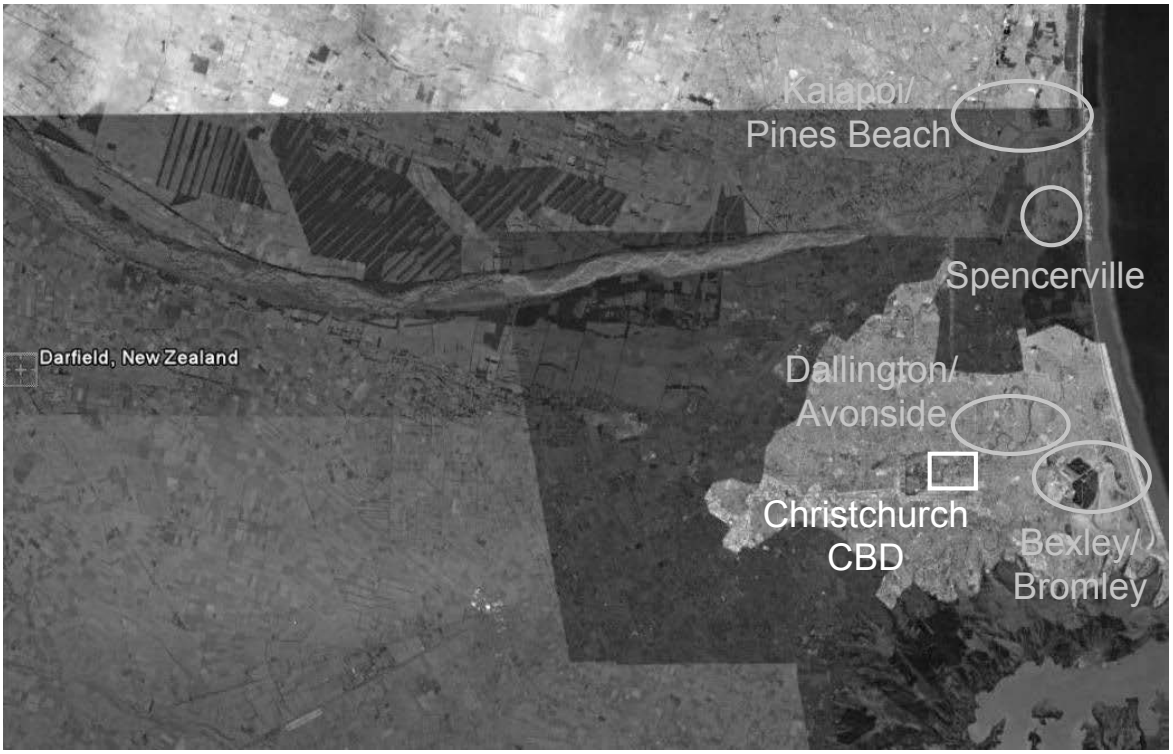

Figure 3. Sites where extensive liquefaction was observed during the 2010 earthquake.

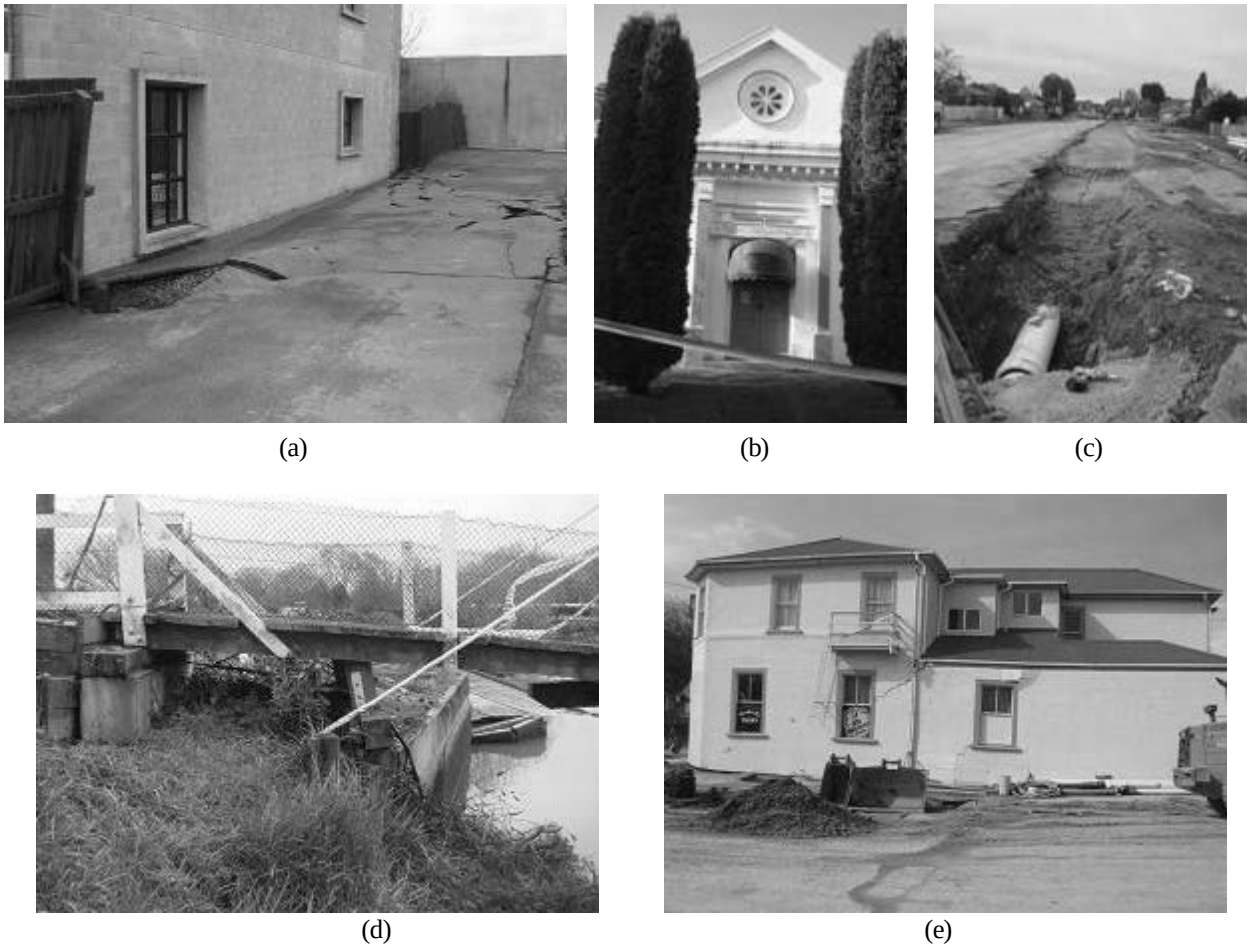

Figure 4. Damage to structures and lifelines in Kaiapoi town.

4.1 Kaiapoi

In terms of liquefaction, the township of Kaiapoi is probably the worst-hit area, with many residential houses, several commercial buildings and other infrastructure facilities suffering damage due to lateral spreading, ground subsidence and differential settlement. Kaiapoi is located in the northeastern end of Canterbury Plains, about 20 km north of Christchurch. The Kaiapoi River, which cuts through the centre of the town, joins the Waimakariri River on the eastern edge of town and flows to the sea.

A reinforced concrete building along Williams St., with 2 storeys in front and 3 storeys at the back, sank and tilted as a result of liquefaction of the foundation ground. Based on the ocular inspection of the site, the building, with a footprint measuring 13m x 20 m, underwent non-uniform settlement, with the southwestern side sinking by as much as 30 cm (Figure 4a), while the northeastern side of the building moving laterally by about 20 cm in the direction of Kaiapoi River. Ground cracks were observed at the back of the building, and sand boils were evident. The pavements in the parking area of the shopping centre located at the back of the said building were also cracked and deformed, with floor slabs of some stores showing large ground cracks. From observation, it appears that the cracks observed were more or less continuous, from the shopping centre cutting through the RC building, passing through Williams St and damaging a house on the opposite side.

Damage was also widespread in other areas north of the river, especially along Charles Street and Sewell Street, which are both parallel to the river. Liquefaction and lateral spreading caused damaged to structures, such as in Southern Cross Lodge (Figure 4b) which tilted and suffered shear cracks on its façade, and was red-tagged (no entry permitted). Sand boils and ground cracks were also observed in the vicinity. Water pipes were broken, and repair works were ongoing during the site visit (Figure 4c).

Berrill et al. (1994) reported that this area underwent liquefaction during the 1901 Cheviot Earthquake. They quoted newspaper reports describing the ejection of sand through cracks and lateral spreading at the east end of Sewell Street. The reports mentioned that cracks can be probed up to a depth of about 2 m. Subsequent field investigation performed at different sites showed cone resistances of about 2-3 MPa throughout layers extending from about 2-6 m, where denser coarse sands and fine gravels were encountered.

The historic Mandeville Swing Bridge, a pedestrian bridge over the Kaiapoi River, buckled (Figure 4d) as a result of liquefaction-induced lateral spreading, which seemed to be more evident on the southern side of the river.

(a) (b)

Figure 5. Damage to a structure and to stop bank along the Kaiapoi river.

Near the abutment, the south bank moved towards the river by about 20 cm, resulting in the deformation of the girders of the bridge. Cracks parallel to the river, as well as sand boils, were observed in the nearby park.

Residential houses and commercial establishments on the south bank of Kaiapoi River underwent settlements in the order of 10-20 cm, and were covered by ejected sands (up to 20 cm thick in some places) immediately after the earthquake. Several houses were structurally damaged due to lateral spreading and uneven settlements (Figures 4e). The railway track near the Fire Station appeared to be damaged as well, as the track was re-ballasted in this area when the visit was made.

The stopbanks confining the flow of Kaiapoi River also suffered damage at various locations. These embankments, measuring about 2.5 m high (from water line) and 2.7 m wide, has slopes of approximately 2H:1V at the riverside and 3H:1V at the landside near the bridge along Williams St. The structure housing the Visitors Information Centre on the north side of the river sank and tilted as a result of liquefaction and lateral spreading (Figure 5a). Ground cracks, as wide as 30 cm and as deep as 100 cm, were observed running parallel to the river. The foundation ground of the structure was laterally displaced towards the river, resulting in settlement and tilting of the structure. The two-storey Waimakariri-Ashley Coastguard building adjacent to the Visitor Centre also suffered the same fate. At some locations east of this building, ground cracks, in the order of 100 cm wide and 150 cm deep, were also observed along the gentler slope of the embankment (Figure 5b), with sand boils scattered all over. Settlement/slumping of foot path on the crest of the banks in the order of 10-30 cm were also noted.

From field investigation, it was observed that liquefaction appears to be extensive in alluvial fan sites adjacent to river channels, such as the Kaiapoi River. Moreover, investigations of old maps by by Wotherspoon et al. (2010) showed that that much of the most significant liquefaction damage in and around Kaiapoi during the Darfield event occurred in areas where river channels had been reclaimed or in old channels that have had flow diverted away. The highly modified nature of the

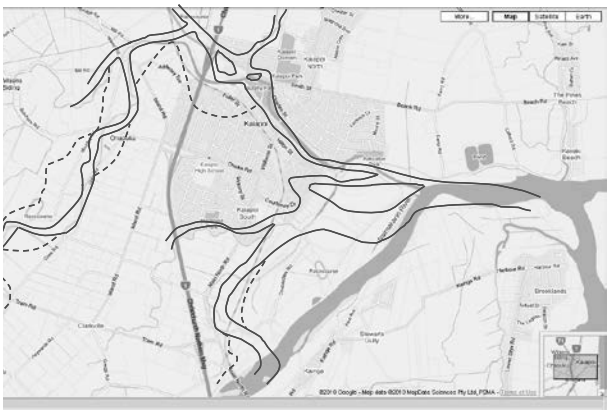

Figure 6. Map of riverbeds in 1865 superposed to the present-day map of Kaiapoi (modified from GoogleMap).

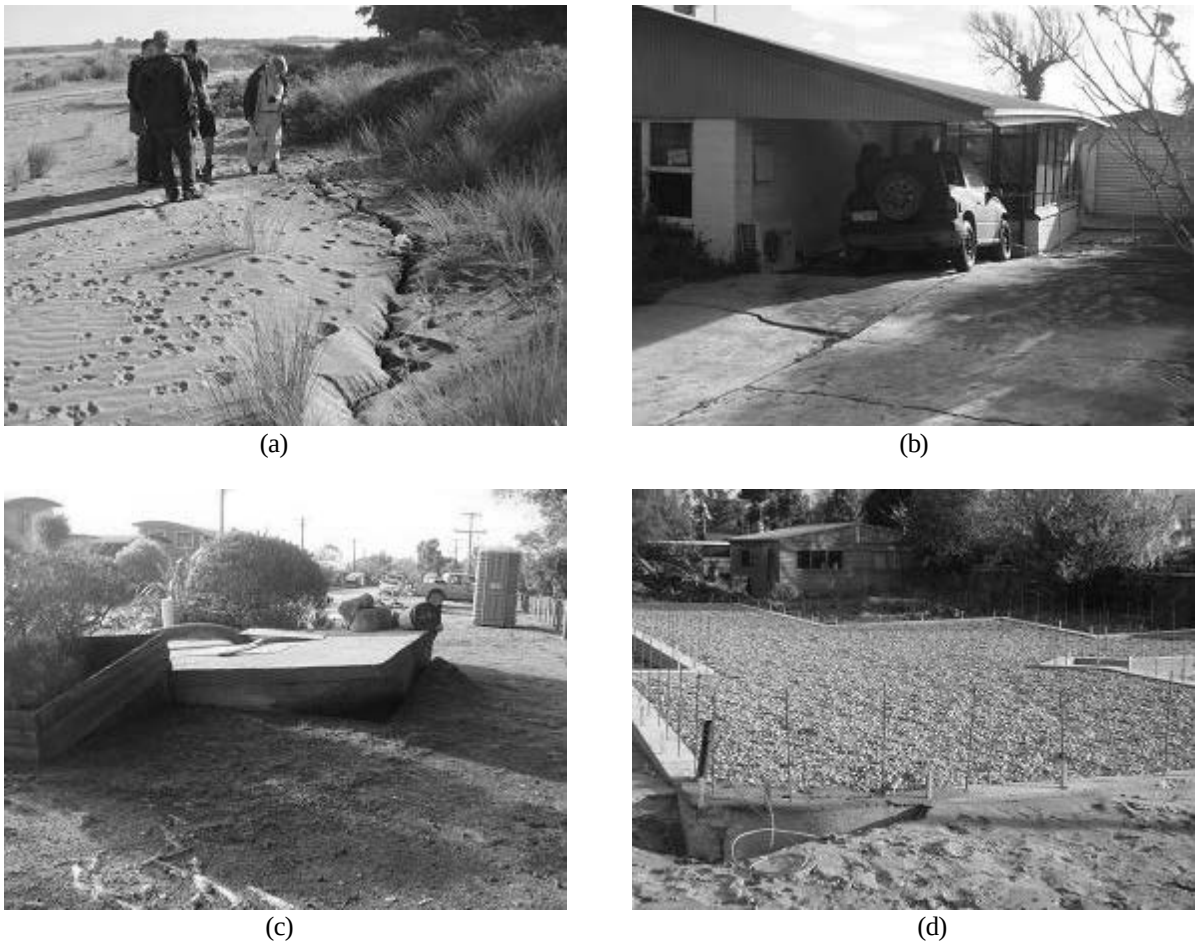

Waimakariri River and its proximity to Kaiapoi meant that some of these areas overlapped areas that have since been developed as the town has grown, as shown in Figure 6.

Thus, what was observed during this earthquake is consistent with the prediction of Christensen (2001) whose studies indicated that the eastern side of Waimakariri District (including Kaiapoi) has high susceptibility to liquefaction and settlements of up to 300 mm may occur for the earthquake scenarios considered in his study.

4.2 Pines Beach

The town of Pines Beach is situated to the east of Kaiapoi. In Kairaki Beach, ground cracks and sand boils were observed, with the cracks oriented parallel to the sea, indicating lateral spreading (Figure 7a). The cracks were as wide as 80 cm and lengths of several tens of meters. Subsequent measurements showed that the beach laterally spread by about 200 cm over a distance of 140 m.

Along Featherstone Avenue, a house settled by about 30 cm (Figure 7b) and sand boils were observed within the property. Interestingly, the ejected sand observed in the area was much less in volume when compared with those observed in most parts of Kaiapoi. The adjacent properties appear to have no damage. Along the same street, a sewer

(a) (b)

(c) (d)

Figure 7. Damage observed in Pines Beach.

tank was uplifted by about 40 cm (Figure 7c). Lots of sand boils were also observed in the nearby Featherstone Park.

In Pine Oval, houses were also damaged due to formation of cracks on the foundation ground. An unfinished house with the foundation exposed was seen in the area, shown in Figure 7d. Sand boils were observed adjacent to the exposed foundation. The perimeter beams, measuring 250 mm x 530 mm, has one D12 reinforcement each at the top and bottom, with concrete cover of about 80 mm. The protruding bars consisted of D10 bars, which will be bent inward and concrete will be poured over the site to form the unreinforced concrete slab. If this was the type of foundation used in many houses in the area, it is clear that these houses do not have enough resistance against uneven settlement or lateral spreading due to liquefaction.

4.3 Spencerville

Some residential houses in Spencerville, located north of Christchurch, were also affected by liquefaction and associated lateral spreading. Spreading was evident in areas along Riverside Lane paralleling the Styx River, where five large and newly constructed houses were severely damaged. These houses appear to be resting on slab foundations and have relatively large footprints (about 200-300m2). Compared to Kaiapoi and other areas affected by the earthquake, little ejected sand was observed but large ground cracks, in the order of 40-50 cm in width, were observed in some places (Figure 8a). The houses underwent minimal settlement, but the laterally spreading ground cut through the houses, destroying slabs and causing structural damage to houses (Figure 8b).

4.4 Bexley

The suburb of Bexley is located southeast of Christchurch CBD. The southern portion of the area was formerly a swamp and formed part of the Bexley wetlands. It has been reclaimed in the late 1990s by filling the area with fill materials and the subdivision was built over it. Interviews with homeowners indicate that the area was fairly new, with some houses built as recent as 5 years ago.

As expected, earthquake shaking triggered liquefaction of the loose swampy deposit, resulting in ground settlement and lateral spreading. Sand boils were observed at the entrance to the Bexley Wetlands Park (Figure 9a), as well as in the swampy areas. Large ground cracks, about 50 cm wide and 60-80 cm deep, were observed at the backyards of some houses and these cracks were oriented parallel to the marshlands (Figure 9b). Ejected sands filled up the whole neighbourhood, as thick as 30 cm in some areas (Figure 9c). Because of liquefaction, houses either tilted (Figure 9d), or were displaced laterally, with some houses showing cracks in the flooring slab. Most of the affected areas were

(a) (b)

Figure 7. Damage induced by lateral spreading in Riverside Lane, Spencerville

(a) (b)

(c) (d)

Figure 8. Observed liquefaction and associated ground deformations in Bexley.

concentrated on the southern portion of Bexley, where houses were built over the uncompacted reclaimed portion of the wetland.

Based on interview with the residents, the design plan for the foundations appear to be similar to those shown in Figure 7d, with perimeter beams and concrete slabs. Because of this, the houses were easily destroyed by the uneven settlement and lateral spreading induced by liquefaction.

When the visit was made, most of the ejected sands have been cleaned up and some home owners were already on the move. Moreover, Bexley Road on the western side of the subdivision was being re-paved and sand boils were also observed in the vicinity of the road.

(a) (b)

Figure 10. Damage to road and pond banks in the oxidation ponds.

4.4 Bromley Sewage Treatment Plant

The Sewage Treatment Plant operated by the Christchurch City Council is situated at Bromley, approximately 6.5 km east of Christchurch CBD and southwest of Bexley subdivision. Here, the domestic and industrial sewage of Christchurch are discharged into this estuary of the Avon and Heathcote Rivers. According to Robb (1974), up to 30 million gallons per day of treated sewage have been discharged since 1962 from a purification installation designed to give primary and secondary treatment, including a period of retention within a series of oxidation ponds.

Dyers Road along State Highway 74 cuts through the oxidation ponds and connects Ferrymead to Bexley. Road pavements were cracked at the site of the oxidation ponds and the road was impassable immediately after the earthquake. According to the engineer interviewed at the site, a 50 cm crack opened near the centreline of the road, although it was already paved during the site visit.

The pond bank separating Ponds 1 & 2 also cracked and slumped as a result of liquefaction (Figure 10a). Boiled sands were evident in many places. A sewage pipe running parallel to the bank was laterally compressed and was seen protruding through the water when the pond water was subsequently drained, as shown in Figure 10b. Note that because of the slumping of the pond banks, engineers decided to drop the pond level. Moreover, sheetpiles were driven into the bund to stabilize them and arrest further movement.

Seismic dilatometer tests were performed in the nearby Bromley Park and the results are shown in Figure 11. It can be seen that the upper 10m of the site consists of sand/silty sand with shear wave velocity less than 200 m/s.

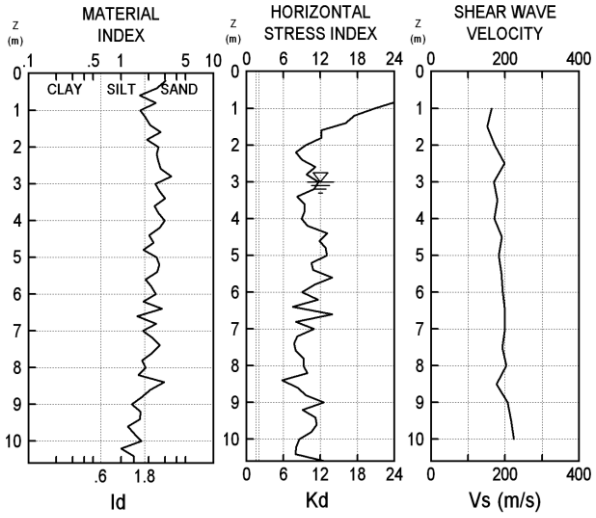

Figure 11. sDMT test results in Bromley Park site.

4.6 Dallington/Avonside

Evidence of liquefaction, such as sand boils and ground cracks, were also seen in many areas adjacent to the Avon River. For example, the hockey field in Porritt Park was destroyed by liquefaction, with boiled sands covering the green artificial cover and cracks and slumps evident underneath (Figure 12a). In the adjacent park, ejected sands and cracks were observed in the grass parallel to the river (Figure 12b). Adjacent to a bridge leading into park, the pavement was cracked, while the adjacent portion of Avon River was filled with mud and peat. From inspection, it appears that the south side of the river had moved towards the north side due to lateral spreading. The excess pore water pressure generated by the shaking could have pushed up the mud into the centre of the river. Note that this area is an abandoned meander of the Avon River, which resulted when the river was straightened for the rowing competition. As a result, it is expected that the ground underneath the park is very loose and prone to liquefaction.

Another area where extensive liquefaction was observed was in Dallington Terrace, located in the inner side of the meandering Avon River. Along Gayhurst Road, sand boils were observed everywhere. The approach to Gayhurst Bridge cracked and settled, rendering the bridge impassable immediately after the earthquake (Figures 13a). Cracks were also observed in the bridge abutments.

St. Paul Church, located also within the bend of Avon River, was damaged as a result of ground cracks induced by lateral spreading toward the river. Sand boils and cracks

(a) (b)

Figure 12. Damage to Horritt Park hockey stadium.

(a) (b)

Figure 13. Damage to Gayhurst Road bridge (courtesy of TV-3 website) and crack in the vicinity of St. Paul Church.

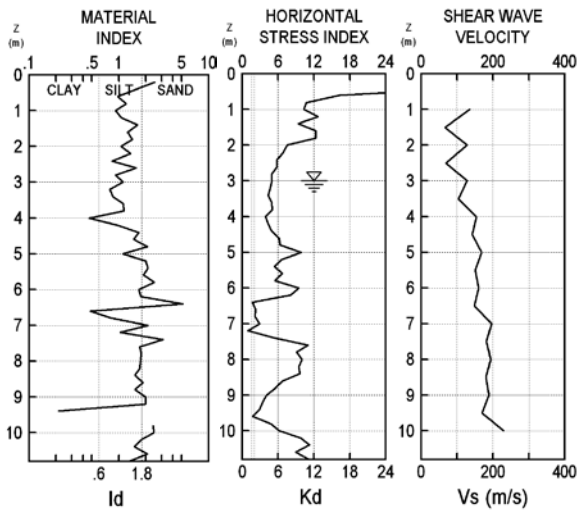

Figure 14. sDMT test results in St. Paul Church.

were observed in the vicinity of the church (Figure 13b). One long crack, about 40 cm wide with vertical offset of 20 cm, cuts through the church and halving it into two, as evident from Figure 18b. The grass adjacent to the church and the parking lots, were all littered by cracks, which were mostly oriented parallel to the river.

Seismic dilatometer tests performed at the back of the church revealed that the upper 10m of the site consists of silty sand materials with shear wave velocity between 100-200 m/sec, indicating that it is susceptible to liquefaction.

Along Locksley Avenue adjacent to Avon River, liquefaction was also evident. The footpath on the west side of Avon River buckled and slumped in several places (Figure 15a), and roads were cracked at several locations (Figure 15b). During the visit, repairs were being made on damaged water pipes. The damaged locations were at the same location as the ground cracks (Figure 15c), suggesting that lateral spreading of the ground induced the damage to underground pipelines.

5 SAND BOILS

In all places visited, the appearance of the ejected sands as a result of liquefaction were very similar, typically grey to dark grey in colour and consisting of very fine sands. Samples were taken at various locations and the grain size distributions were obtained using laser diffraction analysis. Figure 16 shows the grain size distribution curves of soil

(a) (b) (c)

Figure 15. Damage to footpath along Avon River in Locksley Ave.

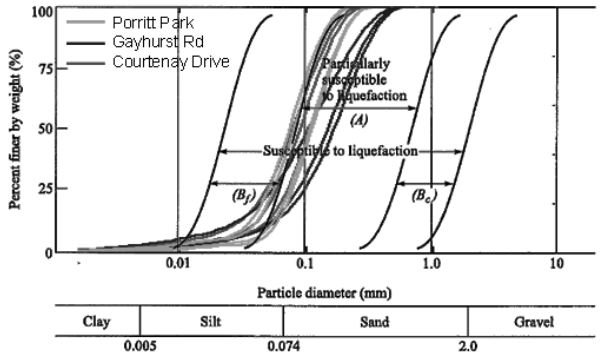

Figure 16. Grain size distribution of ejected sands taken at various locations plotted with respect to distributions observed to be susceptible to liquefaction (Modified from PHRI, 1997).

samples taken at Porritt Park, Gayhurst Road and Courtenay Drive (in Kaiapoi). It can be observed that the distributions of grain sizes were fairly similar, and they plot over a narrow range. The fines contents were low, ranging from 10-25%.

Also shown in the figure are the range of grain size distributions of sands which are deemed to have high possibility of liquefaction (A) and possibility of liquefaction (B). These ranges were obtained from past historical earthquakes in Japan and stipulated in the Japanese design code for port and harbour facilities. Note that there are problems associated with the use of compositional criteria as a measure of liquefaction susceptibility because there are no generally accepted criteria and the difference between natural and reclaimed deposits. Nevertheless, using these criteria, it can be seen that the ejected sands obtained at different locations in Christchurch can be said to be have high potential to liquefy.

6. CONCLUDING REMARKS

Based on the observations derived from the site visits, liquefaction during the 2010 Darfield Earthquake occurred in areas which are known to have high potential to liquefaction - former river channels, abandoned meanders, wetlands, and ponds. These areas are characterized by the presence of loose saturated sandy deposits, which are susceptible to liquefaction. In other words, liquefaction during this earthquake occurred in sites which are expected to liquefy. Liquefaction caused extensive damage to residential houses and other infrastructures through lateral spreading, ground subsidence, and differential settlements.

Abstract: On September 4, 2010, the Darfield Earthquake hit around the Canterbury region, New Zealand. This report summarizes results from field investigations in Christchurch city conducted by the Japanese Geotechnical Society survey team. The earthquake-induced liquefaction caused severe damage to residences, buried lifelines and river dikes. High ratio of occurrence of liquefaction was reported in areas which may be linked to the soft subsurface ground, lowland areas, former river channels and reclaimed lands that were constructed on the swamps. By conducting Swedish weight sounding tests, subsurface soil conditions with high ground water table and soft sandy deposits were investigated at several sites where liquefaction occurred in Christchurch city.

1. INTRODUCTION

The Darfield earthquake measuring the moment magnitude Mw of 7.1 (USGS, 2010) occurred at 4:35 local time on Saturday, September 4, 2010 with a focal depth of about 10km. The most affected city was Christchurch, a city about 40km east of the epicenter (Fig. 1). Fortunately, there are no reports of casualties by this earthquake.

Figure 1 Location of epicenter of Darfield earthquake (GeoNet, 2010)

Figure 2 shows the peak ground accelerations that were recorded in the Canterbury region during the earthquake. The ground motion shaking as a result of the main shock was widely felt in the Canterbury region as shown in Fig. 2. Although the recording above 1.0g can be seen in the near epicenter, the most devastated area, Christchurch city, was marked with 100-300gals. According to GNS Science, MMI-VIII was observed in Christchurch city.

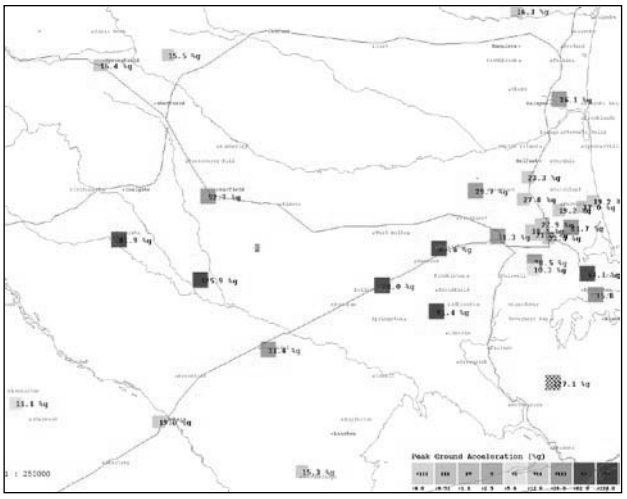

Figure 2 Peak ground accelerations in the Canterbury region during Darfield earthquake (GeoNet, 2010)

Since occurrence of liquefaction-induced damage had been reported by Yasuda (2010), the Japanese Geotechnical Society dispatched a survey team from September 11 to 16 in order to conduct detailed geotechnical investigations. Swedish weight sounding (SWS) device was brought from Japan, and SWS tests were carried out at several sites in Christchurch city. This report summarizes results from the above investigations in Christchurch city.

2. LIQUEFACTION-INDUCED DAMAGE

The business area of Christchurch city is located about 8.5km west of the coast line as shown in Fig. 3. A meandering stream, Avon-river, flows through center part of Christchurch city. Based on the damage aspects found in this survey, Christchurch city can be divided into three areas, business area, Dallington area and Bexley area. The results of the field survey are summarized below for each area.

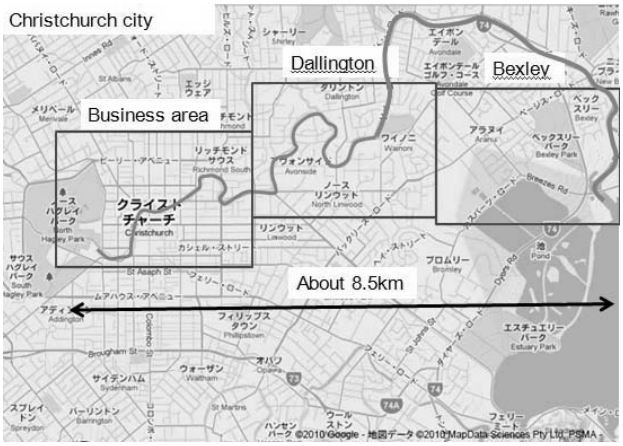

Figure 3 Map of Christchurch city

2.1 Business Area

Figure 4 shows the map of the business area. At site 1 in the park, sand boiling occurred as shown in Photo 1. This suggests that soil deposits in the park have been liquefied. However, in this park, the occurrence of sand boiling was very limited.

No sand boiling could be observed at the center of business are. Although some old buildings including historic sites suffered from cracking and dropping of masonry parts of the building, there was no damage to the symbol of the city, Christchurch cathedral, at site 50 (Photo 2). At site 25, a two stories old brick building was damaged as shown in Photo 3.

At sites 56 (Photo 4), sand boiling was found in residential which clearly indicates occurrence of liquefaction. The boiled sand that was retrieved from this area was fine sand with D_{50} of 0.14 mm and fines content of 17%. At sites 62 and 63, as shown in Photo 5 and 6 respectively, roads and levees along Avon-river suffered from ground deformation, which may be caused by liquefaction of subsoil deposits.

At site 55 about 300m from the Avon river channel, the trace of liquefaction was not observed.

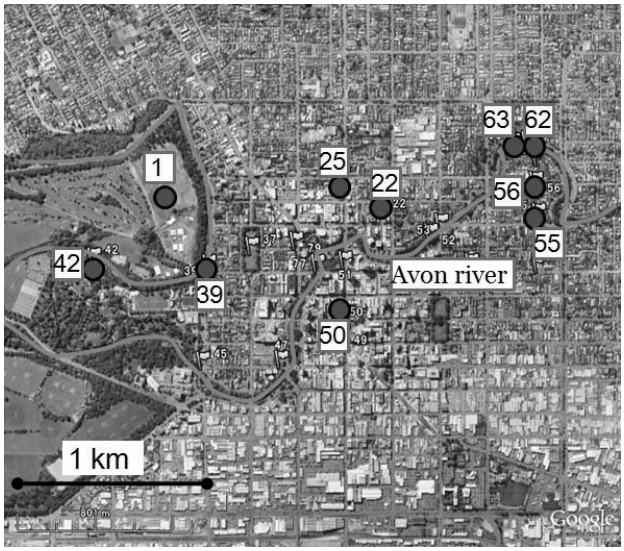

Figure 4 Survey map of business area in Christchurch city

Photo 2 No damage with Christchurch cathedral in business area (Site 50 in Fig. 4)

Photo 3 Brick house suffered damage (Site 25 in Fig. 4)

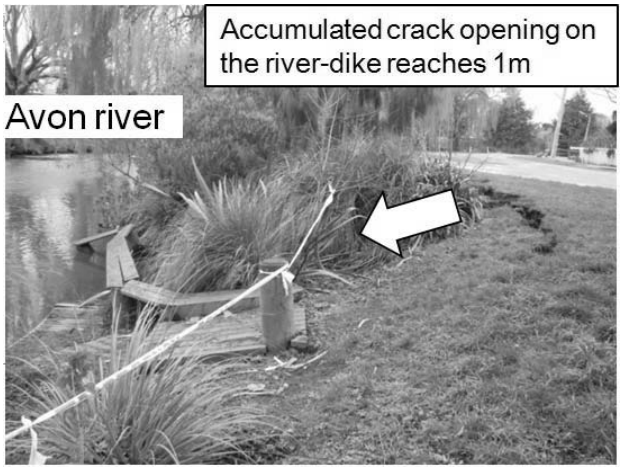

Photo 6 River dike along Avon-river suffered from large crack and lateral deformation (Site 62 in Fig. 4)

Photo 4 Sand boiling occurred at residential district in Business area (Site 56 in Fig. 4)

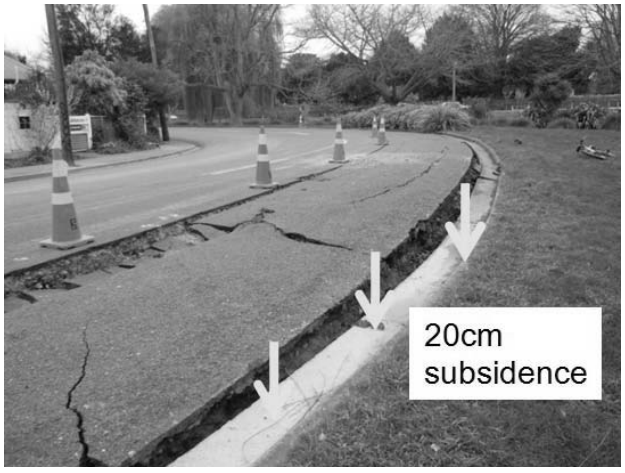

Photo 5 Road on river dike suffered from settlement and cracking (Site 63 in Fig. 4)

2.2 Dallington Area

Since the preceding survey by Yasuda (2010) had reported that extensive damage to houses and roads by liquefaction was concentrated in Dallington district in Christchurch city, attempts were made in the present survey to reveal the soft soil conditions in Dallington district as well as possible effects of liquefaction. The survey map of Dallington area is shown in Fig. 5.

At the time of the earthquake, the areas along Avon-river were inundated with boiled sand and ground water. However, at the time of survey that was conducted in 8 days after the earthquake, no water could be observed on the street, and the sand was placed at the side of the street (Photo 7).

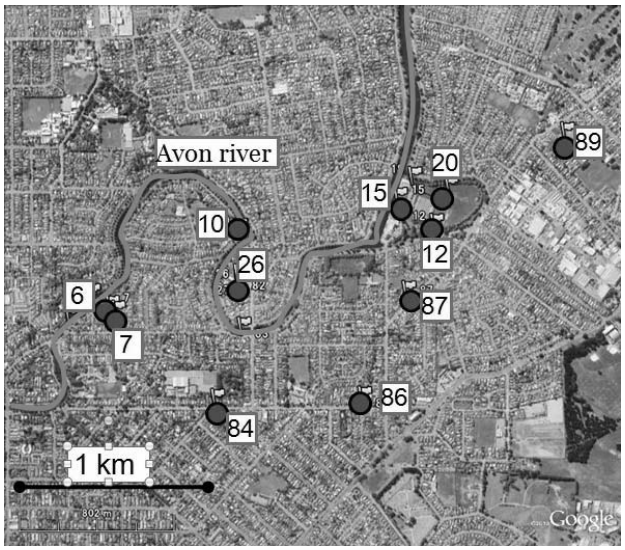

Figure 5 Survey map of Dallington area in Christchurch city

Photo 7 Boiled sand was placed at side of the street. (Site 6 in Fig. 5)

In order to investigate the subsurface soil properties, Swedish weight sounding (SWS) tests were carried out at five sites in Christchurch. Two of them were conducted in Dallington area while the others will be reported next section.

SWS test results conducted at sites 7 and 26 in Dallington district are shown in Fig. 6. Photo 8 shows the implementation of SWS test at site 7. Herein, the measured values of W_{SW} and N_{SW} has been converted into equivalent SPT-N value, N_{SPT}, by using the equation as follows (JIS A 1221).

$$N_{SPT} = 0.002W_{SW} + 0.067N_{SW} \qquad (1)$$

where Wsw is the minimum load required for penetration with 1000N or less than 1000N after starting penetration and N_{SW} is the value of static penetration resistance, which is the number of half rotations per penetration amount of 1m with the load of Wsw=1000N.

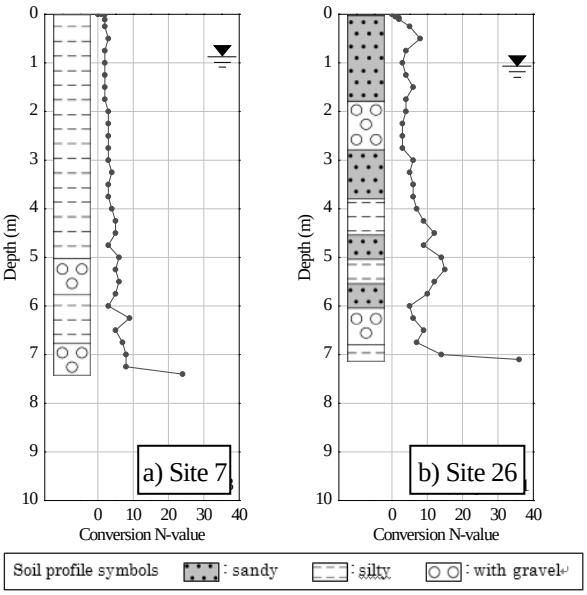

Figure 6 SWS test results (Sites 7 and 26 in Fig. 5)

At site 7, housing floors suffered from cracking that was caused by uneven settlement of the ground, and the boiled sand covered their garden with a thickness of 30cm. As shown in Fig. 6a), the ground water table was shallower than 1m from the ground surface, below which soft soil deposits with N_{SPT} values less than 5 could be found for a thickness of about 5m. It clearly indicates occurrence of liquefaction with this soft layer. The boiled sand that was retrieved at the same location as SWS test was fine sand with D_{50} of 0.12 mm and fines content of 18%.

Photo 8 SWS test (Site 7 in Fig. 5). Behind of experimenters, there is house suffered from cracking.

At site 26, St. Paul's Church that is located near the Avon-river suffered from uneven settlement. As shown in Figure 7, the settlements of 95cm and 109cm were measured at each side of cracking at the center part of the church, and the maximum settlement was measured around the tall structure. The pattern of the settlement of the church could be recognized from the angle of inclination of the wall as shown in Fig. 7. In addition, the pavement around the church also suffered from cracking for a maximum differential settlement of about 50 cm as shown in Photo 9. These damages may have been caused by liquefaction because the extensive sand boiling occurred around the church.

SWS test result conducted at an open space next to the church is shown in Fig. 6b). The ground water level was about 1m from the ground surface, below which soft soil deposits with N_{SPT} values less than 7 could be found for a thickness of about 4m. The boiled sand that was retrieved around the church was fine sand with D_{50} of 0.11mm and fines content of 28% (PI= NP). This suggests that soil deposits around the church may have liquefied significantly.

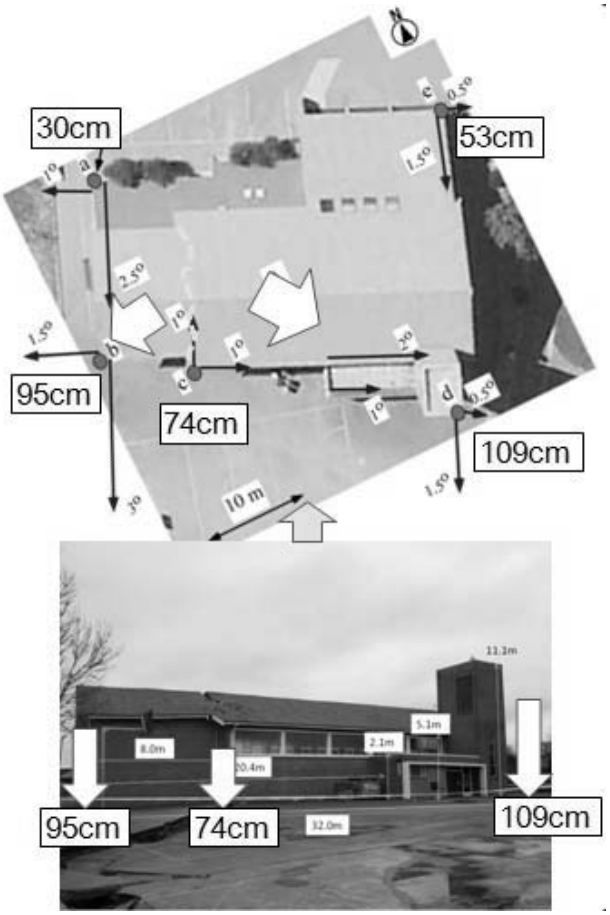

Figure 7 St Paul's church (built in 1956) suffered uneven settlement due to liquefaction (Site 26 in Fig. 5)

Photo 9 Pavement around St Paul's church suffered from large cracking and settlement (Site 26 in Fig. 5)

An unusual aspect of liquefaction observed in this survey is the low height of sand boiling. When liquefaction occurred, splash of both groundwater and liquefied sand to a height of several meters has been frequently observed in past earthquake. Although large amount of boiled sand could be observed throughout the city, there is little evidence of mud marking on the wall which would be resulted by sand boiling. This suggests that liquefied soil deposits may have a wide distribution with homogeneous condition, so that excess pore water pressure at local site became insignificant. In addition, we didn't find any up-lifted manholes and pipes during this survey, which could be frequently observed in past earthquake in Japan.

At site 20 at Porritt Park that is located about 1km east from the St. Paul's Church, sand boiling occurred throughout the park. Although the SWS test was not conducted in this park, the sand deposits were expected to be very soft because this park is surrounded by existing and previous river channels where the loose soil deposit is expected to be. Numerous cracks having a maximum opening width of 70 cm occurred in ground surface (Photo 10). These cracks were caused by liquefaction because almost all crack openings were filled with boiled sand. Since most of these cracks seem to be parallel to the previous river channel, the surface subsoil may have moved to the previous river channel and upraised riverbed as shown in Photo 11.

In the adjacent area (site 15), as show in Photo 12, river levee was damaged due to settlement and cracking, possibly caused by liquefaction of subsoil deposits.

Photo 10 Number of cracking and boiled sand could be observed in Porritt Park (Site 20 in Fig. 5)

Photo 11 Riverbed of previous river is upraised (Site 12 in Fig. 5)

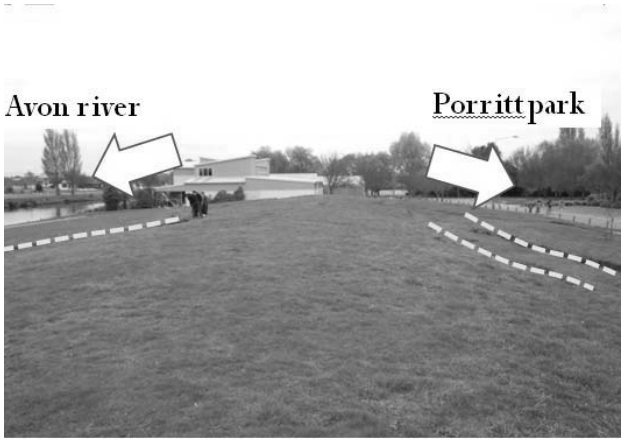

Photo 12 River levee was damaged due to settlement and cracking (Site 15 in Fig. 5)

As mentioned above, damage to the infrastructures due to liquefaction could be observed at many places along Avon-river. However, no sand boiling was observed at sites 84, 86, 87 and 89, about 300-500 m from Avon-river, so that possibility of liquefaction occurrence at these sites seems to be limited.

2.3 Bexley Area

The survey map of Bexley area is shown in Fig. 8. At site 91, about 1 km west from Bexley area as well as Avon river, there was no damage by liquefaction as shown in Photo 13. However, towards the Bexley area, the boiled sand came to be recognized on the street as shown in Photo 14.

Reportedly, the residential area in Bexley had been swamp, which was elevated by soil filling about 5 years ago. The swamp condition may be preserved south of residential area.

High damage ratio of houses was observed along the margins of landfill, and the slope of the filling was damaged due to excessive settlement and cracking (Photo 15). The boiled sand caused by liquefaction of fill material was observed around the damaged area.

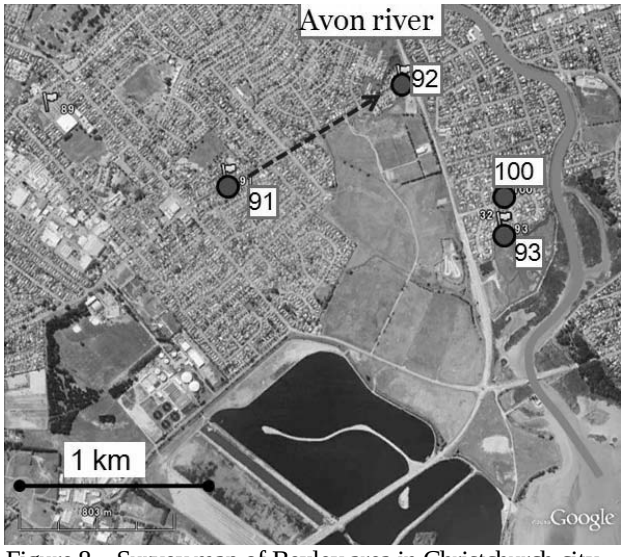

Figure 8 Survey map of Bexley area in Christchurch city

Photo 13 No damage due to liquefaction was observed (Site 91 in Fig. 8)

Photo 14 Street covered with boiled sand (Site 92 in Fig. 8)

Photo 15 Foundation of house suffered from large cracking (Site 93 in Fig. 8)

The result of SWS tests at site 93 that were conducted at the side of damaged house (Photo 15, Fig. 9a)) and the edge of swamp water (Fig. 9b) are shown in Fig. 9. The groundwater level in Fig. 9a) was about 1.5m from the ground surface, below which very soft sandy soil deposits with N_{SPT} values less than 5 could be found for a thickness of about 4m. This suggests that the soil compaction for landfill may not be enough at the time of the construction of

landfill. The boiled sand that was retrieved at the same location of SWS test was fine sand with D50 of 0.13mm and fines content of 12%.

As shown in Fig. 9b), there existed very soft silty soil deposits at the edge of swamp water with N_{SPT} values less than 5 for a thickness of more than 9m.

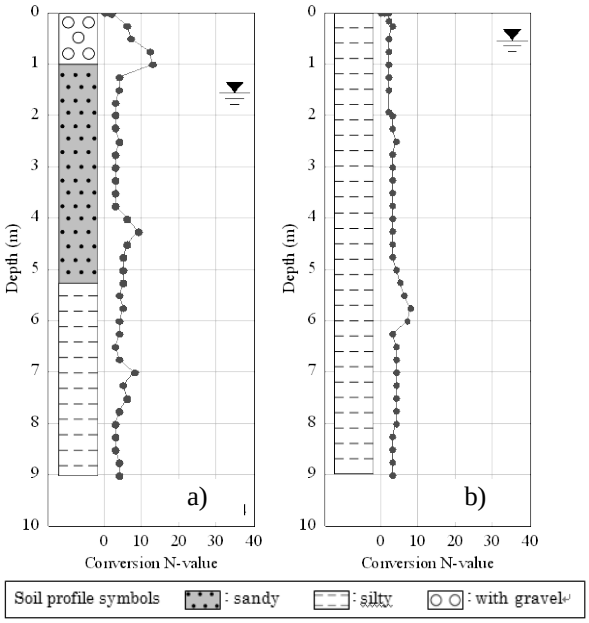

Figure 9 SWS test results (Sites 93 in Fig. 8)

Figure 10 shows the result of SWS test that was conducted on the landfill at site 100, about 300m from the margins of the landfill. The ground water level was shallower than 1.5m from the ground surface, below which soft soil deposits with N_{SPT} values less than 10 could be found for a thickness of about 5m. The N_{SPT} values at this point were slightly higher than those measured at the margins of landfill and the edge of swamp water as shown in Fig. 9. In fact, sand boiling around the site 100 was not significant as compare with other site.

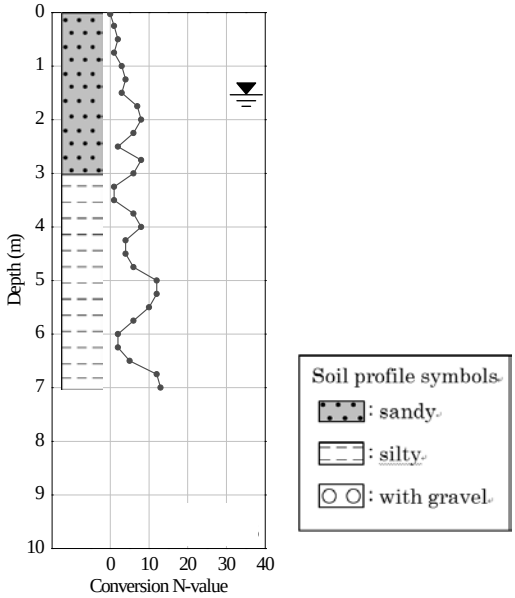

Figure 10 SWS test results (Sites 100 in Fig. 8)

3. SUMMARY

The authors conducted damage survey after the Darfield Earthquake in Christchurch city, New Zealand. The results from the survey can be summarized as follows:

Significant liquefaction occurred in Dallington and Bexley areas, the east part of Christchurch city. It caused severe damage to residences, buried lifelines and levees in Dallington area while the landfill suffered from cracking and deformation in Bexley area. By conducting Swedish weight sounding (SWS) tests, subsurface soil conditions with high groundwater table and soft soil deposits were investigated at several sites in Dallington and Bexley areas. Although sand boiling was seldom observed in business area, some old brick buildings suffered from cracking and dropping of masonry parts of the building.

Based on the survey, the earthquake-induced damages in Christchurch city can be summarized in Fig. 11. The liquefaction-induced damage to the infrastructures including houses could be observed along Avon-river except for business area, while possibility of liquefaction occurrence seems to be limited at the sites that more than 300m from the river.

It should be noted that, as shown in Fig. 11, the classification of damage in Christchurch city has not been completed in every location. Further wide-range of investigations is required.

Abstract: We report on a reconnaissance survey on the seismological and geotechnical aspects of the 27 February, 2010 Maule mega-earthquake, Chile, carried out between April 27 and May 1, 2010. The survey was sponsored by the Japan Science and Technology Agency and JICA (SATREPS). In this study we surveyed the cities of Concepción Viña del Mar and Santiago. We also performed microtremors measurements at strong motion stations that recorded the earthquake. We will give an outline of the fault rupture process and strong motion characteristics of the earthquake and the site effects estimated from microtremor measurement.

1. INTRODUCTION

The 2010/2/27 Maule (Chile) mega-earthquake, the fifth largest earthquake in instrumental history, was located in the subduction of the Nazca plate in Meridional Andes beneath the South American plate. This earthquake fills a well studied seismic gap between the source areas of the largest ever recorded 1960 Great Valdivia earthquake (M 9.5), and the 1985 Valparaiso earthquake (M7.8) (Ruegg et al. 2009). In this study we report on a reconnaissance survey on the seismological and geotechnical aspects of the 27 February, 2010 Maule mega-earthquake, Chile, carried out between April 27 and May 1, 2010. The survey was sponsored by the Japan Science and Technology Agency and JICA (SATREPS), under the framework of a newly launched 5 years SATREPS project entitled "Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru" (Yamazaki et al. 2010). In this study we surveyed the heavily damaged city of Concepción, as well as moderately damaged cities of Viña del Mar and Santiago (Figure1). We performed microtremor measurements at strong motion stations that recorded the earthquake in order to evaluate their site characteristics. We also surveyed the damage to buildings due to tsunami effects in Dichato and Talcahuano among other areas but these results are reported elsewhere (Shoji et al 2010).

2. SOURCE PROCESS OF THE MAULE EARTHQUAKE

The Maule earthquake ruptured a source area of nearly 450 km extending from southern Santiago in the North, down to the Arauco Peninsula south of Concepción city. The intensity distribution obtained from a questionnaire survey soon after the earthquake (Astroza et al 2010), indicates that a region of nearly 350 km above the fault plane experienced an intensity larger than 5 upper in the JMA intensity scale (Figure 2). This earthquake was an inter-plate mega-subduction event with a pure reverse mechanism, and had a seismic moment magnitude of 8.8 (Figure 3). The source rupture model of this earthquake was obtained by inversion of 38 P-wave teleseismic waveforms of the FDSN and GSN global seismic networks and using an inversion technique that incorporates an error component in Green's function calculation and the Akaike's Bayesian Information Criteria (ABIC) (Yagi and Fukuhata 2008). The source process is characterized by two asperities with a peak slip of more than 10 m and a rupture area of approximately 450 by 200 km^2 (Pulido et al. 2010). The first asperity is located at the hypocenter and the second is located approximately 150 km north-east of the hypocenter. The rupture propagated bilaterally starting slightly south of Constitución and with an average rupture velocity of 2.8 km/s, however the main moment release was located towards the North in the Pichilemu region. The source moment function has a total source duration of 150 s and display two sub-events separated by 30s (Figure 3).

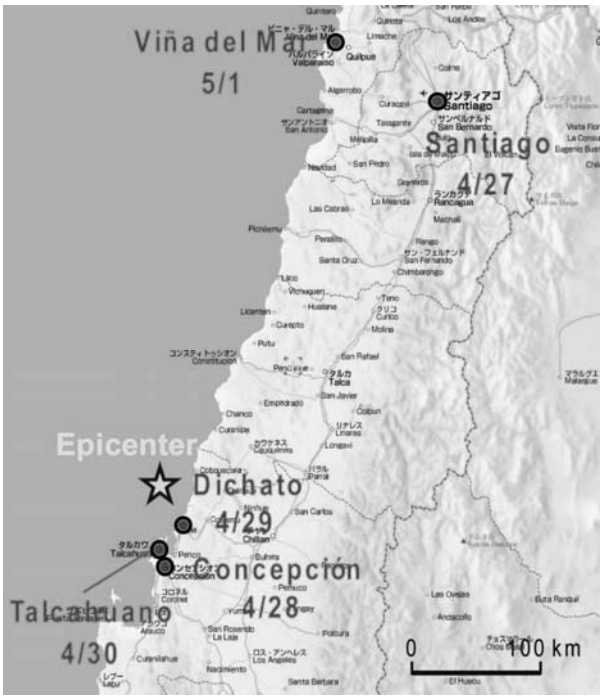

Figure 1 Location of sites for field survey

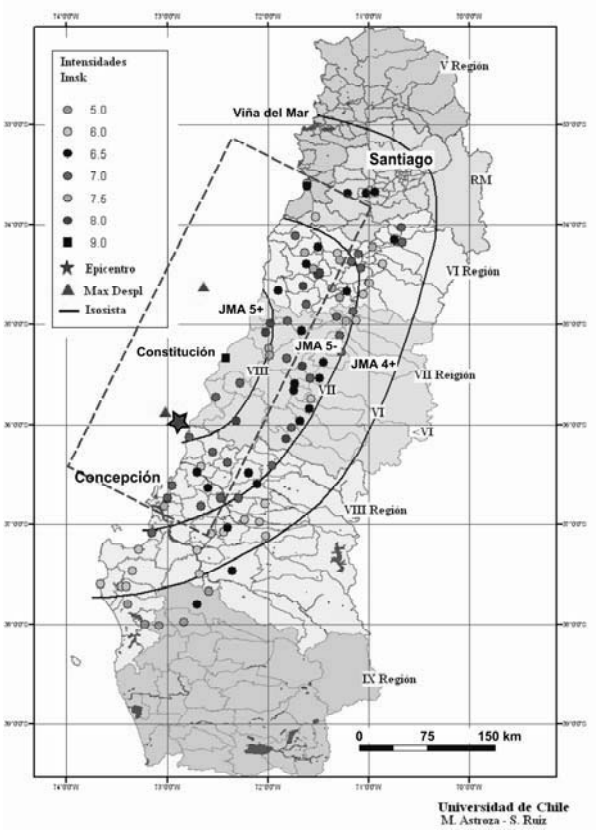

Figure 2 Intensity distribution of the Maule earthquake based on questionnaire survey (Astroza et al. 2010).

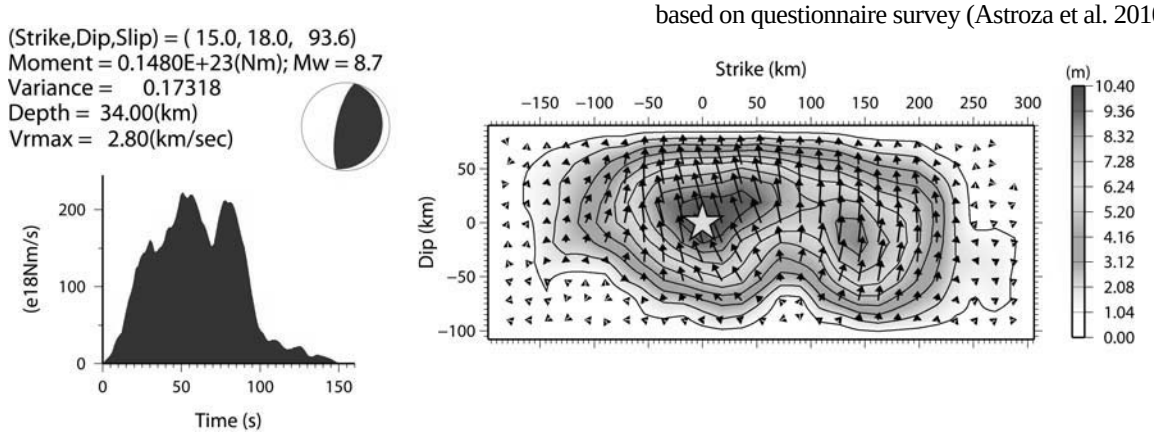

Figure 3. Source model of the 2010/02/27 Maule mega-earthquake (Pulido et al. 2010).

The average rake angle of this earthquake is 93 degrees which approximately corresponds to the oblique convergence of the Nazca plate beneath the South American plate.

3. STRONG MOTION CHARACTERISTICS

The Maule earthquake was recorded by 30 strong motion stations belonging to Universidad de Chile (Servicio Sismológico Nacional SSN, Geophysics department, 10 stations, and Red Nacional de acelerógrafos, RENADIC, Civil Engineering department, 20 stations). Instruments are mostly digital (21), and a large number of them is localized in Santiago (10) (Table 1). Published maximum PGA and PGV values reached 909 cm/s^2 at the Angol station south of Concepción, and 69 cm/s at Constitución (Table 1, Figure 4). Strong ground motions recorded in the northern region of the source area such as Curicó, Santiago and Viña del Mar display two clear sub-events separated by 15s to 30s, which is consistent with a rupture propagation velocity value of 2.8 km/s (Figure 4). Stations towards the central and southern regions of the source area such as Constitución, Concepción and Angol do not diplay distinct sub-events, as the rupture propagation of the northern asperity gradually runs away from southern stations. Angol station displays the largest PGA which indicates the possibility of large slip below the Arauco peninsula (around latitude -37.5 degrees), that is not sufficiently simulated in our current slip model. In fact a recent study indicates that the Arauco peninsula experienced a maximum coseismic uplift of 2.5m along the

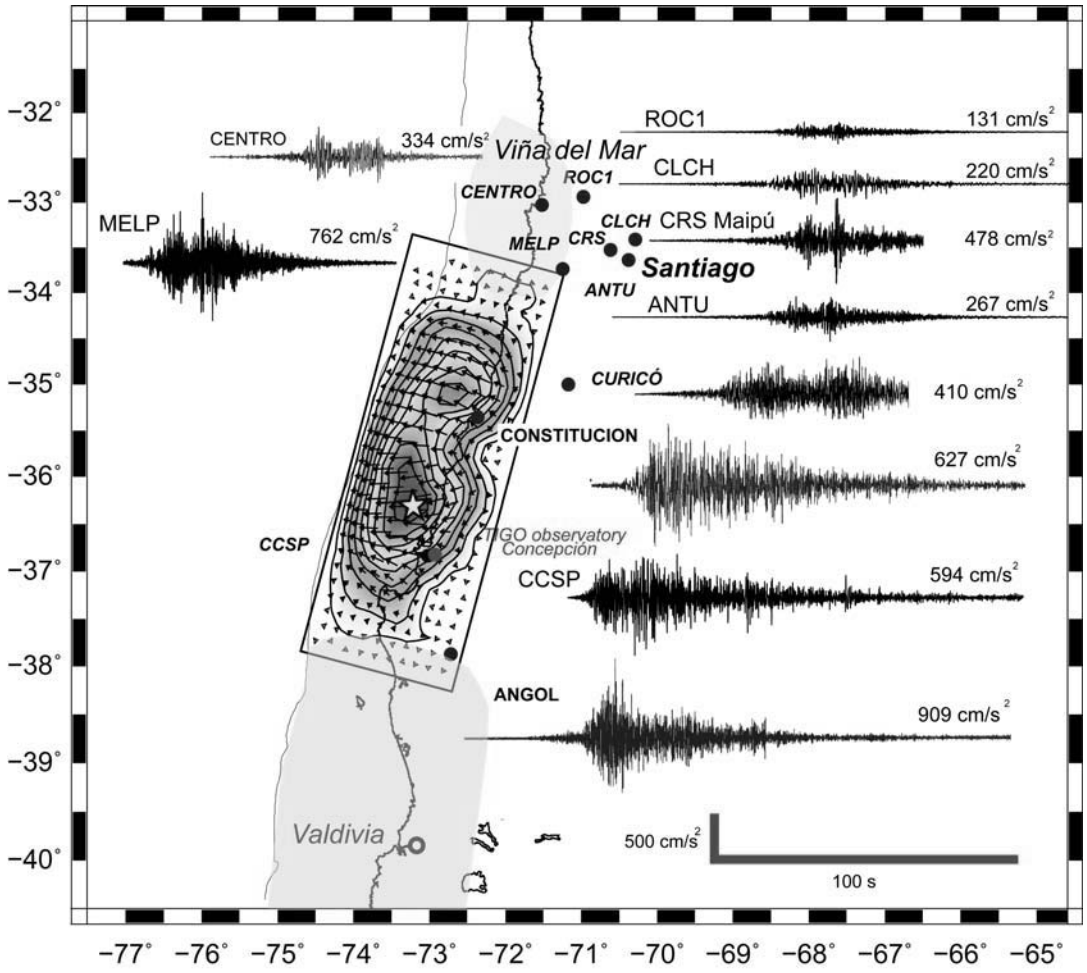

Figure 4. Source model and strong ground motion recordings of the 2010/02/27 Maule mega-earthquake (Pulido et al. 2010).

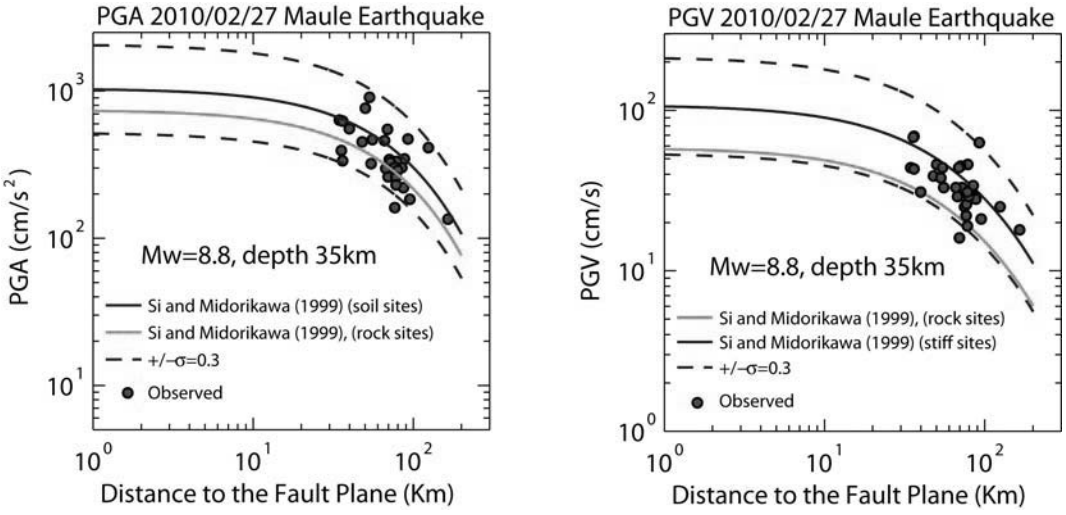

Figure 5. Attenuation of PGA and PGV for observed strong motions Maule mega-earthquake (Chile)

coast, suggesting that the source area could have reached a latitude as far as -38 degrees (Farías et al. 2010), which approximately corresponds the northern end of the 1960 Valdivia earthquake.

In Figure 5 we plotted the PGA and PGV attenuation characteristics of observed strong ground motions of the Maule earthquake, for all the sites described in Table 1. We plot the data together with an empirical relationship of PGA and PGV for inter-plate subduction earthquakes (Mw=8.8, depth 35 km) for soil, stiff soil and rock site conditions (Si and Midorikawa 1999). We may observe that all observed data falls within one sigma (+/-0.3) around the values for a

stiff soil. This result implies that the observed peak ground motions characteristics from the Maule earthquake can be satisfactorily explained by a typical empirical attenuation relationship for inter-plate subduction earthquakes.

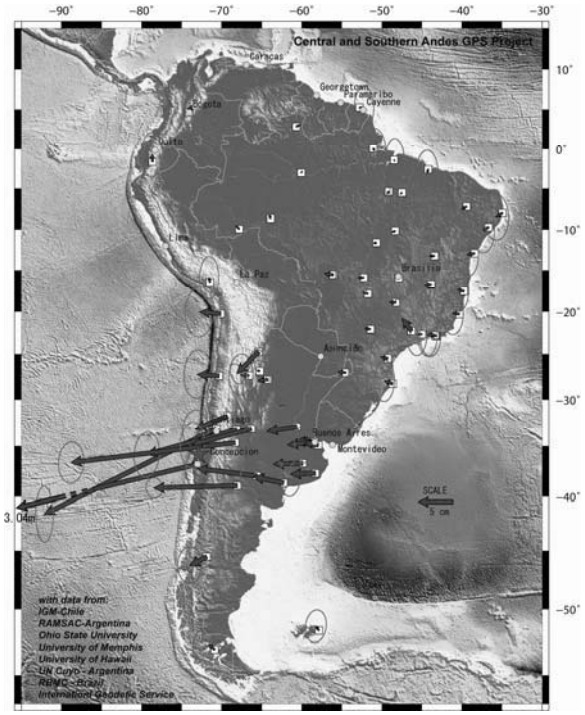

Figure 6. Coseismic displacements at South American GPS stations during the 2010/02/27 Maule mega-earthquake (Chile). Displacements at Concepción are as large as 3 m to the West (Foster and Brooks 2010).

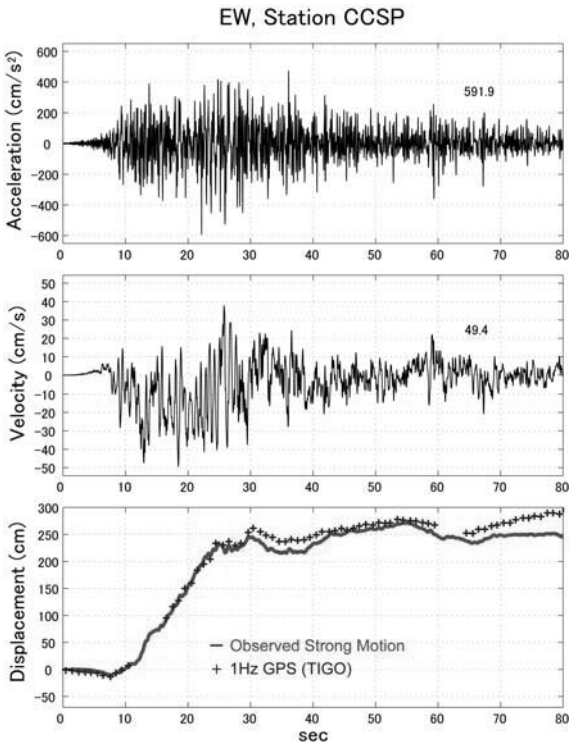

Figure 7. Strong ground motion recording of the 2010/02/27 Maule mega-earthquake (Chile) at the Colegio San Pedro (Concepción), strong motion site. Upper panel shows the unfiltered acceleration, middle panel the unfiltered and de-trended velocity, and the lower panel the calculation of the permanent displacement at this station (Pulido et al. 2010)

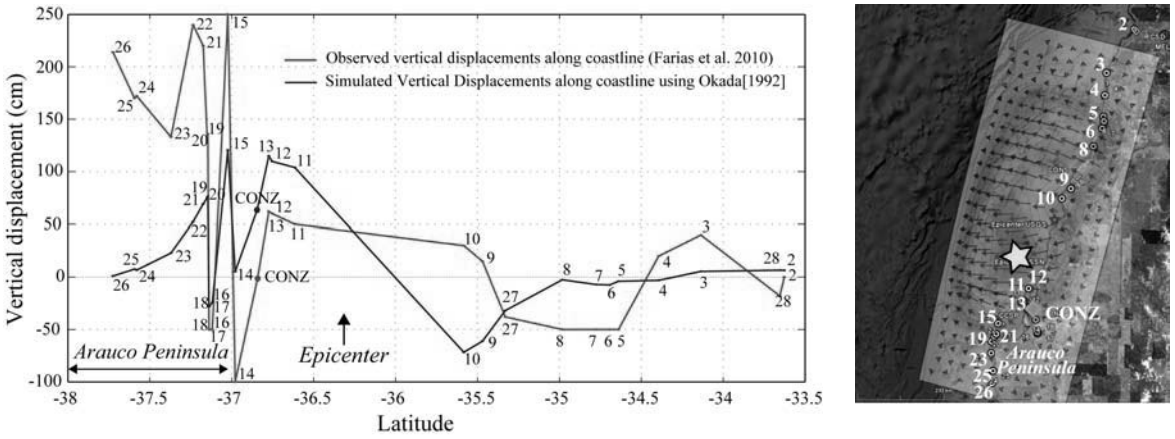

Figure 8. Comparison between observed (red) and simulated (blue) permanent coseismic vertical displacement along the coast during the 2010 Maule earthquake (left figure). Observed vertical uplifts where measured from observation of changes in coral algae along the coast (Farías et al. 2010). Right figure shows the location of vertical displacement measurement points.

4. COSEISMIC PERMANENT DISPLACEMENTS

GPS measurements from the Maule earthquake in South America indicate a coseismic displacement to the West as large as 3m at the CONZ station in Concepción (Figure 6). CONZ is a high sampling GPS (cGPS) station located at the Transportable Integrated Geodetic Observatory (TIGO), which recorded in real time the Maule earthquake (Sierk and Hase 2010). We attempted to calculate the permanent displacement at Con-cepción by using a strong motion recording of the earthquake at the CCSP station, which is closely located to the TIGO observatory. For that purpose we double integrated and de-trended the unfiltered acceleration data. Our results show nearly 3m of permanent displacement to the West, which is in very good agreement with the results by the cGPS recording at TIGO (Figure 7). Displacement time series obtained from this strong ground motion recording are also in close agreement

with the observed cGPS from the arrival of the rupture up the static displacement value.

We also calculated the coseismic vertical displacements along the coastline by using our source model of the Maule earthquake (Figure 3) and analytical expressions for strains and displacements in a half space due to shear dislocations (Okada 1992) (Figure 8). Our simulation results show in general a good agreement with the observed uplift/subsidence values along the coast, estimated from changes in coral algae (Farías et al. 2010) as well as high sampling GPS measurements at the TIGO geodetic observatory [CONZ] (Figure 8). However our simulated vertical displacements underestimate the observed values at the Arauco peninsula, suggestting larger values of coseismic fault slip beneath the Peninsula (Figure 8).

5. MICROTREMORS MEASUREMENS AT STRONG MOTION SITES

In order to estimate the site characteristics at strong motion sites that recorded the mainshock we performed microtremor measurements in Santiago, Concepción and Viña del Mar cities. The microtremor measurements were performed by using a velocity sensor with predominant period of 2 s and a sampling frequency of 200 Hz. Measurement time at each site was set to 300s.

5.1 Santiago City

We surveyed two areas in Santiago city. The first area (MPS) is the RENADIC Santiago Maipú RM strong motion station located in the western region of the city (Figure 9). We found several heavy damaged buildings around this area.

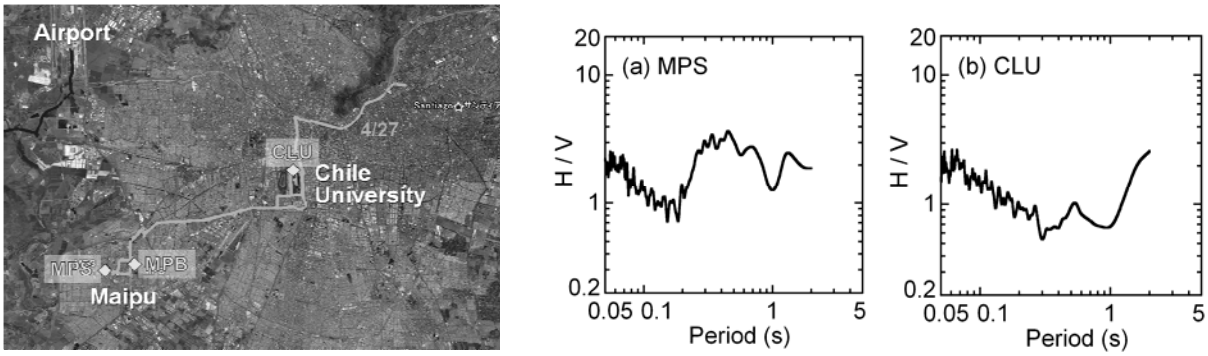

Figure9. H/V of microtremors measurements near strong motion station Maipu [MPS], and Chile university [CLU] in Santiago city

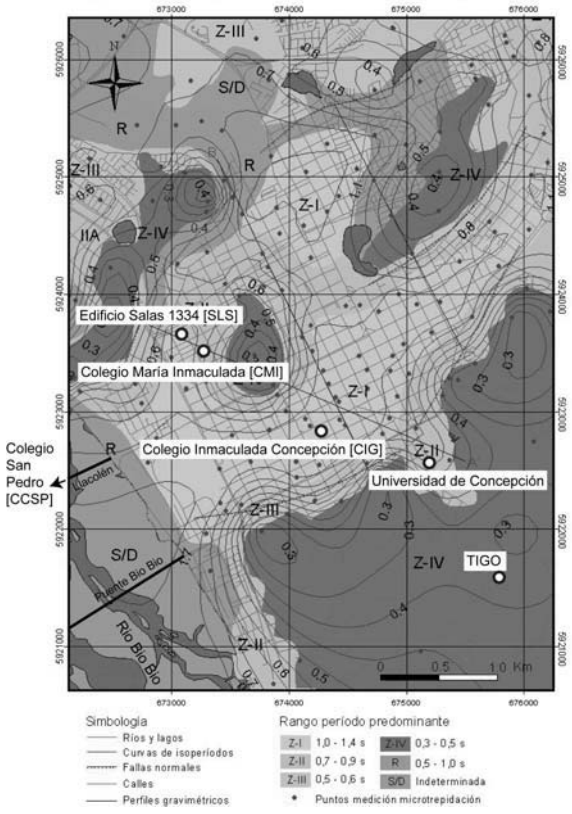

Figure 10. Microzonation map of Concepción city (Ramírez and Vivallos 2009). Survey sites are shown within the figure

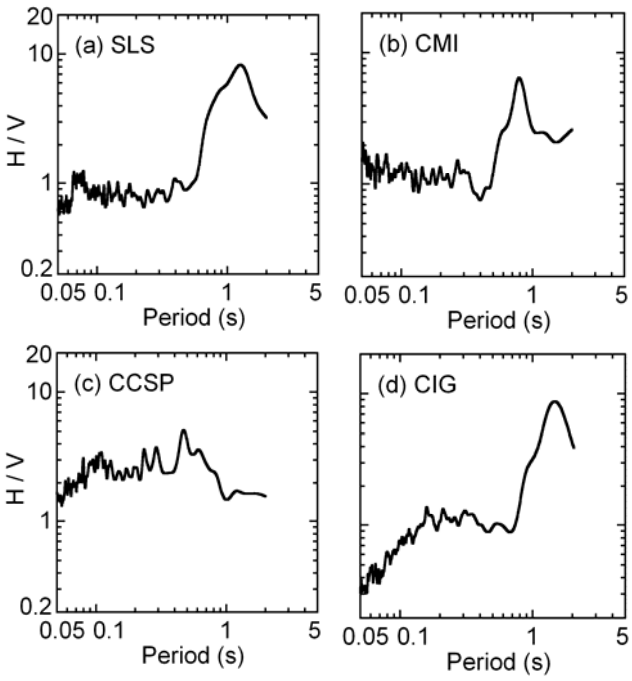

Figure 11. H/V ratios of microtremors in downtown Concepción city

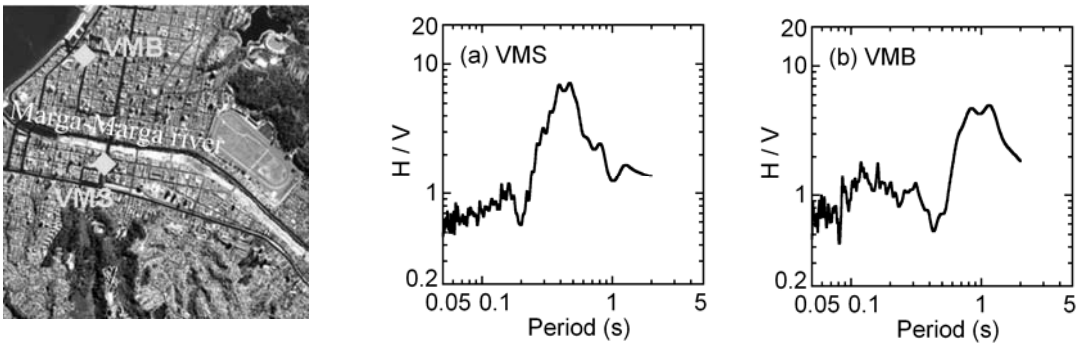

Figure12. H/V of microtremors measurements near strong motion station Viña del Mar Centro [VMS], and within the building damage area [VMB] in Viña del Mar

We also surveyed the area near Chile University in the center of Santiago city (CLU). In this case our survey indicates no building damage around this area. Our H/V measurements at MPS indicate a clear peak around 0.4s. This site experienced a PGA value of 550 cm/s^2 and a PGV of 44 cm/s respectively. On the other hand H/V measurements at CLU don't show a clear peak. These measurements suggest that the site effects may have had a contribution to the building damage near MPS.

5.2 Concepción City

In Figure 10 we show the microtremor measurements sites as well as other survey sites on a microzonation map of Concepción city (Ramírez and Vivallos 2009). This microzonation is based on H/V measurements as well as other geological and geotechnical information. A yellow region on the map (Z-I) corresponds to H/V peaks of 1.0-1.4s. We can observe that the dowtown area is largely characterized by a predominant peak around 1s. On the other hand in the South-West area of downtown runs the Bio-Bio river which suggest that the soil condition in this region might be characterized by thick alluvial deposits. We performed microtremor measurements at four sites including two schools in down-town; Colegio inmaculada Concepción (CIG), Colegio María Inmaculada (CMI), a heavily damaged (to be demolished) 12 stories reinforced concrete building (Edificio Salas 1334, SLS), and another school located in the opposite shore of the Bio-Bio river in a mountain footslope area (Colegio San Pedro) (Figure 10). Our H/V measurements at CIG and SLS show a predominant peak larger than 1s, and a peak of 0.7s at CMI (Figure 11). The heavy damage sustained at SLS might be related with the large H/V peak at this site. The underground floor of the CIG building accomodates a RENADIC analogue acelerograph that recorded a PGA value of 394 cm/s^2 and a PGV of 68 cm/s. This building sustained a moderate damage and according to the shool principal an older section of the school also experienced the 1960 Valdivia earthquake. Our H/V measurements at Colegio San Pedro where located near the CCSP strong motion station within the school premises. This site recorded a PGA value of 637 cm/s^2 and a PGV of 44 cm/s. The school is built on a sandy soil area within a small valley, and the CCSP is located at the egde of the valley near a slope. A 1 story classroom located close to the strong motion station sustained significant damage produced by subsidence of the ground. Although H/V measurements close to the CCSP station do not show significant peaks (Figure 10), another H/V measurement at the school ground in the middle of the valley show a clear peak around 0.3s. This indicates that the CCSP station is located at the edge of the valley sandy soil deposits (Sekiguchi et al. 2010).

5.1 Viña del Mar city

We surveyed two areas in down town Viña del Mar. The first area (VMS) is located in the southern region of the Marga Marga river close to the RENADIC Viña del Mar Centro strong motion station (Figure 12). Our survey indicates no building damage around this area. We also surveyed the area to the north of Marga-Marga river (VMB). In this case we found a heavy concentration of damage to medium rise apartment buildings. Our H/V measurements at VMS indicate a clear peak around 0.4s. This site experienced a PGA value of 327 cm/s^2 and a PGV of 33 cm/s respectively. On the other hand H/V measurements at VMB show a clear peak at 1s. These measurements suggest that the site effects may have had a big contribution to the building damage at VMB, and indicate the ground motion might have been stronger at the Nothern part of Marga-Marga river compared to the Southern area.

6. CONCLUSIONS

We performed a field survey of the 2010 Chile earthquake which included visits to several universities in Santiago, Concepción and Viña del Mar, as well as microtremor measurements near strong motion stations at these cities. Near-source strong ground motions characteristics of the mainshock are largely influenced by complexity in source rupture process. On the other hand ground motion attenuation characteristics of this earthquake can be satisfactorily explained with a typical empirical law for inter-plate subduction earthquakes. Based on a strong motion recording of the mainshock we obtained a 3m

permanent displacement to the west at Concepción city, which is in very good agreement with the results obtained by a 1Hz GPS recording of the earthquake at the TIGO observatory in Concepción. Our theoretical calculations of coseismic displacements along the coast are also in good agreement with the observed data. Our microtremors measurements and field survey indicates a clear relationship between site effects and building damage. Future research work includes the improvement of our source model using constraints from near-source data as well as the strong motion simulation of this earthquake.

SEISMIC RISK PERFORMANCE OF URBAN TRANSPORTATION SYSTEMS CONSIDERING SITE EFFECTS AND INTERACTION WITH THE BUILT ENVIRONMENT

Sotirios Argyroudis[1)] and Kyriazis Pitilakis[2)]

1) Dr Civil Engineer, Dept. of Civil Engineering, Aristotle University of Thessaloniki, Greece
2) Professor, Dept. of Civil Engineering, Aristotle University of Thessaloniki, Greece
sarg@civil.auth.gr, kpitilak@civil.auth.gr

Abstract: Transportation systems play a vital role in urban areas, which is more crucial in an emergency situation such as after a strong seismic event. In areas with high build density and seismicity it is of particular interest to estimate the risk for blockage of roads due to collapsed buildings. A probabilistic framework is described considering the geometrical characteristics of roads and buildings, together with their failure probabilities. The vulnerability of bridges due to ground shaking and the fragility of roads due to soil liquefaction are also estimated based on appropriate fragility curves. The reliability of the network to connect hospitals with residential areas is assessed based on the damage probabilities of the road components. Moreover, the total risk depends on the importance of the network elements, which is classified through a global value analysis, considering different functional and urban criteria. An analysis of this type is performed for the roadway network in the city of Thessaloniki, for scenario seismic events that are based on a detailed microzonation study. Through this approach the role of site effects in the risk assessment of the roadway network is highlighted, while the interconnection between bridges, roads and urban elements (buildings, hospitals, population) is considering.

1. INTRODUCTION

Experience from past earthquakes reveals that road components are quite vulnerable, while their damage could be greatly disruptive due to the lack of redundancy, the lengthy repair time or the rerouting difficulties. For example, the disruption to the road network can strongly affect the emergency efforts immediately after the earthquake or the rebuild and other business activities in the following period.

The complexity and variability of elements at risk, the spatial variability of ground motion, and till recently, the lack of well validated damage and loss data from strong earthquakes, make the vulnerability assessment of each particular component and of the network as a whole, a quite complicated problem. Adding to that the spatial extend of transportation networks, the synergies with the urban system and the inherent uncertainties in seismic hazard estimates, it is obvious that the risk assessment is indeed a complex and challenging issue. Several methodologies have been developed and applied worldwide, which can be assigned to the following three levels:

- Level I is focused on the functioning of the network in terms of pure connectivity (Nuti and Vanzi 1998, Franchin et al. 2006). The considered vulnerable elements are those internal to the network itself, which generally consists of bridges, viaducts, tunnels, retaining structures, etc, and other elements of the surrounding environment, such as buildings or hospitals. These studies focus on one of the services provided by the network, e.g. most typically the rescue function immediately after the earthquake, and may be of interest in identifying portions of the network which are critical with respect to the continued connectivity of the network, while allow the estimation of direct economic loss.

- Level II is further considering the network capacity to accommodate traffic flows (Shinozuka et al. 2003, Kiremidjian et al. 2006, Werner et al. 2006). A first approximation of the indirect loss and travel time delays caused by the earthquake is assessed, sometimes taking into account the repair process.

- Level III is the most general approach, which aims at obtaining a realistic estimate of total loss, inclusive of direct physical damage, network-related loss (increased travel time) and loss due to reduced activity in the economic sectors (industry, services) (Veneziano et al. 2002, Karaca 2005). At this level the relevance and the complexity of the economic models become dominant over that of the transportation network.

In the present paper a level I methodology for the seismic risk assessment of urban road network is described and applied for the city of Thessaloniki, Greece. The expected direct damages of the network are estimated, while the effect of possible building collapses to the functionality of the network is examined. Moreover, the importance of the network components is classified based on a global value system approach and the connectivity between critical origin-destinations of the damaged network is assessed. Representative examples are given for each step of the analysis.

2. METHODOLOGY FOR THE SEISMIC RISK ASSESSMENT OF ROAD NETWORK

The main points of the methodology (Argyroudis 2010) are summarized hereinafter (fig. 1):

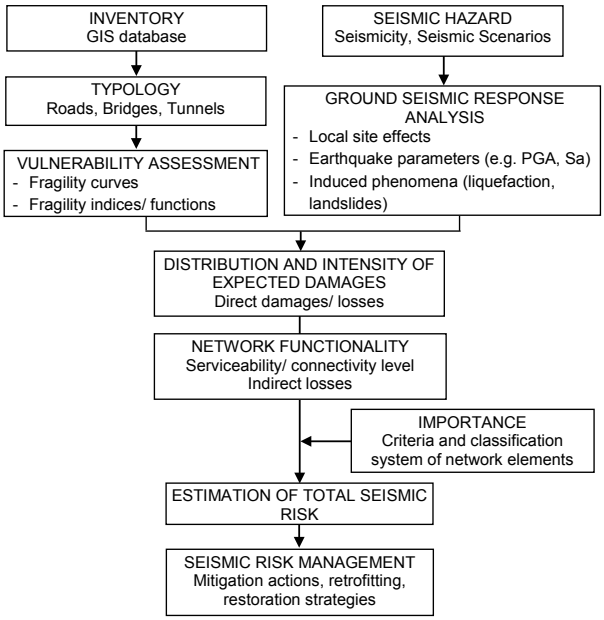

Figure 1 Methodology for the seismic risk assessment of roadway network.

- Inventory is an essential step to identify, characterize and classify all elements of the road network according to their specific typology and their distinctive geometric, structural and functional features. GIS offers the perfect and indispensable platform to implement any inventory inquires.

- Seismic hazard must be specified according to the precise needs for the particular network components as well as the models used to describe vulnerability. The spatial variability of ground motion should consider the effect of local soil conditions, topography etc (Pitilakis et al. 2006).

- The vulnerability of road elements at risk is assessed through appropriate fragility curves or indexes, which are based on analytical, empirical or expert judgment approaches. The earthquake parameter that describes the seismic intensity depends on the typology of the element and the type of seismic hazard. For example when the ground shaking is examined, the best descriptor is a response spectral value at a specific period (i.e. T=1.0sec for bridges) or the peak ground acceleration (i.e. tunnels, bridges). For other components (i.e. embankments, pavements) the permanent ground deformation due to ground failure (i.e. liquefaction, landslide) is used.

- An essential risk for urban roads is the closure due to collapsed buildings. It is assessed based on the fragility of buildings and simplified relationships between the geometry of the buildings and the area of collapse.

- The serviceability of the network for the expected distribution and intensity of damages is assessed based on simplified or more advanced approaches.

- The classification of importance is based on a set of indicators that compose the global value of each element at risk. Such criteria describe the importance and role of each element within the urban system in normal, crisis or recovery periods.

- The total seismic risk is a combination of the vulnerability and importance assessment. The main issues of the system are identified and the priorities for efficient risk mitigation strategies, such as retrofitting actions or restoration works are identified.

Further details of the methodology are given in the following, together with representative examples of the application in the main urban network of Thessaloniki city in Greece.

3. APPLICATION IN THESSALONIKI ROAD NETWORK

The inventory for the roadway network in the metropolitan area of Thessaloniki includes about 600 km of road-lines and 80 bridges. It is rather insufficient, especially in the centre, where the densely built up area creates a complex network, with narrow streets and inadequate parking areas. Roads are classified in freeways, major and secondary arterials, primary and secondary collectives, based on their geometry and functional role in the network. The majority of bridges are in the ring road and the main exits of the city. Their classification is based on the number of spans (single or multiple), the design seismic code level (low or upgraded), the pier type (single or multiple columns) and the span continuity (continuous or simple support). The vulnerability analysis of the network includes the estimation of direct losses such as bridge and road damage due to ground shaking or ground failure, and indirect such as street blockades, due to debris of collapsed buildings.

3.1 Seismic scenarios

The seismic hazard study is based on the seismotectonic environment and the seismicity of the study area. In the framework of the detailed microzonation study of Thessaloniki, three seismic scenarios are considered, with mean return period equal to 100, 475 and 1000 years (Pitilakis et al. 2010). The study is based on the results of a probabilistic seismic hazard analysis using recent data regarding the seismicity, the corresponding seismic zones and the seismic faults in the greater area. A detailed model of the surface geology and geotechnical characteristics, for site effect studies, was generated. The resulted geotechnical map (Anastasiadis et al. 2001) was based on numerous data provided by geotechnical investigations, geophysical surveys, microtremors measurements, classical geotechnical and special soil dynamic tests (Pitilakis et al. 1992, Pitilakis and Anastasiadis 1998, Raptakis et al. 1994a, 1994b, Raptakis 1995, Apostolidis et al. 2004). The dynamic properties of the main soil formations have been defined from an extended laboratory testing including resonant column and cyclic triaxial tests (Pitilakis et al. 1992, Pitilakis and Anastasiadis 1998, Anastasiadis 1994).

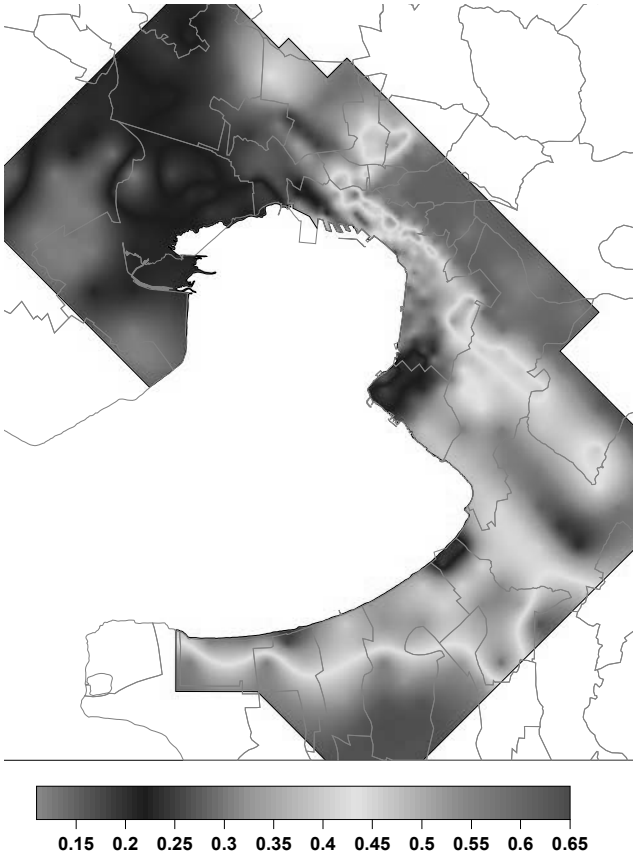

Figure 2. Mean peak acceleration values (g) at the ground surface for the 1000 years seismic scenario.

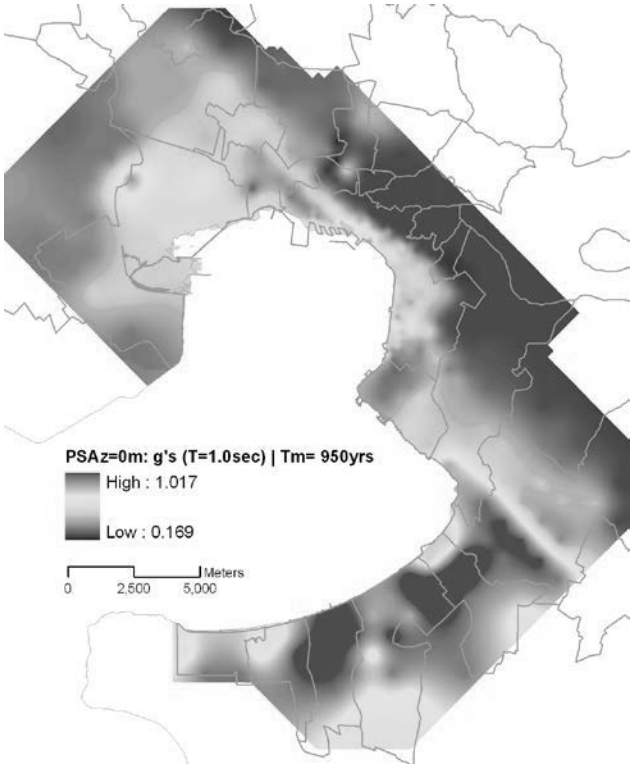

Figure 3. Mean spectral acceleration values at T=1.0sec (g) at the ground surface for the 1000 years seismic scenario.

Site effects due to local soil conditions, are taken into account through 1D linear equivalent response analyses. The analysis is conducted for five different scaled real accelerograms (for bed rock motions), which were selected according to the seismic hazard study, for three scenarios (mean recurrence period of 100, 475 and 1000 years) (Papaioannou 2004). As an example, the characteristics of the calculated seismic ground motions at the free surface, in terms of peak acceleration (PGA) and spectral acceleration (Sa) at T=1.0s are presented in fig. 2 and 3 for the earthquake scenario with mean return period of 1000 years. Similar maps have been generated for all seismic scenarios, and for several other ground motion parameters.

In order to account for the liquefaction-induced phenomena, the evaluation of permanent ground horizontal and vertical displacements (lateral spreading and settlements), has been performed for the three scenarios using empirical and analytical procedures (Ishihara and Yoshimine 1992, Elgamal et al. 2001). Figure 3 illustrates the spatial distribution of permanent ground settlements for the 1000 years scenario, which vary from 5.0 to 30.00cm.

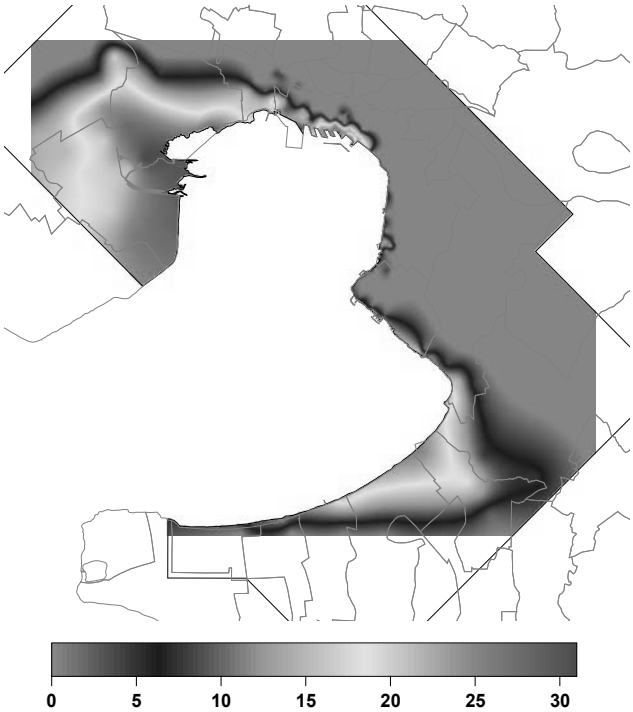

Figure 4. Permanent ground settlements due to liquefaction (cm) for the 1000 years seismic scenario.

3.2 Vulnerability of bridges

The expected level of damages for bridges is assessed based on the fragility curves that are provided in HAZUS (NIBS 2004), for the input earthquake hazard scenario and the estimated mean spectral acceleration at T=1.0sec. The estimated damage state for each bridge for the 1000 years seismic scenario, is presented in fig. 5. The majority of bridges will respond in a satisfactory way, but there are still several bridges, which are expected to sustain serious

damage for the specific seismic hazard scenario. This is due to the higher vulnerability of these bridges (single column, simple support bridges and inadequate seismic design), and the higher values of the expected surface spectral acceleration. The latter is attributed to the local soil conditions and the proximity of the seismic source (e.g. southeast part). For instance, in the west part of the city, deep soft alluvium deposits of sandy-silty clays to clayey sands-silts, with low strength and high compressibility, (category C and D in EC8), present stronger amplification at longer periods.

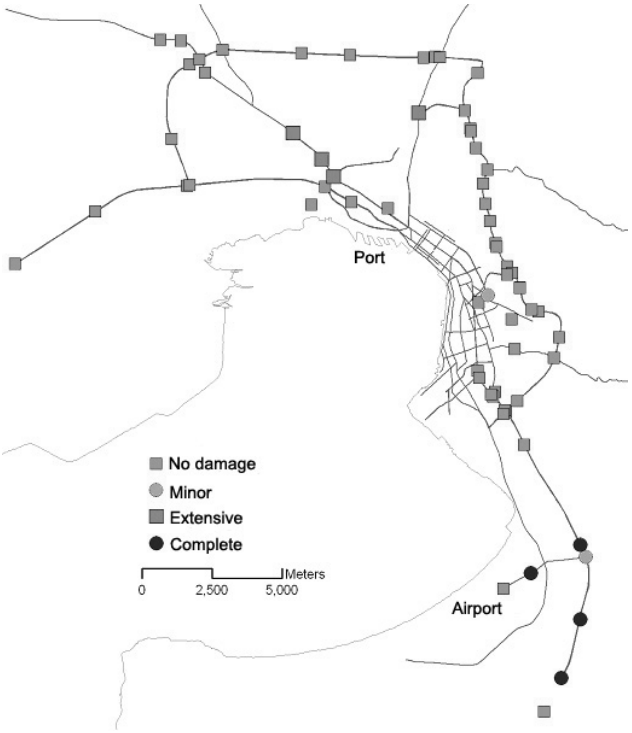

Figure 5 Expected damage states of bridges in Thessaloniki due to ground shaking for the 1000 years seismic scenario.

3.3 Vulnerability of roads due to ground failure

Road pavements are susceptible to damage due to permanent ground displacements which can be induced by liquefaction (settlement or lateral spreading), surface fault rupture and sliding of embankments or slopes. In the present study the vulnerability of the road network due to liquefaction is estimated. The fragility curves that are proposed in HAZUS (NIBS 2004) methodology are applied as they are considered to describe adequately the response of a road pavement due to ground failure. The expected level of damage (none, minor, moderate, extensive/complete) is assessed for the road segments that are lying on liquefiable soils, based on the estimated distribution of the permanent ground deformations (fig. 4). A representative example is shown in figure 6 for the case of the seismic scenario with T=1000 years. Minor damages are expected in few parts of the network, concentrating in susceptible to liquefaction areas, especially near the coastline, where loose sand-silt formations with low plasticity and variable percentage of clay are presented.

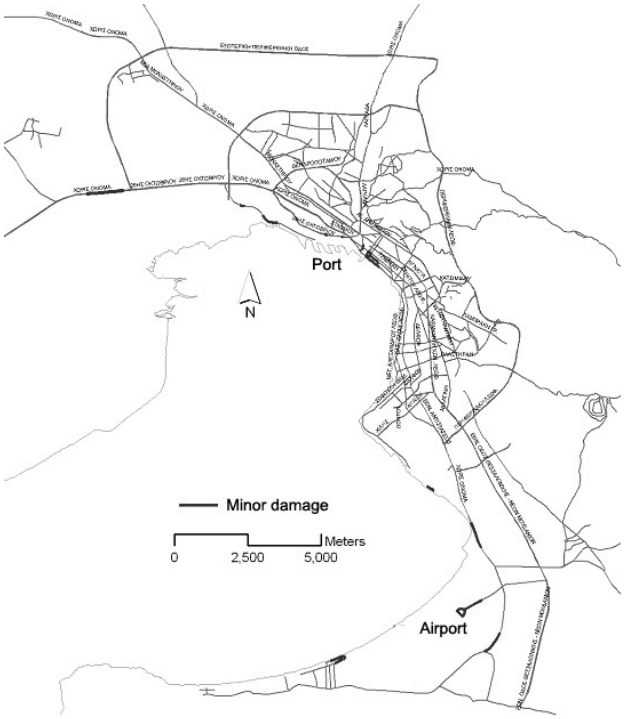

Figure 6 Expected damage state of roads in Thessaloniki due to ground failure for the 1000 years seismic scenario.

3.4 Vulnerability of roads due to building collapses

The impact of collapsed buildings to the functionality of roads just after the earthquake is estimated based on a correlation between building's geometry and width of the induced debris. A Gaussian distribution describes the variation of the debris width, which is a function of the building collapse angle (φ) and the building volume reduction (kv) (fig. 7). This model is used in order to estimate the exceedance probability of certain road function levels (100% open, 50% open, 0% closed or one lane open). The collapse probability of buildings is estimated based on appropriate fragility models which have been developed for the building types commonly presented in Thessaloniki, as a function of the peak ground acceleration (Penelis et al. 2002, Kappos et al. 2006). The spatial distribution of the collapsed or heavily damaged buildings is depending on their typology and the site conditions.

Past experience in Greece reveals that a percentage of collapses ranging between 10 and 20% can have such form and amount of debris, which can result to road closure. The probability of closure due to building collapse is calculated based on the combination of the aforementioned probabilities for each road segment (node to node). Figure 8 illustrates the probability of closure for the main roads in the central city due to building collapses for the scenario with a mean return period 1000 years. The reduction of the road width depends on the distance from the buildings, the width of the road and the induced debris width, while the closure probabilities depends on the concentration of the most vulnerable building type, the length of the road segment and the discrete collapse probabilities related to the local site conditions.

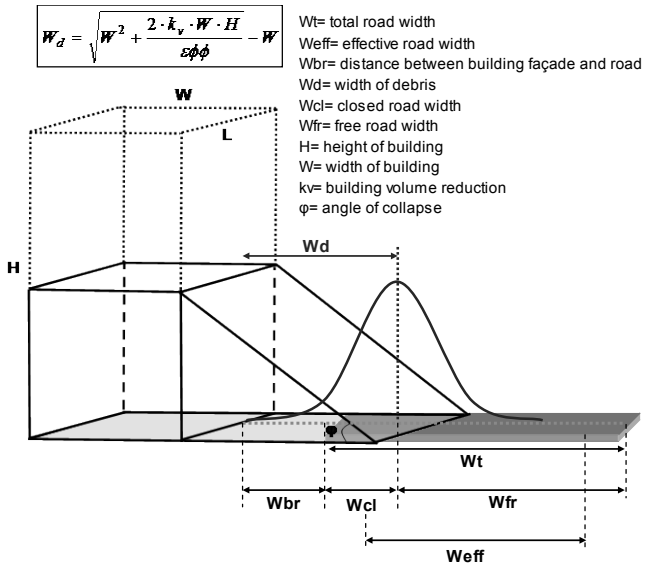

Figure 7. Estimation of debris width and road closure.

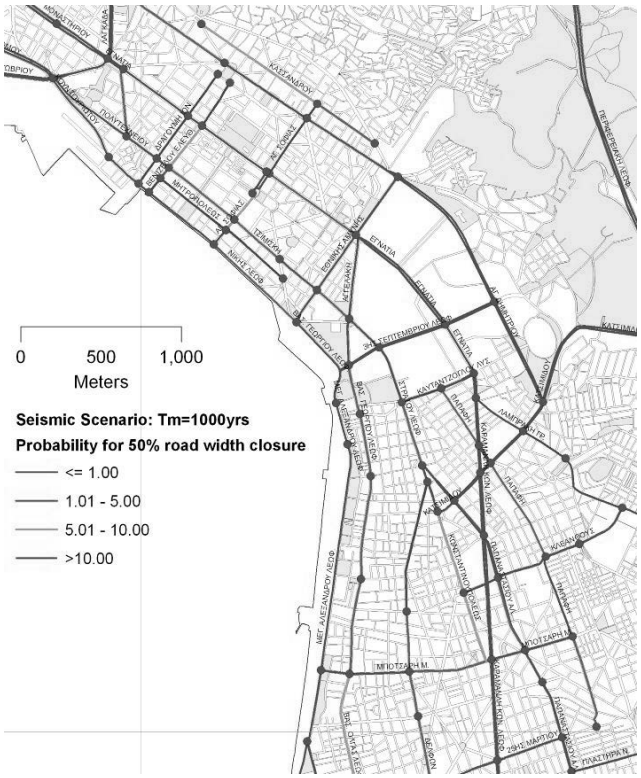

Figure 8. Sample map with probabilities for 50% road width closure of the main road network due to building collapses for the 1000 years seismic scenario.

3.5 Classification of importance-Global value analysis

Within this step, the main issues and relative importance of the road network are identified, through appropriate ranking of the value of the exposed elements (Anastassiadis and Argyroudis 2007, Pitilakis et al. 2010). Various factors and criteria that describe the role of each element in the urban system are used. In that way, the global value of each element at risk depends not only on its direct specific value but also upon its indirect/immaterial value, which is represented by the usefulness and relative role in the whole urban system, at a specific time. Three periods are identified in respect to the occurrence of an earthquake event: normal, crisis and recovery. The criteria for road network include operational attributes, emergency use and urban features (Argyroudis 2010). Qualitative or quantitative indicators and measuring units are defined for each period and the "main", "important" and "secondary" elements are estimated, based on their global value ranking. The indicators used for the classification of the importance of Thessaloniki's road network in each period are described in Table 1, while the relative values of the indicators are given in Table 2. The indicators that describe the interaction of roads with critical services (direct or indirect access) and land uses are ranked based on the classification of importance of these elements. The latter is resulted by applying the global value approach considering different indicators (Anastassiadis and Argyroudis 2007).

Table 1 Indicators and measurement units of global value analysis for urban roads

Indicator	Measurement unit	Period		
		Norm	Crisis	Recov
1. Road hierarchy	Functional classification	✓	✓	✓
2. Traffic capacity	Effective road width	✓	✓	✓
3. Access to critical facilities	Vicinity to critical services (e.g. hospitals, terminal stations, civil protection buildings)	-	✓	✓
4. Emergency use	Importance of road in emergency situation	-	✓	✓
5. Urban factors	a. Population density	✓	✓[1]	-
	b. Trade area density	-	✓[2]	-
	c. Built area density	-	-	✓
1: seismic scenario during non working hours 2: seismic scenario during working hours				

The summation of relative values of each road segment gives its global value, which is used for the classification of importance in the three categories based on appropriate thresholds. A sample map illustrating the definition of main, important and secondary elements at risk is illustrated in fig. 9. Similar approach is followed for the classification of bridges, applying a different set of indicators. The results of this step combined with the outcome of the vulnerability assessment of the exposed elements at risk (roads, bridges, tunnels etc) can contribute to the development of an efficient mitigation and retrofitting strategy and a well-organized emergency planning. In that way, focus will be placed on limiting the necessary recovery period to the least possible extent, in order to provide the related city activities with the optimum feasible operation level.

Table 2 Classification and relative values of measurement units of global value analysis for urban roads

Measurement unit	Description	Relative value
Functional classification	Freeway Main arterial Secondary arterial Primary collective Secondary collective Local	1.00 0.75 0.50 0.25
Effective road width	>15m (>5 lanes) 10-15m (3-5 lanes) 5-10m (2-3 lanes) <=5m (1-2 lanes	1.00 0.75 0.50 0.25
Importance of road access based on the global value classification of the critical services	Main Important Secondary None	1.00 0.75 0.50 0.25
Importance of road in emergency situation	High Low/none	1.00 0.00
Importance of land uses along road axis based on urban indicators (population, trade or built density)	Main Important Secondary None	1.00 0.75 0.50 0.25

Figure 9 Sample map with classification of importance of road network in Thessaloniki for the crisis period (seismic scenario during non working hours)

3.6 Connectivity analysis of road network

The functionality and travel times of the road network could be affected by the direct or indirect damages to road segments or bridges. Moreover, the travel time is important, especially for the transportation of emergency vehicles, after a strong earthquake. A simplified connectivity analysis is performed in the road network of Thessaloniki for specific routes between residential areas and major hospitals, considering the estimated damages of the roadway elements.

A representative example is presented here for two alternative routes (fig. 10) based on the probabilities of road closure due to building collapses and the probabilities of bridge damage along each route. It is presumed that a road is closed when passes over a bridge with at least moderate damage, while the same happens when it passes under a bridge with at least extensive damage. Table 3 describes the alternative routes and travel times, considering an average speed equal to 30km/h for freeways and main arterials, and 25km/h for other road classes. It is observed that the route 1 that is shorter, presents lower reliability (i.e. higher probability of closure) compared to route 2, which is however longer. This is related to the local soil conditions and the higher vulnerability of bridges and buildings along route 1.

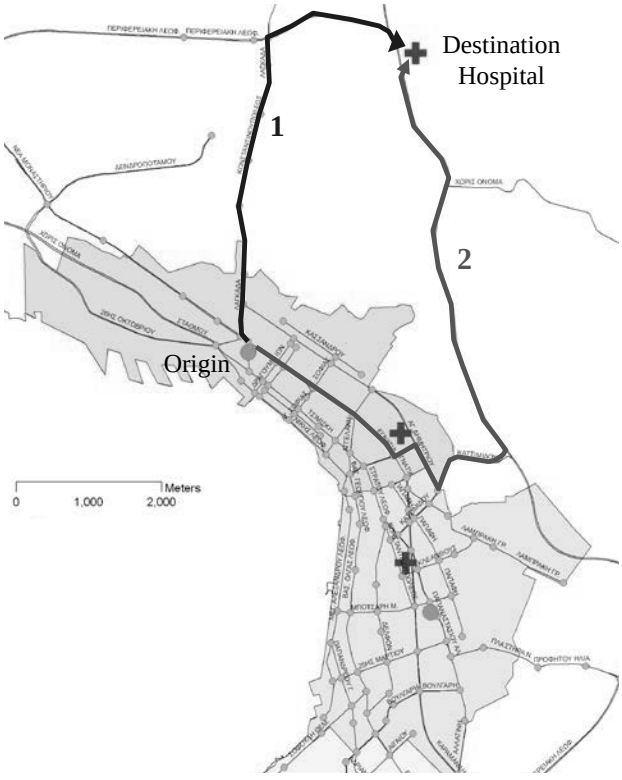

Figure 10 Example of connectivity for the main road network of Thessaloniki, showing two alternative routes between an origin area and a destination hospital.

Through this preliminary approach, the weak areas or points of the network are defined and optimum routes can be proposed. In combination with the classification and hierarchy of importance of the roadway elements it is possible to develop an advanced risk management plan, including efficient pre-earthquake actions and restoration or traffic retour plans.

Table 3 Reliability of alternative routes under study

Route	Length (km)	Travel time (min)	Reliability (probability of non-closure)	
			T=475yrs	T=1000yrs
1	6.90	13.71	0.848	0.780
2	10.50	21.40	0.900	0.717

4. CONCLUSIONS

The seismic risk analysis of transportation network is essential for the efficient seismic risk management and mitigation, especially in urban areas with high seismicity and high population and built densities. A general approach includes the assessment of seismic hazard and seismic ground response for different seismic scenarios, the vulnerability assessment of the exposed elements at risk and the estimation of direct and indirect damages, the classification of their importance and the effects of damages to the functionality of the network.

A short description and an application of a general methodology for the vulnerability assessment and seismic risk management of urban road network are presented. The city of Thessaloniki in Greece is used as test site. The vulnerability and loss estimates of the road network are evaluated on the basis of detailed site specific seismic hazard analysis using available inventory data and adequate fragility relationships. The expected damages of bridges due to ground shaking and of road pavements due to ground failure (liquefaction) are estimated, while the possible road closures due to collapsed buildings are defined. The intensity and spatial variability of the losses are entirely relied on the specific ground response characteristics. Moreover, the connectivity of specific routes to hospitals is examined based on the distribution and intensity of expected damages to the network.

The classification of road elements importance is performed on the basis of a global value analysis, using functional and urban indicators in different periods. In combination with the previous results, this leads in a more efficient prioritization of the pre-earthquake retrofitting actions, and post earthquake restoration efforts. These include upgrading of structural performance of vulnerable elements such as bridges, improvement of existing network performance (road widening, modification to one way or pedestrian roads), planning of traffic retours, implementation of advanced technologies during earthquake emergency (early warning systems, real time damage estimation etc).

Abstract: Design of pipelines is seismic areas requires special attention as these are important lifeline facilities spread over a large area. The seismic hazards that may affect the pipelines can broadly be classified into: (a) fault crossing; (b) locally liquefiable soil zones at shallow depths and/or laterally spreading soils; (c) landslides caused by earthquakes. This paper summarises the observed performance of buried pipelines during the past earthquakes due to various hazards. These failures are further categorised with respect to their various modes of failure. A qualitative study has been carried out to understand the severity of different hazards to refine the seismic design requirements.

1. INTRODUCTION

Pipelines are a vital element of infrastructure in the world today. They support the world's industries, economies and civilisations by transporting precious commodities such as water, gas and oil, wastes and excesses such as sewage and storm water, in a reliable, safe and cost efficient manner. The pipeline industry has grown at a phenomenal rate over the last two centuries (Hopkins, 2007) and continues to grow with hundreds of thousands of kilometres of pipeline proposed in the next decade (Foster, June 2008, August 2008) (Rosner, 2010). Energy analysts predict offshore pipeline installations to increase by 6% annually by 2014 (Infield Energy Analysts, 2009). This development comes alongside considerable increase in risk. Seismic hotspots and faults cannot be avoided, as evidenced by the Trans-Alaskan Pipeline. Worryingly, fault lines may not be identified as in Northridge in 1994 (Yeats et al., 1995) which leads to deficiencies within the design and serious repercussions. It is therefore vital that all hazards are fully understood.

2. OVERVIEW OF PIPELINE HAZARDS

A literature review revealed that currently no comprehensive collation of detailed pipeline failure case studies exists. An attempt at compiling a pipeline failure database was undertaken by Le Val Lund and Anshel Schiff (1992) following the 1989 Loma Prieta earthquake but the records are not in sufficient detail for pipeline failure analysis. This lack of resource precipitated our collation of pipeline failures caused by seismic activity from a wide range of publications, resulting in a total of 30 detailed failures (Table 1). The data was analysed to identify the key hazards affecting pipeline failure (Figure 1) and to locate any pertinent failure trends.

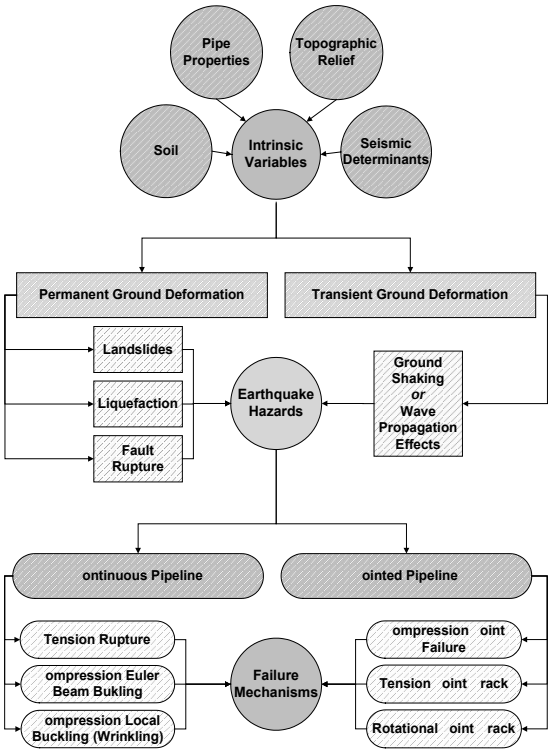

Figure 1 Pipeline Failure Mechanisms as a direct result of seismic activity.

Seismic hazards can principally be divided into two categories – transient ground deformation (TGD) and permanent ground deformation (PGD). Transient Ground Deformation is defined by O'Rourke (1998) as that which "*involves ground waves and soil strains associated with strong shaking*." The principal hazard associated with transient ground deformation is ground shaking or wave propagation. *Ground Shaking or Wave Propagation*

Ground shaking refers to strain and curvature changes generated by seismic wave propagation through the soil. It is rarely solely associated with pipeline failure, with the exception of Michaogan Earthquake in Mexico 1985 (O'Rourke et al., 1990). In this case, the absence of other ground deformations assured the investigators that the pipe wrinkling observed was due to wave propagation alone and is understood to be the only case where a corrosion-free modern steel pipeline has failed in such a way.

On the other hand, O'Rourke (1998) defined Permanent Ground Deformation as that which *"involves the irrecoverable movement of the ground that often is the result of ground failure, but also may result from modest levels of volumetric strain and shear distortion."*These can be categorised into landslides, liquefaction, and fault rupture.

2.1 Landslides

Landslides can typically be generated by earthquakes of 4.0 magnitude and above, where stresses weaken the stability of slopes. The permanent ground deformation tends to be abrupt and concentrated about a specific locale, resulting in severe damage to buried pipelines. The severity of the hazard is reduced by the ease with which it may be predicted from analyses of case history data, as described by Hays (1998). An example of such damage is that caused on the Trans-Ecuador pipeline during 1987 Ecuador Earthquake where landslides were the primary cause of the earthquake losses in the entire region (Bird et al., 2004).

Figure 2 View of valley wall of the Río Malo north-eastern Ecuador, after the 1987 Reventador earthquakes. Similar debris flows were caused throughout the country wreaking havoc. (Photo: *U.S. Geological Survey)*

2.2 Liquefaction

Liquefaction is a permanent ground displacement that results from the increase in pore pressure in a soil reducing its effective stress to zero. This may arise from strong ground shaking in saturated soils, and it is considerably documented by Youd (1978). The most destructive case for buried pipelines is lateral spreading, which involves the horizontal movement of competent soil due to liquefaction on underlying strata. The resulting earth pressures are compressive and tensile, and conducive to damage as noted in the 1994 Northridge Earthquake (O'Rourke et al., 1996).

Figure 3 Tension failure in segmented steel gas pipeline during 1994 Northridge Earthquake. (Photo: Southern Gas Company)

2.3 Fault Rupture

Fault rupture describes the differential movement between two adjoining portions of Earth's crust. The crack or fault within the crust is generally associated with the boundary between the tectonic plates, and when active may generate substantial displacement within a relatively narrow zone. For example the Chelungpu Fault, which flanks the western edge of Taiwan's central mountain range, ruptured over 80km of its length on September 21, 1999 (RMS, 1999). The rupture resulted in scarps 2m-3m high along the southern end, and scarps 4-8m high (EERI, 1999) towards the northern edge despite the lack of previously observed seismicity.

Figure 4 Buckled steel pipe at crossing near Arifiye, during Izmit (Kocaeli) 1999 Earthquake (Photo: Basoz, EERI 1999)

3. PIPELINE DAMAGE DUE TO FAULT RUPTURE

The literature review undertaken focuses primarily on pipeline failure caused by surface fault ruptures in order to appreciate the severity of damage caused. Although the study cannot be considered a quantitive analysis due to lack of consistent documentation of pipeline failure specifics, the 14 cases compiled (Table 1) aid the qualitive understanding of such events. From analysing the incomplete collated data, despite comparing similar

pipeline types, hazards and failure mechanisms, no clear trends were able to be identified. The number of influential variants and the individuality of the conditions at each case make gross comparisons of data in this manner ineffective. This inability to draw any qualitative conclusions suggests that the prediction of failure, and indeed the verification of current Finite Element models should be subject to further scrutiny. However, it can be seen that hazard risk varies principally depending on the character of the fault (types developed bellow) and its relative displacement.

3.1 Strike-Slip Fault

- Movement generated in horizontal plane along fault line.
- High stresses can be safely accommodated by ensuring tension in the pipeline is generated.
- 1968 Meckering Fault generated a maximum dextral movement of 1.5m (Gordon et al., 1980). Goldfields pipe was found shortened by 1.32m as a consequence. The stresses cased brittle failure in the cast iron pipe causing telescoping. Note the pipeline was a surface pipeline, though similar failure may be expected for buried pipes.

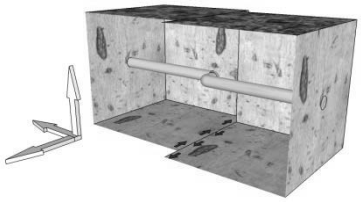

Figure 5 Schematic of buried pipeline subjected to a strike-slip fault.

3.2 Normal Fault

- Movement generated in vertical & horizontal planes perpendicular to fault line.
- Extension of crust commonly generates tensile stresses in the pipeline.
- 1988 Edgecombe Earthquake main shock is believed to have caused the resulting complex series of 7 scarps. The longest scarp being a normal fault 7km long, with 1.5m vertical displacement. Denis (2000) mentions how a gas pipeline crossing the fault was found to have suffered tension yield, though remained functional throughout.

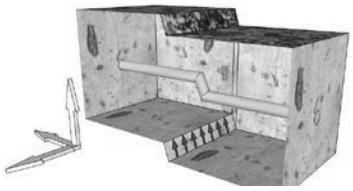

Figure 6 Schematic of buried pipeline subjected to a normal-fault.

3.3 Reverse Fault

- Movement generated in vertical & horizontal planes perpendicular to fault line.
- Shortening of crust commonly generates compressive stresses in the pipeline.
- 2001 Kokoxili earthquake is reportedly the longest documented surface rupture on land. The rural area struck resulted in no casualties, though some damage to temporary houses and telecommunications ensued. Guo et al. (2004) discusses the non-linear finite element analysis conducted on a gas pipeline found during the post-earthquake investigations with Z Shape buckling deformation (compressive failure). The analysis appears consistent with expectations.

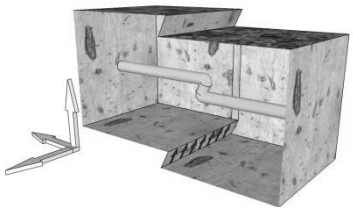

Figure 7 Schematic of a buried pipeline subjected to a reverse fault.

Earthquake reconnaissance also reveals that the typical failure modes that develop for continuous and segmented pipelines during a seismic event are quite distinct. This phenomenon can be understood intuitively; as segmented pipelines typically include joints that are designed to allow for differential movement, these areas are more vulnerable to stress concentrations (bell-and-spigot cast-iron piping system for example). Considerable empirical evidence has been accumulated documenting the structural and stiffness features of ductile iron pipes with push-on rubber gaskets (Singhal, 1984) and other typical pipe joints (Meis et al., 2003). Their findings reveal the importance of cyclic effects amongst other factors, and the latter generated considerable data to be used in modelling. An interesting case is made for the telescoping of a section of segmented pipeline in Meckering Earthquake's Aftershock on the 15th October 1968(Fenton, 2006). The investigator highlights how the Goldfields water pipe must have been severely weakened in the main shock to have resulted in further failure with the subsequent ground surface displacements. The Goldfields water pipeline therefore, can be seen to encapsulate pipelines' performance reliance on not only the primary pipe properties and seismic determinants, but its historic footprint. This makes the task of risk estimation more complex.

4. CASE STUDY (SAP MODELLING)

A failure case of the Gas Line 115 during the 1971 San Fernando Earthquake described by SCGC (1973) and O'Rourke et al., (1996) is now subjected to SAP modelling. This study aimed to investigate the response of a pipeline while subjected to an oblique fault, which includes strike and thrust faulting.

4.1 Modelling details

The considered gas pipeline failed due to the surface faulting of the Sylmar segment of the San Fernando fault zone. Near the Sylmar segment, there were of the order of three compression and ten tensile ruptures of the pipeline. The type of Sylmar fault segment was thrust upward with a dip angle of approximately 15^o to vertical and left lateral oriented 70^o to North. The maximum strike and reverse dip-slip component of fault displacement were 1.9m and 1.5m respectively. The fault zone was ranging between 45m to 106m. In the present analysis the fault displacement was considered at the middle of the fault zone. The pipeline was crossing the fault line at an angle of about 80^o.

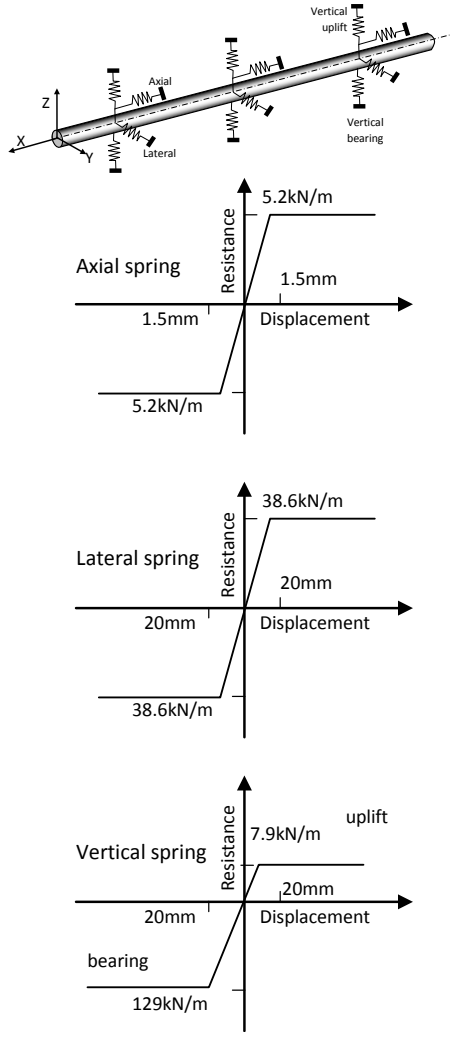

Figure 8 Estimated nonlinear properties of soil springs used in SAP model.

The pipeline was modelled in SAP (CSI, 2010) using a BNWF (Beam on Nonlinear Winkler Foundation) model, where the pipe elements were modelled as beam-column elements, and the soil was modelled as non-linear springs lumped at discrete locations of the pipe. The sectional properties of the pipe were taken as: diameter = 0.4m, wall thickness = 6.5mm. The pipe was buried at an average depth of 80cm from the surface. The pipe elements were discretised with 0.25m segments near the fault zone (for middle 100m) and 5m segments away from fault zone (i.e., 50m away from fault line). The ends of the pipeline were fixed 300m away from the fault line.

The nonlinear properties of soil springs were estimated according to the ASCE guidelines (ALA, 2001). The angle of friction and unit weight of the soil was assumed 30^o and $18kN/m^3$ respectively. Figure 8 shows the estimated values of axial, lateral and vertical soil springs.

The ground displacement due to both strike and thrust fault in the pipeline axis was estimated to be:

- Parallel to longitudinal axis of pipeline = -1.2m
- Lateral to longitudinal axis of pipeline = 1.87m,
- Vertical uplift to longitudinal axis of pipeline = 3.8m.

Figure 9 schematically shows these displacements applied to the ground moved during faulting. The displacements were applied at the fixed ends of the soil springs.

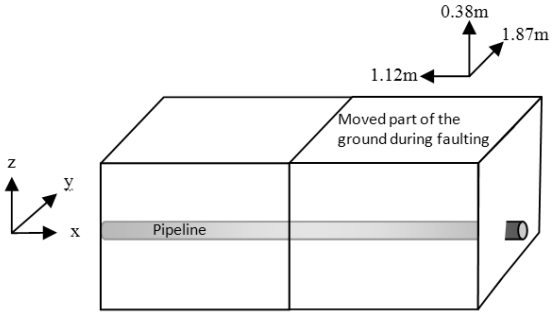

Figure 9 Schematic displaying the displacements applied to modelled ground for fault movement.

4.2 Results and discussion

The deformation pattern of the pipeline due to fault movement in both horizontal and vertical plane is plotted in Figure 10. Most of the deformation is within 10m distance from the fault line in either side for both the planes. The horizontal deformation pattern is symmetric about the fault line. However, the vertical displacement is higher in the stationary section than moving section of the fault model. This is due to the fact that the stationary side of the pipe is pulled upwards and subjected to lower soil resistance in uplift as compared to the opposite half of the pipe, which was pushed into the soil and subjected to higher soil resistance in bearing.

The bending moment of the pipe in both x-z and y-z plane is plotted in Figure 11. The location of maximum bending moment in x-z plane occurs at a distance of about 10m away from the fault line on both sides, where the curvature in the pipe is very high. However, in y-z plane, the bending moment is non uniform with respect to the fault line. The bending moments in both planes are comparable in magnitude. Therefore, while designing pipelines subjected to this kind of oblique fault, it should be designed for biaxial bending moment.

Figure 12 plots the axial compressive force distribution in the pipe. The axial compression in the pipe

was mainly due to the axial shortening of the thrust fault movement. However, the distribution of axial force is more dependent on the end fixity. In this case history, the location of end fixity was not known. However, the maximum axial force occurs near the fault line. Though not very conclusive, this analysis suggests that the pipeline crossing this fault line should have been designed for the expected bending and axial force for a zone of about 25D on either side of the fault line.

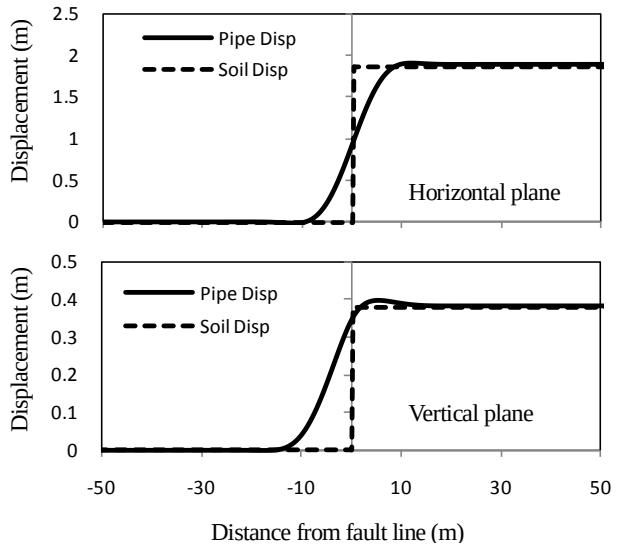

Figure 10: Displacement profile of pipeline due to soil displacement during faulting in both horizontal and vertical plane.

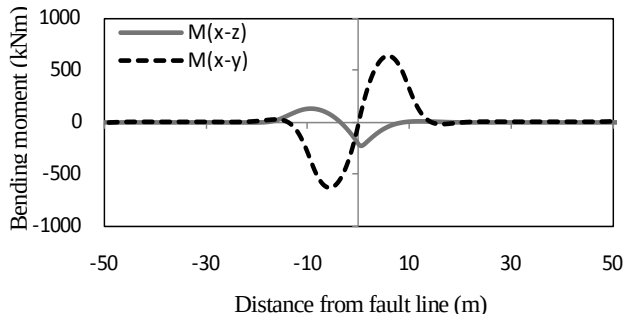

Figure 11: Bending moment in pipeline due to soil displacement during faulting.

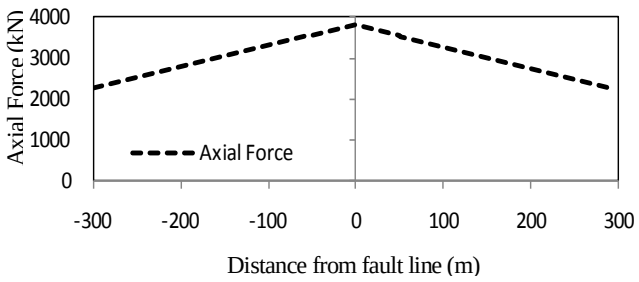

Figure 12: Axial compressive force in pipeline due to soil displacement during faulting.

5. CONCLUSIONS

The literature review shows that seismic fault rupture is a serious hazard to pipeline failure as demonstrated by the impacts associated with the case studies (Table 1). Currently, reporting of these failures are not sufficiently consistent and thorough to allow for conclusions to be drawn and accurate finite element simulation. As the industry expands and sourcing of natural goods becomes more remote, the inevitability of crossing fault lines increases. This industry growth can be expected to drive the need for further understanding in order to reduce associated risks. In order to achieve this, a more detailed earthquake reconnaissance of pipelines will be necessary.

The SAP modelling highlights the elevated nature of the pipeline's stresses close to the fault line during faulting and it is these values that should govern the design. The computer model provides a useful tool for designers but is by no means a guarantor of the field conditions, due to the uncertainties associated with the ground conditions, burial conditions, and loading.

Abstract: In this study, the site effect on peak ground velocity is investigated for Tottori Region. A frequency dependent correction factor (CF) which is the mean of the summation of the ratio of observed ground motion over a reference attenuation model is employed. We tested the method for 150 stations not just Tottori area but near region through 5988 earthquake records. Totally 46 crustal earthquakes with larger than M_w 4.0 and within 100 km epicentral distance are examined. The correlation between CF and average Vs30 is analyzed. By applying the CF, it is achieved to eliminate site effect an acceptable level for the region. It is found out that there is a good agreement between our results and previously proposed methods in literature. By this method CF can be used as an alternative solution to evaluate site effects where there is no Vs30 in a site of interest if there are adequate recorded events.

1. INTRODUCTION

Accurate prediction of ground motion parameters is an important task which various attenuation relationships proposed for many regions, considering effects of source, site, and path. Site effect is the one that get attention recent years evaluated also in Next Generation Attenuation project initiated by PEER. S velocity in 30 meter of stations is one of the frequently utilized in assessing the effect. On the other hand, Lee and Trifunac (2010) reported that an older site characterization in terms of the soil site parameter proposed by Seed et al. worked better because it included a measure of the thickness of the soil layers to considerably greater depths. While the debates continue, Si et al. (2010) introduced a new and simple method to correct site effects and applied it to well-known 1994 Northridge earthquake. In proposed method, the site effect correction factor for an observation station is defined as the residual between the observational strong motions with that predicted by a reference attenuation model defined on bedrock. Consequently, if a station always shows stronger or weaker motion it will be corrected to show average ones on bedrock. This method is useful for peak ground velocity and longer period components, but may be not enough for peak ground acceleration and shorter period components because of the possible nonlinear behavior. For the latter case, the effect of the nonlinear behavior should be examined when using the proposed method, and if necessary the correction for nonlinear behavior should be performed.

In this study site effect correction factor is investigated and tested in Tottori region, Japan. The peak horizontal ground velocity is adopted as the strong motion parameter since the nonlinear effects can be neglected, and its value on bedrock can be defined by an existing attenuation model developed by Si and Midorikawa (1999). We have compared the results with previous relationship models and have showed that this method can be adopted for evaluation of site effect especially if there is no VS30 information available.

2. METHODOLOGY

The site effect has great influence on strong motion and is important to evaluate in an attenuation relation. The average velocity of shear waves in the top 30 m of soil has become the parameter used by many engineering design codes and most recently by published empirical-scaling equations to estimate the amplitudes of strong ground motion. Si et al (2010) assumed that if seismic source and the path effect can be represented by the reference attenuation model, site effect correction factor can be estimate by performing an average operation using a number of records at the observation station, as shown in Eq. 1

$$R(\omega) = \sum_{i=1}^{n} \left(G(\omega) / G^{'}(\omega) + \varepsilon_i \right) \quad (1)$$

where, i is a specific record from an earthquake, n is the total number of the records used in estimation of the site effects. Since ε_i is a random number, with the increase of records in a station, the term $\Sigma\varepsilon i$ /n will be smaller. This means that R (ω) can represent the site effects if there are sufficient records. R(ω) is defined as site effect correction factor, which to be used to correct the site effect as dividing observation motion to R(ω) to get corrected measures on bedrock.

We compared this method with the previously proposed two relationship equations, Midorikawa et al. (1994) and Fujimoto & Midorikawa(2006). They have described influence of site effect as a function of Vs30 (Eq 2, 3): these equations were derived according to Vs30 however in case of no available information in a station (such as many stations of K-net) they applied a correction to convert Vs20 or Vs12 to Vs30.

$$\log(R) = 1.83 - 0.66 \log(Vs30) \quad (2)$$

$$\log(R) = 2.367 - 0.852 \log(Vs30) \quad (3)$$

46 earthquakes (figure1Figure **1**) with Mjma > 4 were chosen for analysis. The criteria for selecting events were:

(1) events of focal depth less than 30 km within an epicentral distance of 100 km,

(2) stations that recorded less than 10 gal for PGA are not included

(3) the events occurred with a boundary of 33.00N-36.00N latitude and 132.00E-135.00E longitude.

Total 5988 acceleration record is investigated over 150 stations in the area. 0.1-10 Hz butterworth band pass filter is applied before getting PGVs. We used the biggest peak ground velocity of two horizontal records. Because Vs30s are not available for all station in K-net, we calculated them according to procedure develop by Ghasemi H (2009). Also main shock of Tottori earthquake with 7.3 M_{jma} in 2000 is omitted. In order to analyze fitting of method, root mean square error and fundamental statistical analysis of each event is evaluated. Well known attenuation relationship proposed by Si and Midorikawa(1999) is utilized as a reference attenuation model. The model for PGV is defined on engineering bedrock with a shear wave velocity of about 600 m/s. All the earthquakes are used in this study are crustal events. The adopted reference attenuation equation is expressed below

$$\log PGV = 0.58 M_w + 0.0038D - \log(X + 0.0028 \cdot 10^{0.5 Mw}) - 0.002 X - 1.29 \quad (4)$$

where X, M_w, D are fault distance, moment magnitude and focal depth.

This attenuation model is verified with many independent studies and is currently being used national earthquake early warning system for predicting intensities through estimating PGV.

3. RESULTS

Figure1 shows the epicenteral distribution of 46 earthquakes and 150 K-net stations in the investigated region. Red stars shows the epicenters and triangles are the stations. Light grays (total 85 stations) indicate stations that recorded less than three events. Dark gray (36 stations recorded 3, 4 events), blue (17 stations recorded 5 to 9 events), and green triangles (12 stations recorded more than 9 events) are indicated in the Figure. Table 1 gives the origin time of events together with depth, Mw and location. Last column is the number of stations recorded individual event. Most of earthquakes are between 5 to 15 km depths, especially fore- and aftershock of 2000 Tottori Earthquakes.

Relation between moment magnitudes with distance is plotted in Figure 2. M_w less than 4 in the figure and also in tables is due to usage of M_w solution of F-net. We searched for available M_w in F-net database and used them instead of M_{jma}; in case of no information, M_{jma} are directly used in reference attenuation model.

Figure 3 shows the attenuation of two events for PGA and PGV and attenuation curves of Si and Midorikawa, 1999. These are the 13th and 22rd events in table 1 with 4.4 (left two) and 5.1 Mw. Depth is 10 km for both. 10 and 32 stations in the region recorded each event respectively. PGAs for both events are almost in the interval between upper and lower standard deviation of attenuation equation. On the other hand same tendency seen in PGV for the earthquake in 2002 with 5.1 attenuated more rapidly for far distances.

A statistical analysis (Root mean square error, average and standard deviation) is performed for individual event. Observation PGVs are divided to predicted ones which 1.00 means perfect match. Average of RMSE, mean and standard deviation of 46 events are 0.37, 1.02 (with 0.39 std), and 0.57 (with 0.34 std) respectively. Residuals with the variation of hypocentral distance are plotted in figure 4. It is seen here that observed PGVs are smaller than predicted ones in near field due to shorter period components and possible nonlinear behavior. However there is no a general tendency to be mentioned for all records.

According to the proposed method, the accuracy of estimation of site effect depends on the number of records per station. Since the correction factor is derived by the average operation of the residual between observation and prediction. Increasing number of observations per station leads to more accurate estimation. Number of events recorded in each station and their correspondence correction factors are shown in figure 5. Variation of R in stations that recorded only one event is very large (reaches about 10) and also stations recorded only two events decreased to 0.2. Deviation of R is acceptable for stations recorded more than 5 events which indicate average operation is functional and useful for these sites.

Comparisons of the R and the average S-wave velocity of top 30 m are plotted in figure 6. Stations are grouped as same color which defined in Figure 1. Blue line, and black line shows Midorikawa et al. (1994), and Fujimoto and Midorkawa (2006) respectively (refer to equations). There are total 150 correction factor which characterize the factor for relevant station (shown with circles). There is a correlation between Vs30 and R calculated by proposed method. Results also fit with the previous equations. There are four stations that R's are bigger than 4 and eleven stations less than 0.6 which is due to lack of records in these stations. Rest of data especially (green and blue circles) is almost between standard deviation of Midorikawa et al. (1994). Although the number of data used in this study is limited Tottori region, we can conclude that the method proposed in this study is adequate in evaluating the site effects.

4. CONCLUDING REMARKS

We have applied the method proposed by Si et al. (2010) to the area including the western Tottori prefecture. The results show that the estimated site effect is generally consistent with the previous studies. Implicating that the method is effective for estimating site effects.

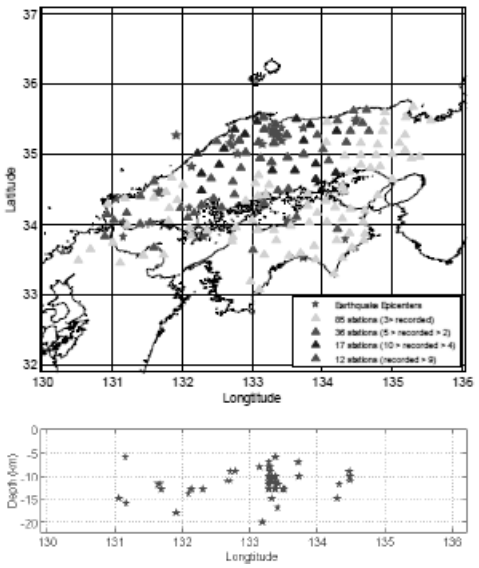

Figure 1. Location of 46 earthquakes and 150 K-net stations in the Tottori region. Red stars shows the epicenters and triangles are the stations. Colors of triangles indicate the number of recorded events in a station. Light grays (total 85 stations recorded 1 or 2 events), dark gray (36 stations recorded 3 or 4 events), blue (17 stations recorded 5 to 9 events), and green triangles (12 stations recorded more than 9 events). Most of earthquakes are between 5 to 15 km depths, especially fore- and aftershock of 2000 Tottori Earthquakes.

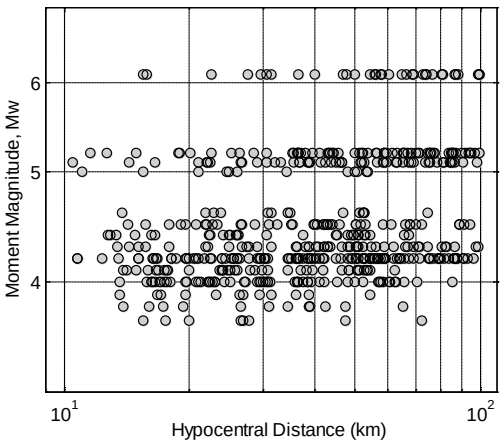

Figure 2 Moment magnitude verses distance distributions. Mw less than 4 is due to usage of Mw solution of F-net. We searched for available Mw in F-net database and used them instead of Mjma; in case of no information, Mjma are directly used in reference attenuation model.

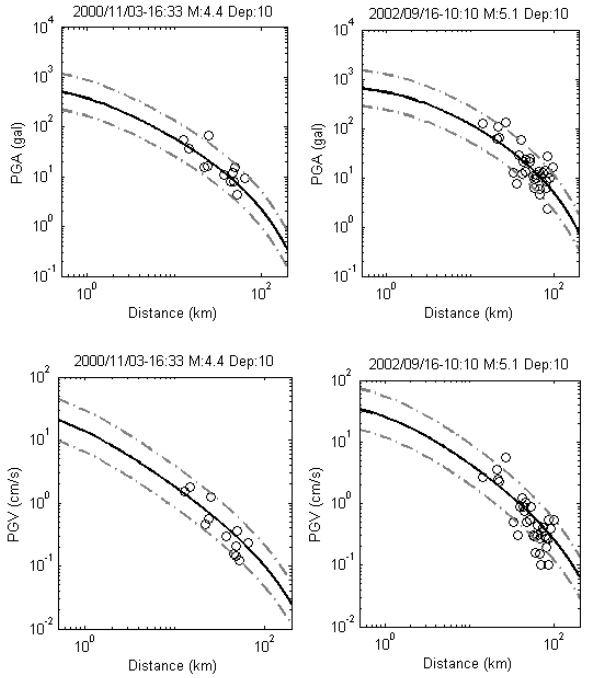

Figure 3 Attenuation curves of Si and Midorikawa, 1999 and observed PGA and PGV for two earthquakes. These are the 13th and 22rd events in Table 1 with 4.4 (left two) and 5.1 Mw. Depth is 10 km for both. 10 and 32 stations recorded each event respectively.

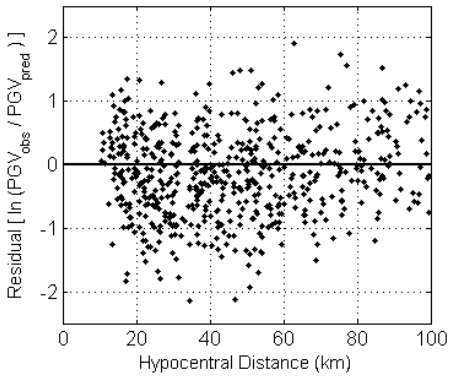

Figure 4 Relationship between residuals and hypocentral distance of all records for PGV.

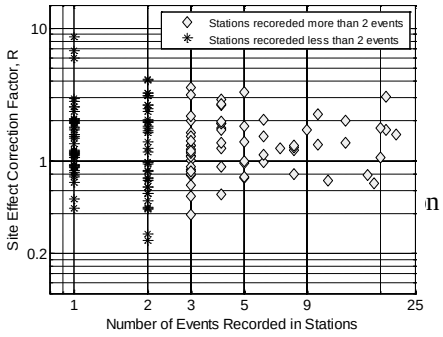

Figure 5 Number of events recorded in each station and their correspondence correction factors. Axes Y is in log scale. Variation of correction factor in stations recorded only one event is very high (reaches about 10) and also stations recorded only two events decreased to 0.2. Deviation of R is acceptable for stations recorded more than 5 events means average operator is functional and useful for this site.

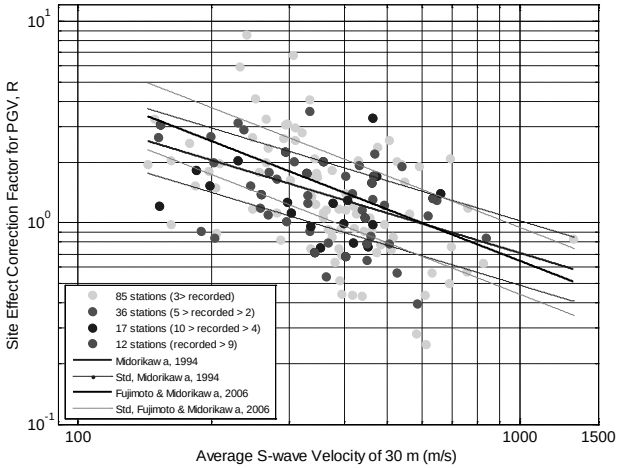

Figure 6 Comparisons of the R and the average S-wave velocity of top 30 m. Stations are grouped as same color which defined in Figure 1. Blue line, and black line shows Midorikawa, 1994, and Fujimoto and Midorkawa 2006 respectively (refer to equations).

Table 1. The events list

Abstract: Numerical simulations are conducted to study the effects of water flow and dissipation patterns on liquefaction-induced ground surface deformations. The numerical approach is validated against a centrifuge test, in which lateral spreading and shear-strain localization at a sand-clay interface were observed and measured. Time histories of acceleration, displacements, and pore-water pressures, as well as displacement profiles are compared and found to be successfully approximated by the simulation results. Volumetric strains tracked by the simulations suggest that a 1-m thick sublayer at the top of the liquefiable sand has significantly loosened from D_R=40% to D_R=30% due to the inflow of water caused by the upward hydraulic gradient following liquefaction. The simulations show that the diffusion of excess pore pressures can lead to shear strain localization in sand below a lower-permeability layer, without reaching critical state or necessarily leading to flow failure.

1. INTRODUCTION

1.1 Void Redistribution

The potential effects of drainage and pore pressure redistribution on liquefaction-related ground-surface deformations have been articulated by Whitman (NRC 1985; Whitman 1985) and have since been demonstrated in shaking table tests, centrifuge model tests, numerical simulations, and inferred from field studies (Kokusho 2003; Kulasingam et al. 2004; Malvick et al. 2006; Seid-Karbasi and Byrne 2007). These studies suggest that pore-water flow, resulting from liquefaction-induced hydraulic gradients, may be impeded by lower-permeability layers which overlay or interbed the liquefiable sand. The impeded flow can lead to loosening and softening of the sand neighboring such permeability-barriers, resulting in strength-loss and excessive deformations.

Liquefaction-induced shear-strain localization has been observed as one of the possible consequences of such dissipation-related softening and strength-loss (Seid-Karbasi and Byrne 2007; Malvick et al. 2008; Kamai and Boulanger 2010). A series of 14 centrifuge tests and accompanying shaking table tests, which involved an embedded silt arc within a liquefiable sand slope, has shown that similar profiles can develop shear strain localization at the sand/silt interface in some cases and uniform strains in others (Kokusho 2003; Kulasingam et al. 2004; Malvick 2005). The occurrence of shear strain localization was found to be dependent on the soil properties (such as density and permeability), layer thickness and geometry (e.g. slope angle), and loading parameters (history, duration, and magnitude).

To better understand the physical mechanisms that tie between pore pressure dissipation, strength-loss, and the eventual localization of shear-strains, a numerical approach is adopted in which boundary conditions can be easily controlled and the problem can be studied under different scales and conditions. In this paper, the numerical approach is validated against a centrifuge-test in which pore-pressure migration, lateral-spreading, and shear-strain localization were observed and measured. The following sections will shortly describe the constitutive model used for the simulations and the centrifuge test configuration, followed by a comparison between simulation and physical test results.

1.2 The Constitutive Model

The constitutive model used for simulating the sand is a bounding surface plasticity model (Boulanger 2010), developed primarily for earthquake engineering applications. It is largely based on the stress-ratio controlled, critical-state compatible, bounding surface plasticity model for sand presented by Dafalias and Manzari (2004). On a p'-q space, the model has a narrow stress-ratio based elastic cone and three other key surfaces – the bounding, dilation and critical-state surfaces (see Figure 1). The locations of the dilation and bounding surfaces are dependent on the relative state of the soil, such that they move towards the critical state surface in a scissor-like movement when the soil is sheared towards critical state, with all three surfaces coinciding when the soil reaches critical state. Modifications to the original model were primarily made to improve its

ability to follow a set of experimentally- and case history based- empirical correlations commonly used in earthquake engineering applications, while remaining relatively user-friendly and easy to calibrate (Boulanger 2010).

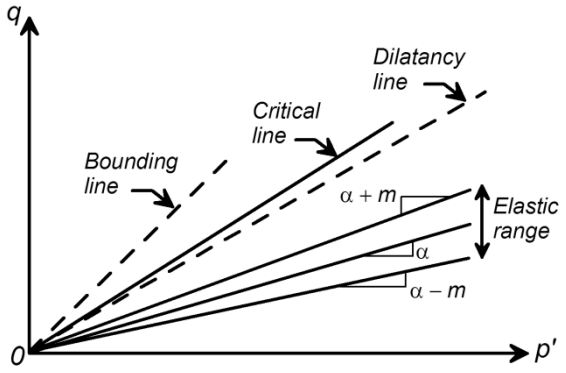

Figure 1 Schematic representation of the *PM4Sand* model, showing the yield, critical, dilation and bounding surfaces.

The constitutive model has 21 input parameters, from which 18 can be left at their default values in case the available experimental data is not sufficient for further calibration. A detailed explanation on the model parameters and their default values is provided in Boulanger (2010). For this study, the three primary parameters – D_R, h_{po}, and G_o (which relates to shear-wave velocity), as well as four additional secondary parameters – h_o, n_b, c_e and z_{max} – were calibrated to obtain the desired response, based on available data from experiments with Nevada Sand. An example response of an undrained DSS, with D_R=40% and σ'_{v0}=100 kPa is presented in Figure 2 and compared with experimental results.

1.3 The Centrifuge Test

The centrifuge test, SSK01, was performed to evaluate the effectiveness of geosynthetic drains for mitigating liquefaction of sands (Kamai et al. 2008; Marinucci et al. 2008). The test was performed in a flexible shear beam container (0.8-m wide, 1.65-m long, 0.5-m deep) on the 9-m radius centrifuge at UC Davis. The test was performed at a centrifugal acceleration of 15 g and the results are presented in equivalent prototype units unless otherwise stated (for description of centrifuge scaling laws see Kutter (1995)).

The soil profile was constructed of two symmetrical sides, sloping at 3˚ towards a central channel. Both had a 5-m thick liquefiable layer of Nevada Sand (D_R=40%) overlain by a 1-m thick layer of clayey-silt (plasticity index, PI=13). Model-scale plastic drains were installed on one side of the centrifuge container prior to pluviation. Close to 100 sensors were placed within the soil and on the surface. The model was saturated under vacuum. The model was subjected to five main shaking events separated from each other by sufficient time for full dissipation of any excess pore water pressures. The five successive shaking events consisted of 20 uniform sinusoidal cycles at 2 Hz with single-amplitudes of 0.01, 0.03, 0.07, 0.11, and 0.3 g. They will be labeled in this paper as “shake 08”, “shake 09”, “shake 10”, “shake 11”, and “shake 12”, respectively (shakes 01-07 had amplitudes less than 0.02 g and did not lead to any significant development of pore pressures).

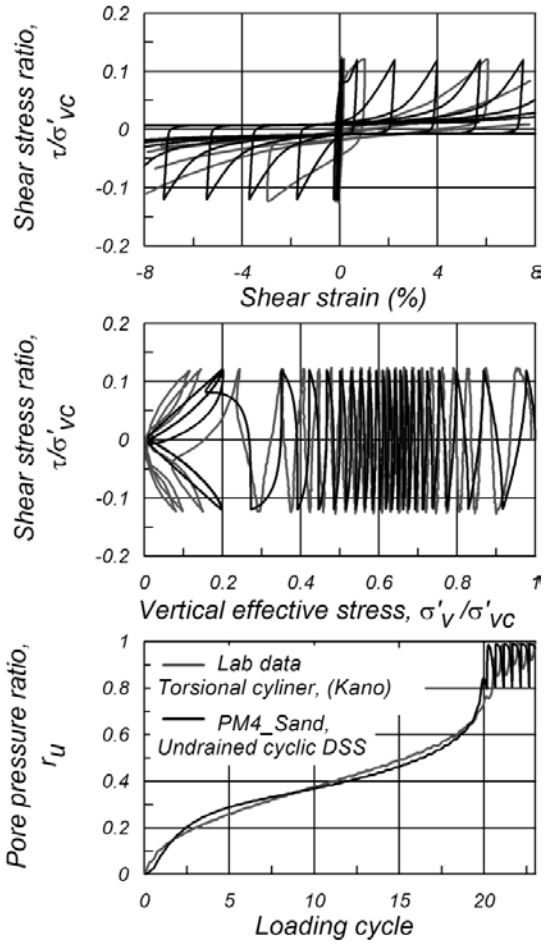

Figure 2 Comparison between simulation results of undrained DSS using *PM4Sand* and lab data of torsional cylinder – Nevada sand, D_R=40%, σ_{v0}' = 100kPa.

2. SIMULATIONS OF A CENTRIFUGE TEST

2.1 Model construction and boundary conditions

The simulations are performed using the commercial finite-difference program FLAC (Itasca 2009), using three different material models, as presented in Figure 3. The aluminum and rubber rings of the container are assigned an elastic material model, following Armstrong (2010). The clayey-silt crust is assigned a Mohr-Coulomb material model with the appropriate properties, as derived from the physical test. The sand layers, both loose (D_R=40%) and dense (D_R=80%), are assigned the user-defined material model *PM4Sand* (Boulanger 2010), which was described earlier.

The prefabricated vertical drains on the drain-treated side are simulated by fixing the pore pressures at vertical columns of nodes (see Figure 3) to their hydrostatic value. This condition is only an approximation of the drainage,

which will produce an over prediction of drainage with comparison to the physical model test, but is sufficient for the purpose of this simulation, which is focused on the response of the non-treated side.

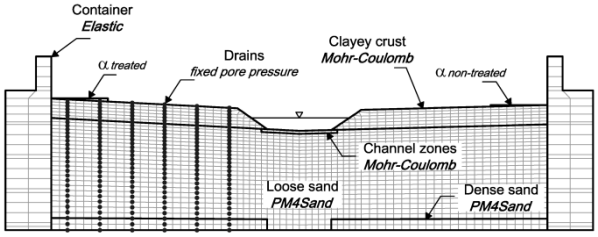

Figure 3 FLAC mesh, showing material models, location of drains and water table height.

The boundary between the soil elements and the container elements is modeled by a frictional interface that allows for relative movement of the soil with respect to the container elements. Vertical displacement of the container is restricted, and container nodes from both sides of the model are slaved to each other in the horizontal direction, to represent the continuation of the container rings in 3D. Pore water is allowed to flow across the top surface of the model, whereas flow across the container boundary is restricted. Water within the central channel is modeled by applying the corresponding pressure to the channel nodes below the water table height. Shaking is applied by subjecting the bottom container nodes to the velocity time history that was measured at the bottom of the container in the centrifuge test. Rayleigh damping is set to 0.5% at a center frequency of 2 Hz, which is the dominant frequency of the input motion.

2.2 Simulation results and comparison with test observations

Simulations of the largest four shaking events were performed (amplitudes of 0.03 - 0.3 g). Two cyclic strengths and two permeability values for sand were compared, to account for scatter in the available data. Simulations were also conducted without 'large deformation' and without 'flow' modes within FLAC, to separate the effects of mesh deformations and of pore water flow within the profile. The full set of results will be presented in an upcoming paper. For purposes of this paper, only one set of results will be presented and discussed. Figures 4 through 6 will show the detailed response of the model to shake 10 (0.07 g) with the higher values of cyclic strength and permeability and with 'flow' and 'large deformations' enabled. Figure 7 will integrate results from four shaking events in a cumulative representation.

The dynamic response of the non-treated soil profile to shake 10 is illustrated in Figure 4. Time histories of crust acceleration, excess pore-pressure in mid-depth of the loose sand layer, surface lateral spreading and vertical settlement at mid-slope for the simulations (in blue) and the centrifuge test (in red) are compared. The numerical prediction is largely successful in capturing the trends and magnitudes of the response. The crust acceleration is slightly overpredicted

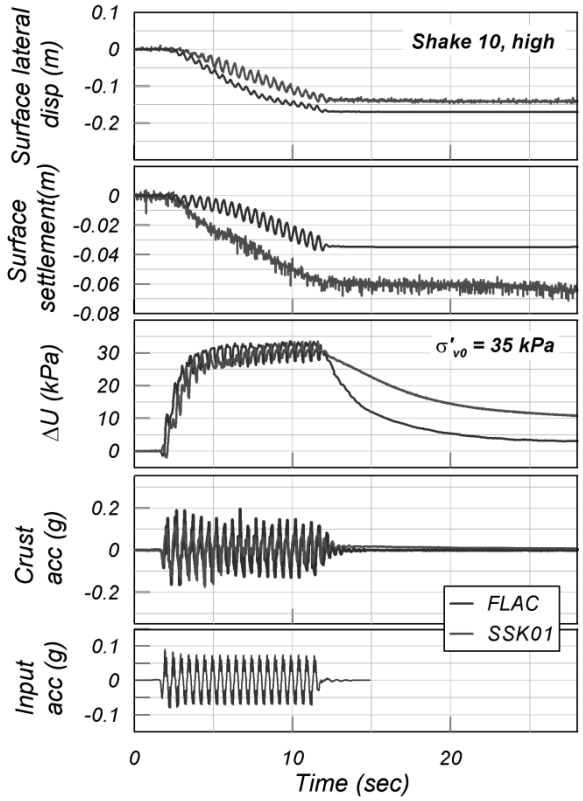

Figure 4 Comparison of centrifuge test and simulation results for shake 10 with high cyclic strength value. Time histories show a reasonable agreement between surface deformations, excess pore pressures, and crust accelerations.

and does not show the same de-amplification as observed in the centrifuge test, but peak magnitudes are similar. Simulations are able to predict the fast accumulation of excess pore pressures and the early triggering of liquefaction throughout the profile, though dissipation rates are faster than in the test. A simulation with 1/3 permeability produces dissipation rates that are in better agreement with measured pore pressure time histories, but over-predict the lateral surface displacements. Figure 4 further shows that the lateral surface displacements in this simulation agree well with the centrifuge test measurements, but that the vertical settlement is under-predicted. This could be a result of slumping and yielding of the crust material itself during the centrifuge test that was not predicted in the simulations. Overall, the dynamic response is in good agreement with the centrifuge test measurements and indicates that the general behavior is achieved in the simulations.

The overall deformation pattern is illustrated by the contour plot in Figure 5. The contours show significantly different deformation patterns in the treated and non-treated sides. On the non-treated side, there is a clear step in displacements across the upper row of sand elements just below the crust, such that the crust deformations are about twice as much as the sand deformations. On the treated side,

there is very little deformation and no concentration of deformations at the interface between the sand and the crust, in agreement with the experimental observations. The large crust displacements result in a gap opening between the non-treated crust and the container wall (only possible with large deformations enabled) and significant flattening of the slope, as also observed in the centrifuge experiment.

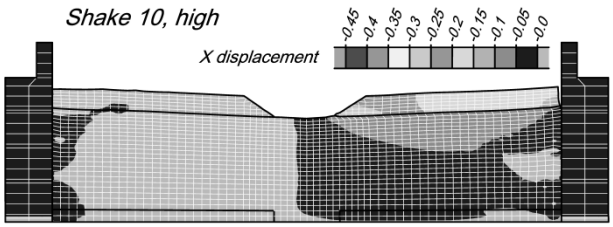

Figure 5 Contour map showing x displacements at the end of shaking. Localization is clearly seen on the non-treated side whereas displacements on the treated side are negligible.

Void-ratio redistribution as a result of the liquefaction-induced hydraulic gradient and upward flow is illustrated by a contour plot of relative-densities at the end of shaking in Figure 6. The top 3-8 sand elements on the non-treated side are loosened by 5-10% relative density, whereas the treated side experiences no loosening, and even some densification towards the container wall. The thickness of the loosening zone is a little less than 1 m, which is in good agreement with previous theoretical and experimental studies (Malvick et al. 2006; Malvick et al. 2008) as well as with the results of inverse analyses of the instrument arrays from this test (Kamai and Boulanger 2010). These other studies had shown zones of dilation at the top of a confined liquefied sand layer that were about 0.6-m to 1.0-m thick, which is much greater than the expected thickness of any eventual localization (i.e., 10 or 20 grain diameters).

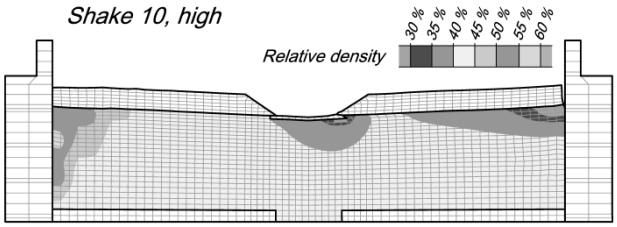

Figure 6 Contour map showing relative density at the end of shaking. On the non-treated side, the upward pore-pressure dissipation which is impeded by the crust layer leads to the loosening of a ~1 m thick sub-layer below the crust.

Cumulative deformation profiles for the non-treated side (approximately at a mid-slope location) at the end of each shaking event are presented in Figure 7. Simulation results (represented by solid lines) are in good agreement with surface measurements from the centrifuge test (represented by open diamonds). The concentration or localization of deformations at the top sand element beneath the crust layer is clearly seen in the simulation results for shakes 10 onwards. The extent of deformations across the physical localization in the centrifuge test could only be measured at the end of the test and is represented by the cross symbols, which are in good agreement with the simulations' cumulative deformation across the top sand element (also called a "localization" for simplicity) at the end of shake 12. No deformation profiles are presented for the drain-treated side, since deformation was very limited, and no localization was observed at the interface, in agreement with observations from the centrifuge test.

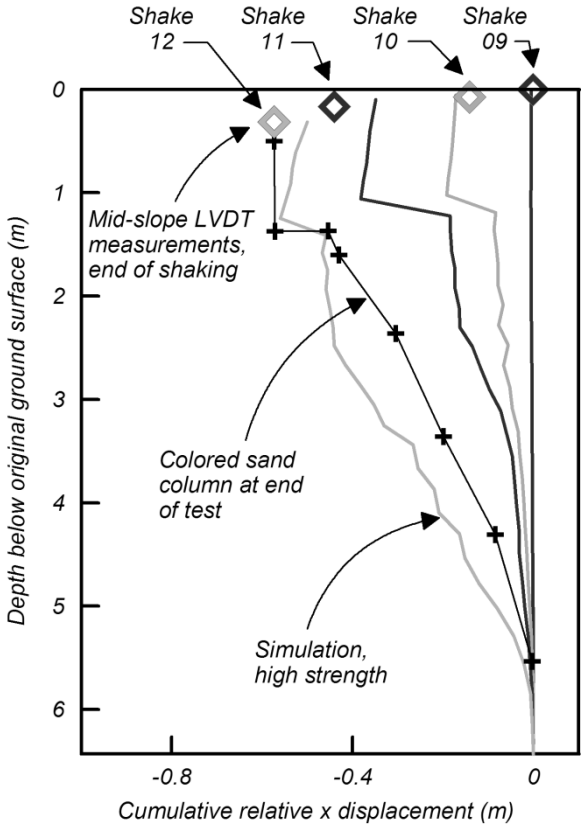

Figure 7 Displaced shape profiles on the non-treated side. Simulation results for shakes 9 through 12 are shown for the high cyclic strength case. The combined lateral and vertical surface displacement, as measured from LVDT's is presented by the open diamonds, and a colored sand column that was measured during excavation of the model at the end of the entire test is shown in the black line with the crosses.

3. DISCUSSION AND CONCLUSIONS

The general trends that were observed in the centrifuge test are successfully captured in the numerical simulations. The predicted surface deformations, pore pressure accumulation and dissipation patterns, and the distribution of strains throughout the profile agree well with the observations and measurements from the test.

The location, initiation, and extent of shear strain localization at the sand/clay interface are consistent with observations from the centrifuge test. This is an indication that the physical mechanism which ties pore-pressure dissipation, void-ratio redistribution, and shear-strain localization is successfully captured by the numerical platform and constitutive model discussed herein. These results were largely independent of element size, within the range of sizes evaluated.

The effective mitigation of surface deformations by liquefaction drains, including the complete prevention of shear-strain localization at the sand/clay interface, is successfully predicted and captured by the numerical simulations. It should be noted, however, that the drains in this study assume drainage walls, so over-prediction of mitigation effectiveness is expected.

Acknowledgements:

Funding for this research was provided the U.S. Geological Survey through Award G09AP00121. Richie Armstrong provided the FLAC model for the centrifuge container. The centrifuge test was performed in collaboration with Ellen Rathje, Antonio Marinucci, Seiji Kano, Carolyn Conlee, and Patricia Gallagher with funding from NSF Award No. CMS-0530478. The above support and assistance is appreciated.

Abstract: The unit weight of buried structure is inherently lighter than that of surrounding saturated soil, so that the buried structure has high potential to float upward once the surrounding soil liquefies. A series of centrifuge shaking table tests was performed to investigate the uplift mechanism of the immersed railway tunnel during the ambient loose sandy soil liquefied. Different viscous fluid was considered in this study to simulate different types of soil layer. A sinusoid wave with acceleration amplitude of about 250 gal, frequency of 1 Hz (16 cycles) was applied to the base of laminar container in prototype scale. Vertically hydraulic gradient contours were plotted to demonstrate the changes of excess pore water pressure during and after shaking. A severe quick sand condition can be expected beneath the tunnel especially at the lower corner of tunnel. The final uplift displacement of tunnel for Test B was less than that of Test A. The reason of smaller uplift displacement of tunnel in Test B may be due to the apparent cohesion and higher viscous force in the MCE fluid saturated soil specimen. The increasing uplift displacement with increasing FS was observed due to the movement of soil around tunnel during dissipation stage for Test A and Test B.

1. INTRODUCTION

The unit weights of buried structures are inherently lighter than that of ambient saturated soil. The apparent unit weight of a typical immersed tunnel is around 10 kN/m^3, however, the unit weight of the saturated sandy soil is of about 20 kN/m^3. When the sandy soil is completely liquefied, it will make buried structures subjected to upward buoyancy, and squeeze out the buried structure toward ground surface. Therefore the buried structures have high potential to float upward once the surrounding soil liquefied. Uplift failure of buried structures, such as immersed tunnels, manholes and pipeline systems, were observed in the 1964 Niigata earthquake, 1995 Kobe earthquake (Liu and Song, 2005), and 2004 Niigata-ken Chuetsu earthquake (Tobita et al., 2010). Chou et al. (2001) indicated that the Taipei Rapid Transit System (TRTS) tunnel with 17 m buried height in Taipei County can be classified as a light to medium degree of risk for the liquefaction related damage. The related soil profile also shows that the depth of liquefiable soil layer is from 5 meters to 24 meters beneath the ground surface in the interesting site. Thus, the situation could become even worse for a sallow immersed tunnel in Taipei County, and a further research study on the behavior of immersed tunnel in liquefiable soil is needed.

Koseki et al. (1997) performed a series of 1 g shaking table tests to simulate immersed tunnels and manhole uplift behavior due to soil liquefaction. Koseki et al. show that the total tunnel displacement is affected by three different soil-structure interactions: 1) lateral soil deformation of liquefied soil; 2) movement of pore fluid; 3) reconsolidation of soil. Ling et al. (2003) conducted a series of 30 g centrifuge modeling tests to investigate the uplift stability and overburden soil improved strategy of a large-diameter pipe. Sasaki and Tamura (2004) predicted the tunnel uplift displacement based on centrifuge modeling tests results, and the predicted results show a well fit with the measured uplift displacements during shaking.

An existing immersed railway tunnel which is located in the potential liquefaction risk area in Taipei County is considered in this study. A series of dynamic centrifuge modeling tests in a acceleration of 80 g was performed to investigated the seismic response of the immersed railway tunnel with the cross-section of 9.15 m (H) × 18 m (W) embedded in saturated sandy soil. Detail testing setup, test results and discussions present in the following sections.

2. CENTRIFUGE MODELING TESTS

2.1 Equipment and Soil Properties

Centrifuge modeling tests were performed by using the 100g-ton geotechnical centrifuge at National Central University (NCU) in Taiwan. NCU centrifuge has a nominal

radius of 3 m and equips a one dimensional electro-hydraulic servo-controlled shaker integrated within a swing platform. The shaker has maximum nominal shaking force of 53.4 kN, maximum table displacement of ±6.4 mm, and could be operated up to 80 centrifugal acceleration with maximum payload mass of 400 kg. A 38 aluminum rectangular ring formed laminar container with the inside dimensions of 710 mm (L) × 355 mm (W) × 355 mm (H) was conducted in the tests.

Tunnel model was made by an acrylic box in order to control its apparent unit weight as light as existing railway tunnel's. The apparent unit weight of the tunnel model is 9.53 kN/m^3, and is lighter than the unit weight of water. Therefore, the tunnel model has the potential for floating upward in all time even in the static condition. The dimension of the tunnel model is 336 mm (L) × 225 mm (W) × 114 mm (H), can be used to simulate a immersed railway tunnel with inner dimensions of 26.88 m (L) × 18 m (W) × 9.15 m (H). Three pore water pressure transducers were installed inside of the tunnel, and used to measure the pore water pressure distribution at the bottom of the tunnel. Eleven earth pressure transducers were distributed around the tunnel. The picture of the tunnel model shows in Fig. 1.

Fine quartz sand is used to prepare the sand deposit in this study. The characteristics of the quartz sand are summarized in Table 1. The relative density of the tested sand bed was controlled around 55% by air pluviation.

Table 1 Characteristics of Tested Quartz Sand

G_s	2.65
D_{50} (mm)	0.193
D_{10} (mm)	0.147
γ_{max} (kN/m^3)	16.3
γ_{min} (kN/m^3)	13.5
Friction Angel, ϕ (Dr=55%)	35.7°
Permeability, k (mm/sec)	7.7×10^{-4}

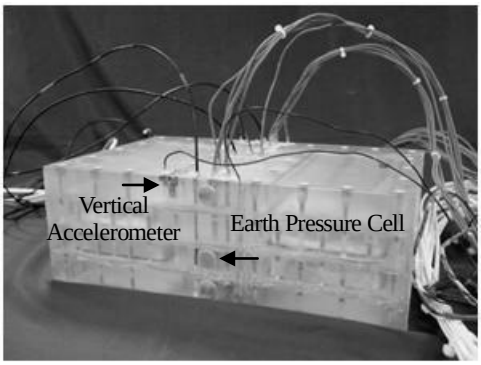

Figure 1 Photo of the Tunnel Model Side View

2.2 Model Preparation and Test Procedures

In the model preparation, the quartz sand was pluviated in a regular path into the container from a hopper at a certain falling height for preparing fairly uniform sand deposits and controlling its relative densities. The pluviation process was interrupted as need for embedding the transducers or tunnel at specified elevations. After completion of the sand bed preparation, the tested model was saturated on the shaker with de-air water or MCE fluid, respectively. The centrifuge was accelerated at an increment of 10 g steps until the centrifugal acceleration field reached to 80 g. A sinusoid wave with acceleration amplitude of about 20 g, frequency of 80 Hz (16 cycles) was applied to the model for duration of 0.2 second. It can simulate an input base ground motion of 250 gal, predominate frequency of 1 Hz and duration of 16 seconds. Various sensors, including accelerometers, pore water pressure transducers and LVDTs, are installed in the model for recording the seismic response of the model during shaking. The configuration of the test setup is shown in Figure 2.Testing conditions are listed in Table 2.

Table 2 Profiles of Testing Conditions

Test No.	Test A	Test B
Viscosity of saturating fluid	1 μ_w	80 μ_w
Input wave amplitude (g)	0.27	0.23
Shaking frequency (Hz)	1	1
Duration (sec.)	16	16
Dr (%)	55.8	55.8
Burial depth (m)	7.68	7.68
Water content (%)	28	28
Saturated soil unit weight γ_{sat} (kN/m^3)	19.1	19.1

* μ_w refers to the water visicosity.

3. TEST RESULTS AND DISCUSSIONS

3.1 Acceleration and Pore Water Pressure Changes

Observed excess pore water pressures (u) in free field were normalized by the corresponding effective vertical stresses (σ'_{vo}) implying the degree of soil liquefaction. In Figure 3, the excess pore water pressure ratio, $r_u = u/\sigma'_{vo}$, presenting the degrees of soil liquefaction in various depths were similar to each other in Test A and B. However, the acceleration response was quite different between Test A and Test B at upper soil layer, see Figure 4. The excess pore water pressure was decreasing during shaking at the depth of 16.8 m (P7) in Test A. It results in the increasing of soil stiffness and the recovery of measured acceleration amplitude at the same depth of tunnel model in the Test A.

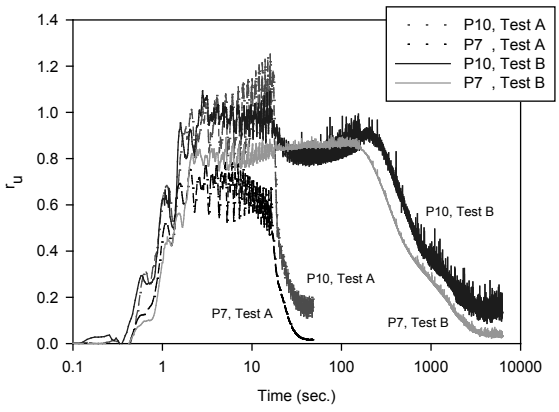

Figure 3 Excess Pore Water Pressure Ratio at Different Depth in Test A and Test B

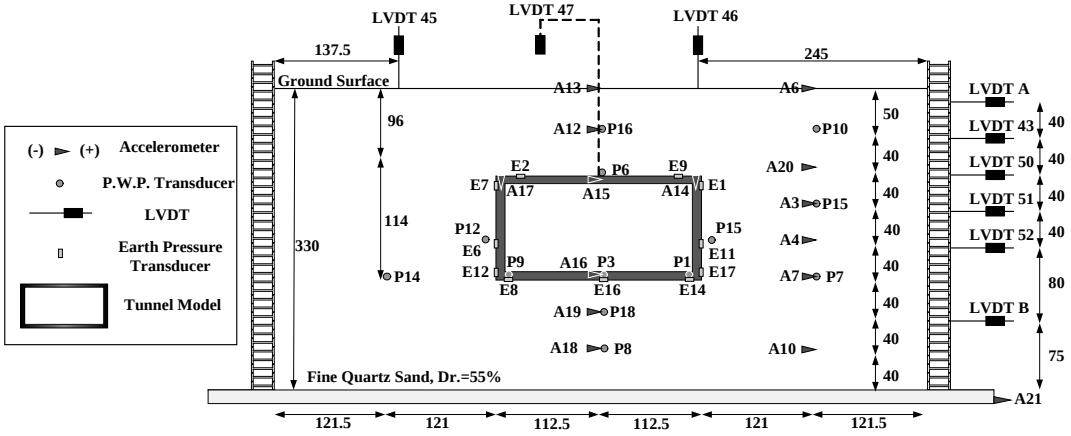

Figure 2 Configuration of Test Setup and Location of Sensors

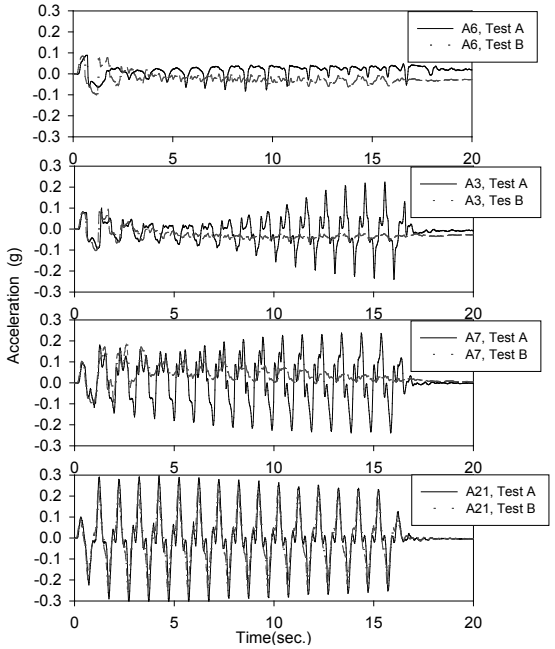

Figure 4 Free Field Acceleration Recordings at Various Depths in Test A and Test B

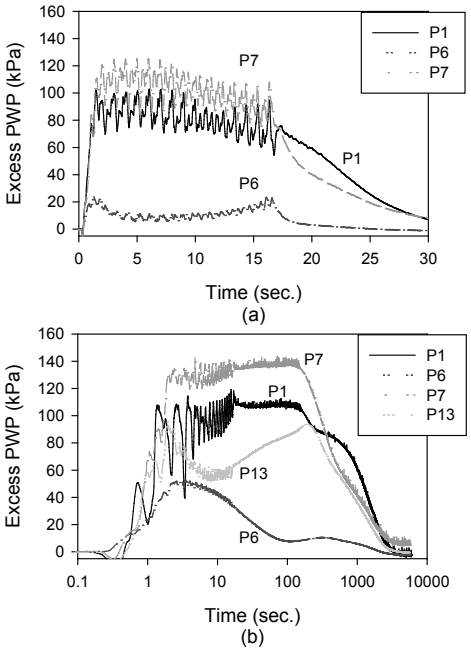

Figure 5 History Recordings for P1, P6, P7 and P13 in (a) Test A ; (b) Test B

In Figure 5, it shows the excess pore water pressure changes measured at the top (P6) and the bottom (P1) surface of tunnel. Measured excess pore water pressure value of P6 was increasing slightly at the beginning of shaking, but it soon decreased during shaking due to the tunnel block effect. It makes the drainage at the upper layer of the tunnel drained toward the ground surface without replenishing from the lower layer of the tunnel. Meanwhile, the drainage generated beneath the tunnel has longer path than that before tunnel existed, and thus the excess pore water pressure may be keeping increase which was discovered in Test B during shaking. The critical hydraulic gradient can be expressed as Eq. (1) :

$$i_c = \frac{G-1}{1+e} \quad \textbf{(1)}$$

where, i_c is the critical hydraulic gradient and e is the void ratio of tested soil.

For the sandy soil used in this study, its critical hydraulic gradient is equal to 0.95. If we took all the pore water pressure transducer recordings into account in Test A and B, the vertically hydraulic gradients were obtained according to Eq. (2).

$$i_v = \frac{\Delta u}{L\gamma_w} \quad \textbf{(2)}$$

where, i_v is the vertically hydraulic gradient, Δu is the difference of adjacent excess pore water pressure readings in vertical direction, γ_w is the unit weight of water and L is the distance between two p.w.p. transducers. The vertically hydraulic gradient is defined as positive as the drainage dissipated toward ground surface. Calculated i_v contour diagram for Test A and Test B was shown in Figure 6. The observed timing was selected at a pair of adjacent local extrema of P1 recordings to investigate the change of vertically hydraulic gradient distribution around tunnel.

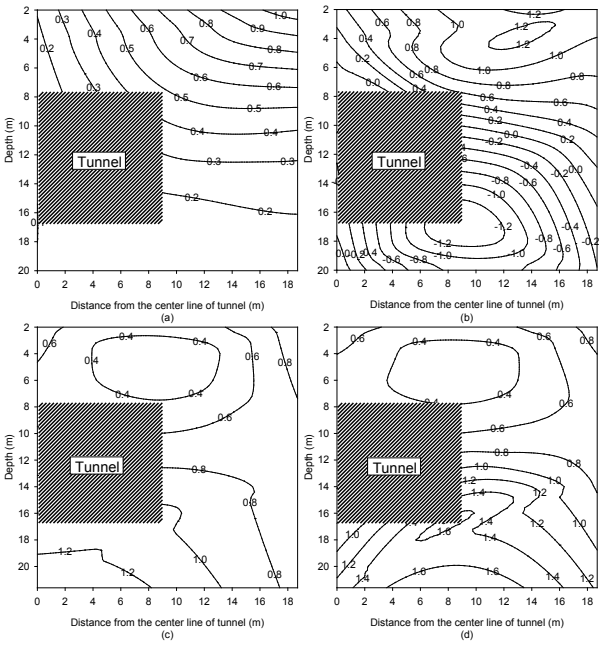

Figure 6 Vertically Hydraulic Gradient Contour Diagram for Test A at (a) 12.768 sec. ; (b) 12.976 sec. ; and for Test B at (c) 7.216 sec. ; (d) 7.712 sec.

While the P1 reading was equal to a local minimum or maximum in Test A, the corresponding vertically hydraulic gradient contour diagrams were shown in Fig. 6 (a) and (b), respectively. In Fig. 6 (a), it was discovered that the maximum vertically hydraulic gradient appeared near the free field ground surface, and its value was greater than the critical hydraulic gradient of tested soil. It is indicated that the quick condition may occur near the ground surface. In Fig. 6 (b), the negative hydraulic gradient distribution region was observed in the right hand side of tunnel. The negative hydraulic gradient distribution may indicate that the ground water flows into the bottom area of the tunnel at this instant, and localized stiffened the soil could be happened due to the increasing effective stresses. The increased soil effective stresses would result in the increase of friction force acted on the side wall of tunnel. While the P1 reading was equal to a local minimum or maximum in Test B, the corresponding vertically hydraulic gradient contour diagrams were shown in Fig. 6 (c) and (d), respectively. It can be found that the value of the hydraulic gradient near the upper corner of the tunnel is relatively smaller than everywhere in the model. In Fig. 6 (d), the hydraulic gradients distributed at the bottom regions of tunnel were greater than the critical hydraulic gradient. A severe quick condition can be expected beneath the tunnel especially near the lower corner of tunnel.

3.2 Uplift Displacement and Earth Pressure Changes

In this study, tunnel uplift displacement was measured by using a wire attached to a pulley LVDT. The measured tunnel uplift displacement and effective earth pressure changes around tunnel in Test A and B were shown in Figure 7 and 8, respectively. The tunnel started to float upward at the beginning of shaking following the increase pore water pressure and the reduction of contacted normal effective

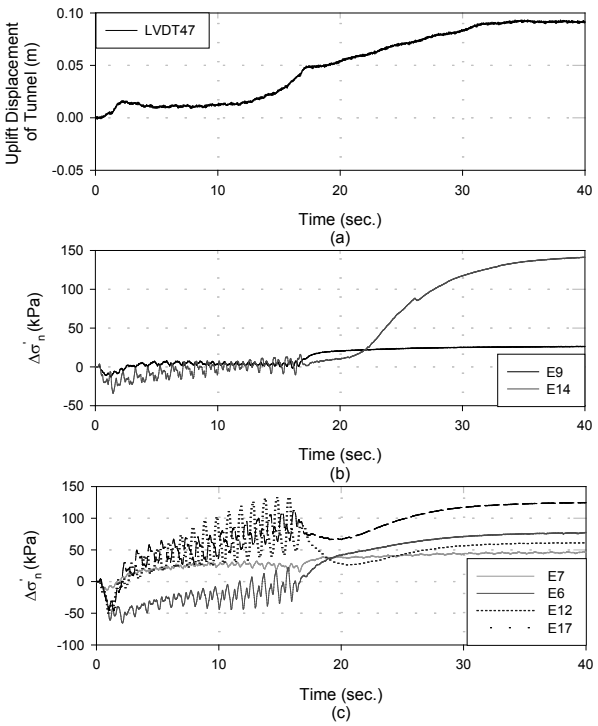

Figure 7 Tunnel Uplift Displacement and Normal Effective Earth Stresses Changes Around Tunnel of Test A

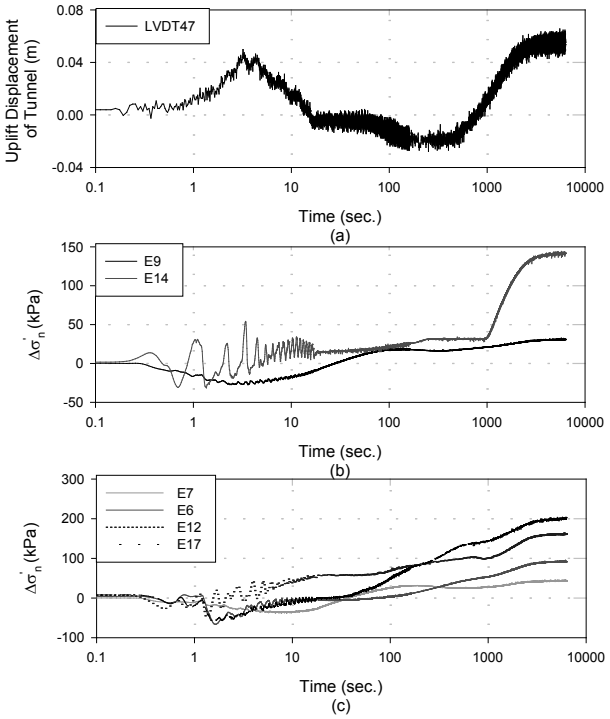

Figure 8 Tunnel Uplift Displacement and Normal Effective Earth Stresses Changes Around Tunnel of Test B

earth stresses (σ'_n). Tunnel uplift displacement variation consists with the change of E9 time history in both tests. However, the tunnel started to settle at 3.1 second of shaking duration in Test B, and began to uplift again in dissipation stage. While the reading of E9 was reducing or increasing,

the tunnel would tend to float upward or to settle downward in both tests. During pore water dissipation, the bottom surface of tunnel would subject to an incremental effective earth pressure, as E14 recording shown, and it may relate to the consolidation and movement of ambient soil. In Test A, a significant earth pressure time history (E12 and E17) oscillation was observed at the lower corner of tunnel, see Fig. 7 (c). For time histories of E12 and E17, it showed a clear out of phase relation, and kept increasing during shaking. Due to the soil lateral compression on the left side of tunnel, the increment of E12 measurement is great than that of E17. The final uplift displacement of tunnel for Test B was equal to 55 mm in prototype, and it was less than that of Test A. The reason of smaller uplift displacement of tunnel in Test B may be due to the apparent cohesion and higher viscous force in the MCE fluid saturated soil specimen. However, an opposite point of view was proposed by Chian et al. (2010). They indicated that the uplift displacement of a large pipe is become greater in the viscous fluid test due to the longer pore water dissipation time. Further investigation on centrifuge modeling test is necessary to clarify the influence of fluid viscosity in such studies.

3.3 Factor of Safety

The safety factor against uplift for the immersed tunnel was defined as Eq. (3):

$$FS = \frac{W_s + W_t + Q_s + Q_t}{U_s + U_d} \quad \textbf{(3)}$$

where W_s is the self weight of soil block above tunnel, W_t is the self weight of tunnel, Q_s is the friction resistance provided of soil block above tunnel, Q_t is the friction force acted on the side wall of tunnel, U_s is the static hydraulic force acted at the bottom surface of tunnel and U_d is the dynamic hydraulic force due to the generation of excess pore water pressure. The relations between *FS* and uplift displacement for Test A and B are shown in Fig. 9 and 10. It can be observed the tunnel uplift displacement would develop until *FS* less than 0.95. However, modeled tunnel would soon start to settle during shaking in Test B. The increasing uplift displacement with increasing FS was observed during dissipation stage for Test A and Test B. While the pore water dissipated toward ground, the volume strain changes and re-distribution of in-situ stress field may result in the movement of soil around tunnel. Therefore,

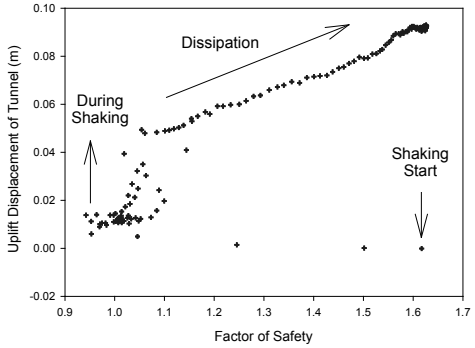

Figure 9 Relation Between Factor of Safety and Uplift Displacement for Test A

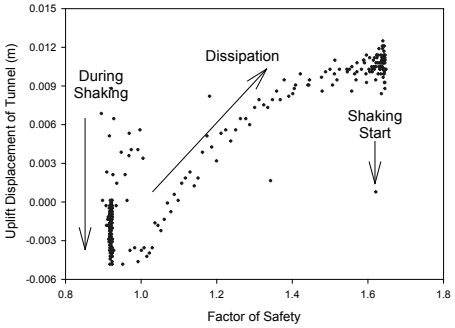

Figure 10 Relation Between Factor of Safety and Uplift Displacement for Test B

significant tunnel uplift displacement supposes to be happened during pore water dissipation.

4. CONCLUSIONS

In this study, a series of centrifuge modeling tests was conducted to investigate the uplift mechanism of immersed railway tunnel which constructed in Taipei County. Acceleration response, pore water pressure variation, earth pressures acted on the model tunnel were observed and discussed. A severe quick sand condition can be expected beneath the tunnel especially at the lower corner of tunnel. The reason of smaller uplift displacement of tunnel in Test B may be due to the apparent cohesion and higher viscous force in the MCE fluid saturated soil specimen. The increasing uplift displacement with increasing FS was observed due to the movement of soil around tunnel during dissipation stage for Test A and Test B.

Abstract: Current research has shown the capabilities and improved seismic performance of rocking shallow foundations for bridges, and much work has been done for implementation of such a mechanism in industry. By properly reducing the size of the footing, rocking behavior due to seismic loading can occur about the footing base. It has been shown experimentally that rocking foundations on competent soils can reduce seismic ductility demand on bridge columns and improve bridge performance. One concern of rocking systems is the potential for significant settlement accumulation in poor soil conditions. This research explores soil, footing, and structural responses of similar bridge structures on poor, liquefiable, and saturated soil conditions in addition to the effectiveness and practicality of using unconnected piles as a potential settlement mitigation technique. A centrifuge test series investigated the performance of six individual footing-column-mass structural models in these soil conditions. Although minimal residual rotations were observed, reiterating the tipping stability and recentering mechanism seen in previous testing on competent soil, significant uniform settlements under the footing were also recorded. Results from this research will help define the appropriate applicability range of rocking foundations in seismic design.

1. INTRODUCTION

Many researchers have been studying the rocking shallow foundations for various structures using different experimental tools. Several consecutive series of centrifuge model tests characterized the static and dynamic behavior of rocking shallow foundation for rigid shear walls (Rosebrook 2001, Phalen 2003, Gajan et al. 2005, Ugalde et al. 2010) or for highway bridges (Deng et al. 2010). Additionally, the behavior of rocking foundations has been experimentally investigated using shaking table tests (Sakellaraki et al. 2005, Paolucci et al. 2008) and in-situ model tests (Algie et al. 2010).

Current research has indicated that shallow rocking foundations on competent soils can reduce seismic ductility demand on columns and improve the performance of the system. If the moment capacity of the footing is designed so that is it smaller than the moment capacity of the column, rocking of the structure about the base of the footing will be initiated (Figure 1). In the conventional fixed-base foundation condition, almost all energy must be dissipated through bending of the column. The rocking of the foundation results in a ductility demand transfer from the column to the footing and surrounding soil. This reduces the magnitude of differential displacements imposed along the column for an otherwise fixed foundation.

However, although the beneficial effects of rocking foundation on bridge systems have been widely explored,

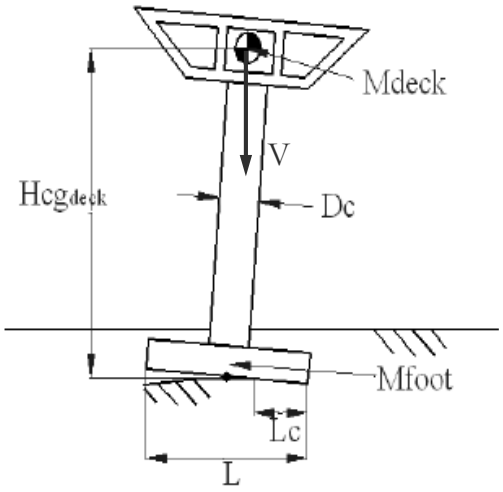

Figure 1: Rocking foundation schematic.

some hurdles impeding the use of rocking shallow foundations in bridge design still exist. One of the hurdles is the excessive displacement and collapse potential due to foundations rocking on poor, liquefiable soils. In responding to this hurdle, one series of centrifuge model test was performed on "single-degree-of-freedom" (SDOF) models that were built upon loose-liquefiable and erosive soil ground. Preliminary results from the model tests will be presented and discussed in this paper.

The overall goals of this research are to (1) delineate the

soil conditions under which rocking foundations would not be acceptable and (2) explore the viability of rocking foundations in poor soil conditions if the foundations are supported on unconnected piles.

2. MECHANISMS

The first centrifuge test aimed at determining potential failure mechanisms due to the interaction of shallow rocking foundations with saturated porous media. It has been analytically and experimentally shown that the introduction of fluid results in settlement associated with traditional shallow foundations in liquefiable conditions (Dashti, 2010a and 2010b). Additionally, other mechanisms may present themselves when coupled with a rocking foundation.

2.1 Suction

A rocking footing in saturated soil has the potential to create high, negative pore pressures at the footing/soil interface. This may cause granular material to move with the uplifting foundation, essentially creating a no-gap condition directly under the footing (Figure 2), resulting in negative settlement or uplift locally around the footing.

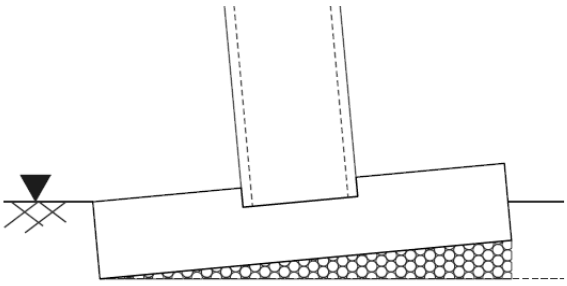
2.2 Erosion

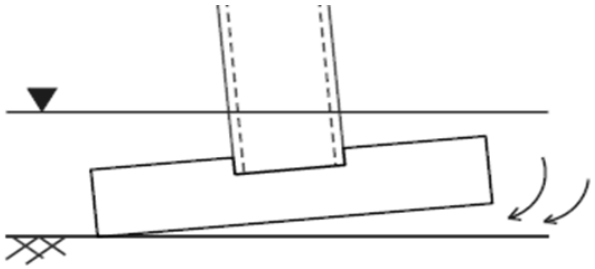
The initiation of particle movement is related to the shear stresses imposed on the soil grains from passing fluid. If the fluid velocity and essentially shear stress is high enough, the soil grains will move or erode. This potential is categorized as the threshold of movement and is dependent on fluid imposed shear stress, neighboring particle movement, fluid viscosity, particle density, particle diameter (*see section 2.3 Grain Size*), and gravity (Henderson, 1966). From these values, the dimensionless Reynolds number and Froud number parameters can be determined to categorize the flow regime and the particle's resistance to flow respectively. The study of incipient particle motion was first quantified experimentally by A. Sheilds, who created the Shields diagram for erosion prediction. Using this diagram in combination with the known parameters of the soil bed and fluid, one can generally predict the system's potential for erosion.

In the case of a rocking foundation, fluid is sucked in and pushed out from under the footing during rocking. This creates the potential for particle movement, resulting in significant settlement and soil rounding under the footing.

2.3 Grain Size

The particular soil grain size has an effect on many of these previously mentioned factors (suction, erosion, etc.). This centrifuge test explores this parameter by using two different grain sizes as the surface fill. Since all other parameters described in Section 2.2 are to be held constant for the test, the use of different grain sizes should have some effect in the footing and soil response. As the particle grain size under the footing is increased, the fluid failure mechanisms have the potential to become manageable. This may be one option for site remediation if a larger grain size shows a benefit in the rocking footing response.





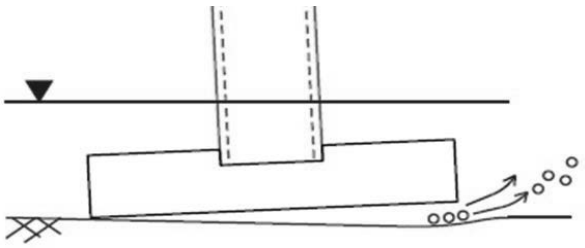


Figure 2: Suction potential in rocking foundations

(a) Water rushes in as foundation uplifts

(b) Soil particles erode as foundation rocks down

Figure 3: Erosion potential in rocking foundations in foundation (a) uplift and (b) gap closing.

2.4 Liquefaction

As previously stated, seismically induced soil liquefaction creates the potential for significant settlement and increased pore pressures. The same holds true in the exploration of failure mechanisms for rocking foundations. However, the dissipation of pore pressure after seismic activity at the liquefiable layer may be significantly affected by the additional pore pressure generation by rocking. This coupling effect needs further investigation.

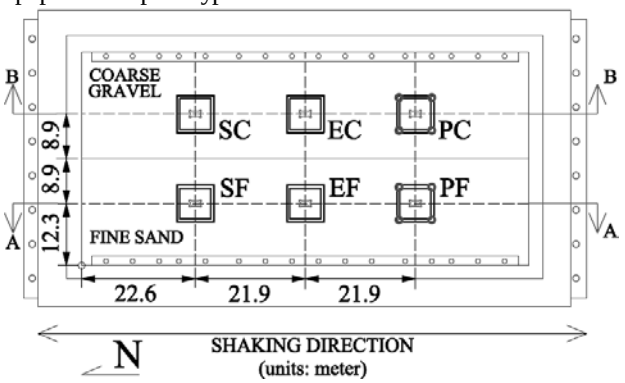
2.5 Deep Foundations

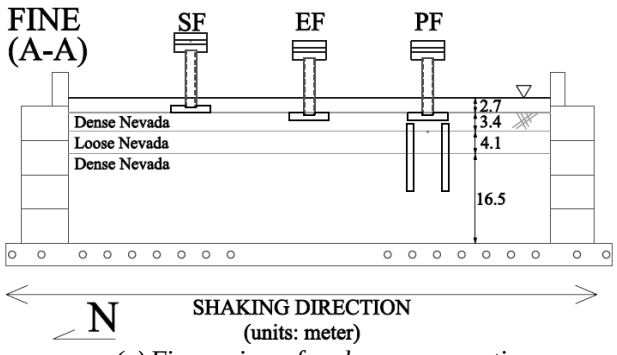
One goal of this research is to consider the potential benefit of coupling the rocking footing with unconnected deep piles. The purpose of these piles would be to bypass the liquefiable or poor layer of soil to set in a more competent, dense layer. If settlements are in fact

unreasonable, coupling the rocking footing with unconnected piles may reduce excessive settlements. Through the use of unconnected piles, the footings are able to rock freely ensuring the desired self centering effect.

3. CENTRIFUGE TEST CONFIGURATION

The first series of tests (JDA01) was completed at the Center for Geotechnical Modeling Facility at the University of California at Davis on the 9 meter radius centrifuge. The test series was comprised of 11 shakes at a centrifugal acceleration of 54g. A plan and cross-sectional view of the rigid container are presented in Figure 4 and Figure 5 respectively. As shown in Figure 5, the experiment used a flexible laminar container box which could enable the interlayer shear strain. All dimensions referenced in this paper are in prototype units unless noted otherwise.





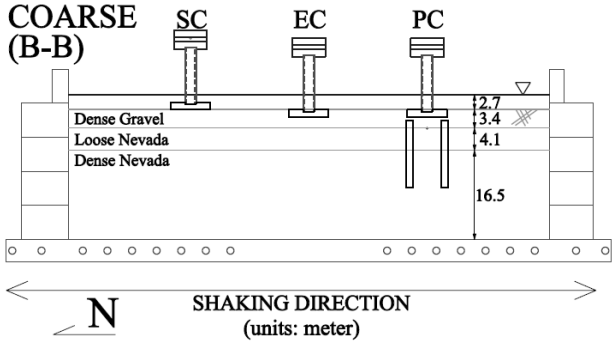


Figure 4: Plan view of JDA01 container

(a) Fine grain surface layer cross section

(b) Coarse grain surface layer cross section

Figure 5: Cross-sectional view of JDA01 container along the (a) Fine grain and (b) Coarse grain surface layer.

3.1 Soil

All soils used in this test were dry pluviated as shown in Figure 5 into the container to ensure consistent relative densities at certain depth intervals. The cross sectional views of the container in Figure 5 show up to 16.5m (304.8 mm model) of Nevada sand was placed at a relative density of 92%. Next, a 4.1m (76.2mm model) layer of "loose" Nevada sand was pluviated at a relative density of 68%. This loose layer was the representative liquefiable layer to be activated during shaking. The remaining 3.4m (50.8mm model) to surface elevation represent the top layer. In this test, two different soil types were used to compare certain response dependencies on grain size.

The "fine" layer consisted of the same Nevada sand (D_{50}=0.17mm) used at depth. The "coarse" layer consisted of Lapis Lustre Medium Aquarium Gravel (D_{50}=1.5mm), also dry pluviated into the container. These two uniformly graded soils were chosen based on particle diameter size. It was determined that the fine grain Nevada sand would erode, while the coarser grain would not, holding all other factors equal (*see section 2.2 and 2.3*). The container was partitioned in two and filled with one type of soil, but with comparable final surface elevation and similar dense relative densities (~90%). Properties for each layer are provided by Allmond (2011).

3.2 Structures

In total, six identical SDOF type models were designed and constructed with an aluminum square 6.1 x 6.1m (114.3 x 114.3mm model) and 3.4m (63.5mm model) high footing, aluminum rectangular tubing column, and aluminum and steel square block deck masses. Each model was labeled with two letters. The first designates footing orientation (S:surface, E:embedded, P:unconnected piles), the second refers to the top layer of soil of which the foundation is seated (F:fine, C:coarse). Therefore, the six structures are identified as follows:

SF	→	footing on **S**urface of **F**ine sand
EF	→	footing **E**mbedded in **F**ine sand
PF	→	footing on **P**iles in **F**ine sand
SC	→	footing on **S**urface of **C**oarse gravel
EC	→	footing **E**mbedded in **C**oarse gravel
PC	→	footing on **P**iles in **C**oarse gravel

The objective of this orientation style was to try and capture the different fluid failure mechanisms previously stated. That is, the surface footings would be susceptible to the rocking induced erosion, the embedded footings to rocking induced suction, and the unconnected pile footings to an improved site condition. The two surface soils were used for comparison purposes, resulting in six different stations of varying footing orientation and grounding. The structures and their respective orientations are also shown in Figure 4 and Figure 5. Summarizes of the period and natural frequency of the fixed case structures can be found in Table 1.

	Natural Period (sec)	
	Longitudinal (Length)	Transverse (width)
Model Scale	0.016	0.026
Prototype Scale	0.871	1.421

Table 1: Natural period of the models.

3.3 Saturation

All soil placed in the container was dry pluviated, which required eventual saturation of the model. Before construction, troughs were placed at both ends of the top container. Tubes were then connected to the base of the troughs, run along the vertical sides of the container, and then fitted with porous stones at the base of the container. After filling it with soil, the container was then placed on the centrifuge arm and prepared for saturation. The container was placed under vacuum, and CO_2 was pumped into the system to fill the voids. The viscous fluid was then pumped to the troughs, saturating the model from base to the surface, and the vacuum was released.

A viscous fluid mixture of water and methyl cellulose was used as the pore fluid in this test. According to scaling laws, the kinematic viscosity of the fluid should be scaled to that of the centrifugal acceleration (54g). However, it has been shown in previous tests and analyses, that the use of a fluid with such a high viscosity dramatically increases the time required for pore pressure dissipation and model saturation (Stewart et al., 1998). The methyl cellulose mixture for this test followed the standards presented in Stewart et al. (1998), resulting in a fluid to water viscosity ratio of eleven.

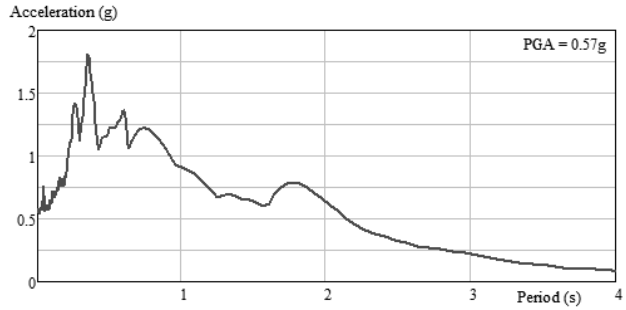

Figure 6: Dry pluviation of Nevada sand.

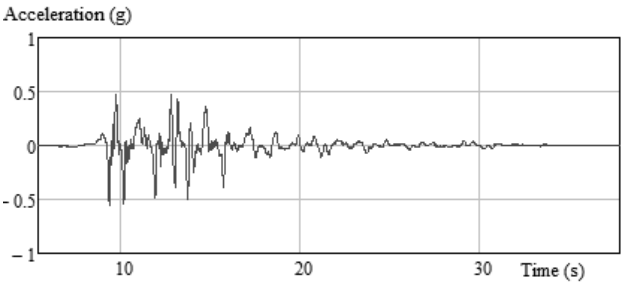

A portion of the test sequence was devoted to analyzing the structural response at different ground water elevations above the soil surface.

3.4 Ground Motions

The model was subjected to 11 events in total in the North-South (longitudinal) direction. These events included several varying amplitudes of a step wave and the Port Island downhole array ground motion recordings of the 1995 Kobe Earthquake. Figure 7 shows the acceleration-time histories as well as the acceleration response spectrum of the largest Port Island event used in this test series.

(a) Acceleration Response Spectrum

(b) Acceleration-time history

Figure 7: Port Island shaking event (PGA = 0.57g) showing (a) Acceleration response spectrum and (b) Acceleration time series.

4. RESULTS AND OBSERVATIONS

Analysis of this test is still ongoing, but preliminary results for the four foundations without piles are provided. All plots shown here after are from one of the large Port Island shakes (PGA = 0.57g) outlined above. The settlement and rotation time series for this shake are shown in Figure 8. The rotation-time series plot shows minimal residual rotations for all the footings, an observation that was consistently seen throughout the testing series. However, the settlement-time plot shows significant amounts of total settlement for the single shake. The moment-rotation curves for these four footings along with the theoretical moment capacity are presented in Figure 9. The data suggests that although significant settlements were observed, the residual rotations after testing were quite minimal. That is, the self centering rocking mechanisms observed in previous testing on competent soil are likewise seen here. Additionally, the moment-rotation curves obtained in this test are much like the trends observed in past testing results, including the fact that the theoretical moment capacity of the

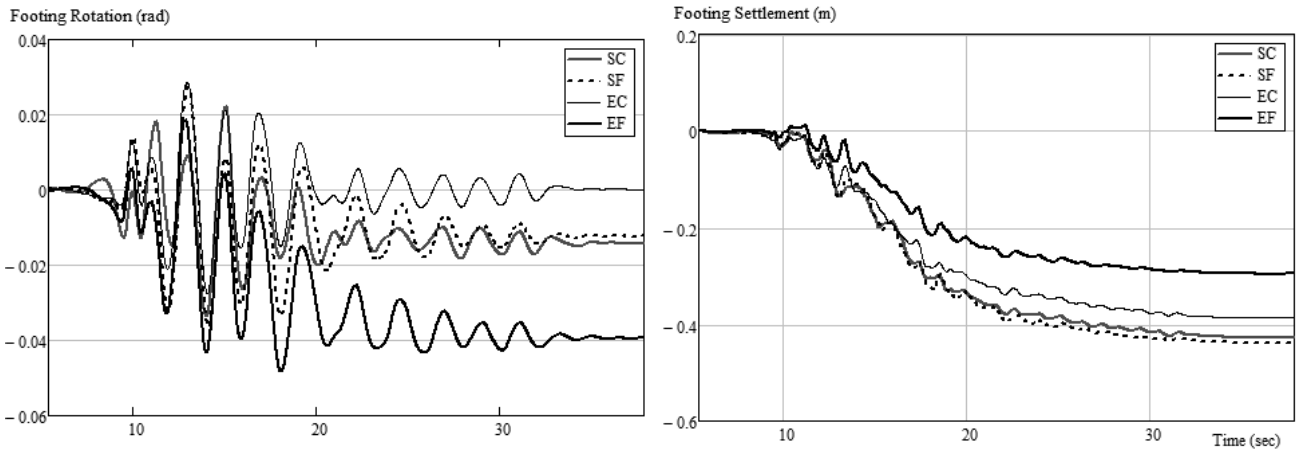

Figure 8: (*Left to Right*) Footing Rotation and Footing Settlement-Time series for the four footings without piles in one of the large Port Island events (PGA = 0.57g).

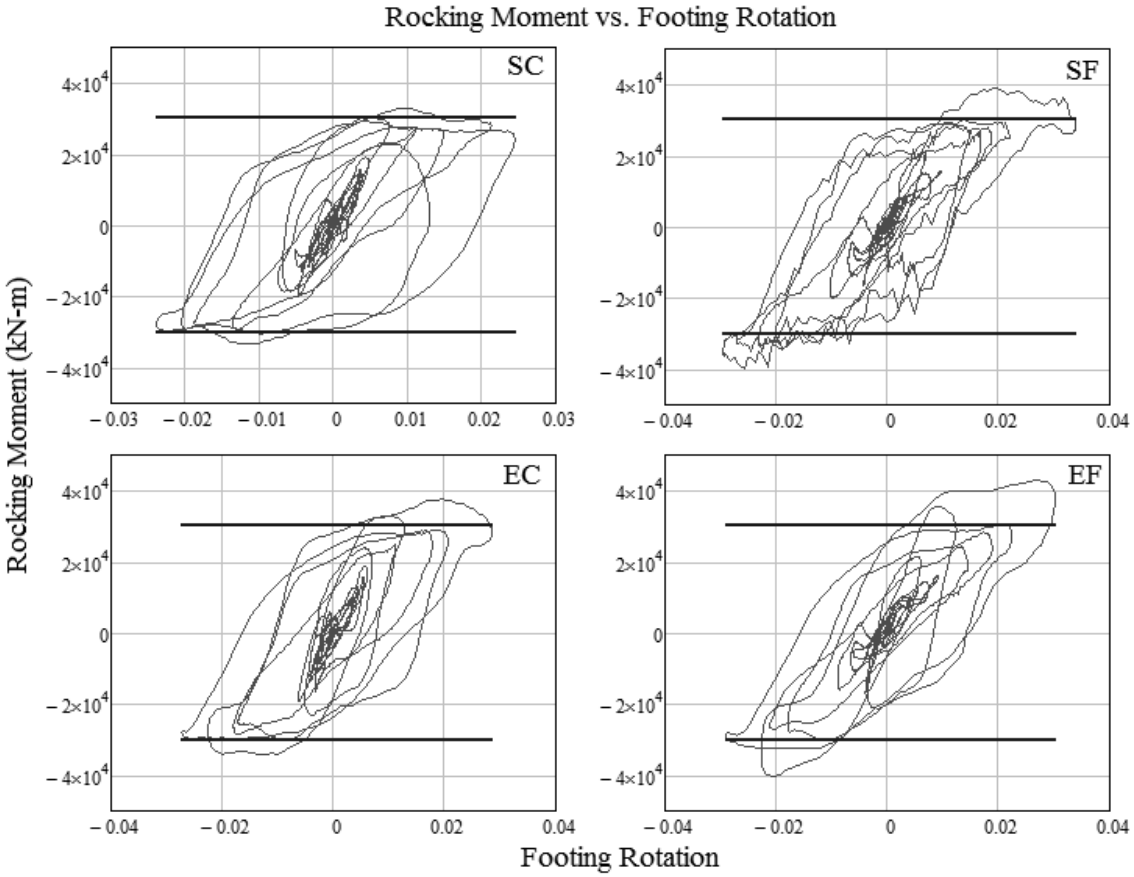

Figure 9: Rocking Moment vs. Footing Rotation curves for (clockwise at upper left corner) Surface on Coarse, Surface on Fine, Embedded on Fine, and Embedded on Coarse foundations with theoretical moment capacity.

footing is still well defined in saturated soil conditions.

Throughout testing, large residual rotations were observed for both structures placed on unconnected piles. During excavation it became clear that the cause of this permanent rotation was due to unseating of the footing from the piles. This result is clearly shown in Figure 10 and the cause of this significant unseating is still unknown. There may have been significant lateral footing displacements from shaking, or the footings may have been not quite centered during model construction. It should be noted that the portion of the footing still placed on the pile after testing experienced much less settlement then those foundations without piles. This leads to the possibility that if the rocking foundation stays centered on the piles, settlements can be minimized in an otherwise settlement prone site. Because of these undetermined factors, the data for the pile foundations has been excluded from this report until further analysis has been completed.

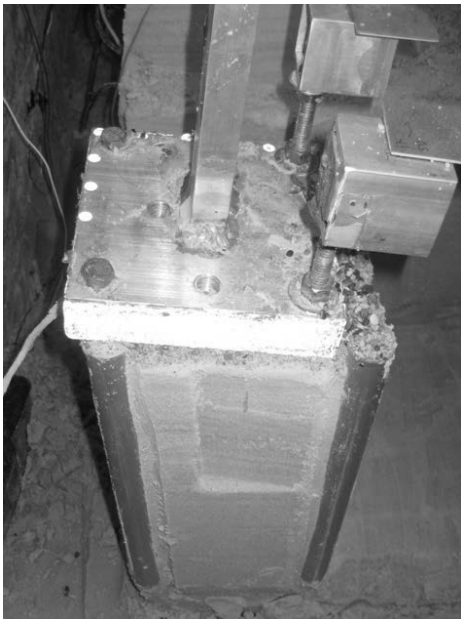

Figure 10: Excavation photo of unseating of unconnected piles.

5. CONCLUSIONS

Previous experimental and analytical research has shown that the rocking foundations could take up most of the ductility demand, rather than the column, from the seismic shear, while still dissipating energy and without imposing significantly increased settlements or residual rotations. Although the system has been analyzed on competent soils, there is a lack of sufficient knowledge of footing and soil response in liquefiable, saturated, and poor conditions. This first centrifuge test results presented here involved different mechanisms one might expect when implementing this design in such poor conditions such as erosion, suction, and liquefaction. Through analysis of the data and observations made during testing and excavation of the model a few conclusions can be drawn. First, although the footings experienced significant settlement during shaking events, the residual rotations were minimal. That is, the recentering mechanism and resistance to tip-over which drive the benefits of the rocking foundation system are still observed in saturated and liquefiable soil conditions. Secondly, the moment-rotation curves obtained in this testing series show similar trends to previous testing data on competent soils, including the capability of defining the moment capacity of the footing. Finally, the unexpected mechanism of unseating of the foundations from the unconnected piles still requires further consideration. However, reduced settlements were observed where the foundation still rested on the pile. This leads to a potential mitigation technique of reducing uniform settlements if the footing stays centered on the piles. Further testing will try to determine a suitable solution to this unseating, while continuing to search for conditions in which rocking foundations are not acceptable. Conclusive results from this research will help determine the limitations of rocking foundations to help guide their implementation and benefit in industry standards.

Abstract: The aim of the study is to investigate the interaction of the ground responding to combined loading. Failure loads and corresponding ground deformations of a strip, surface footing overlying dense sand and subjected to different proportions of planar displacements in the vertical, horizontal and rotational directions were investigated. Ground behavior during centrifuge tests was observed using close-range photography and analyzed with particle image velocimetry (PIV). Results revealed that the vertical stress imposed on the footing largely influences the occurrence of horizontal and moment load failure. Conversely, patterns of soil flow at different parts of the loading events were described. Ruptured surface of horizontally and rotationally loaded grounds was seen to have the same geometrical shape at failure.

1. INTRODUCTION

In recent decades, due to the complex nature of multi-directional loading, bearing capacity solutions have been reconstructed in the context of planar component forces. The intent of these reconstructions was to address the gaps of the classical bearing capacity instated by Terzaghi in 1943. In the classical approach, solutions are (still) formulated under the assumption of a predominant vertical load, where complications rendered by horizontal and moment loads are accounted for only by using a series of linear factors as argued by Houlsby and Cassidy (2002). As such, the classical analysis inevitably neglects any consequences for any change in loading conditions because it does not address the issue of plastic strains pre-failure (Gottardi and Butterfield 1993, Houlsby and Cassidy 2002).

In response, analyses founded on elastic-hardening plastic constitutive model for soil were formed (*e.g.* Tan 1990; Martin 1994; Gottardi, et. al. 1999). In these analyses, the bearing capacity problem is addressed directly in terms of planar components forces and corresponding footing displacements (Roscoe and Schofield 1957). It is postulated that after a given footing penetration, a yield surface is established within the vertical, horizontal and moment ($V,H,M/B$) load space (where B is footing breadth), instantaneously defining a failure surface (Houlsby and Cassidy 2002). The footing behavior within this surface is assumed to be elastic and does not provoke failure while the loads that reach the yield surface may instigate elasto-plastic behavior resulting to footing failure for any conjugate displacements (w,u,θ) (Nova and Montrasio 1991).

Past research on this field has generally been involved with developing optimum shapes of failure surface considering particular foundation geometries and soil conditions; for example employing strip footing on loose sand (Nova and Montrasio 1991), strip footing on dense sand (Butterfield and Gottardi 1994), circular footing on dense sand (Gottardi et al. 1999 and Houlsby and Cassidy 2002) and circular spudcan footing on clay (Martin 1994), to name a few. Several numerical studies have also substantially supported these physical experiments (for example Bransby and Randolph 1998, and Bransby and Yun 2009).

Central theme to the abovementioned studies is the description of failure of foundations in the context of failure curves, characteristically limited to the behavior of the footing in isolation. Such approach employs standard solutions that approximate the stiffness of the soil media arbitrated from the forces and displacements experienced by the footing. However, the significance of soil-footing interaction as indivisible phenomena is inadvertently down played by limiting the investigation to only a particular reference load and displacement point about the footing.

In response to this, it is the aim of the present study to extend the investigation of the interaction of the ground responding to combined loading. It is found that only a few studies have been involved with this intent. For instance, in the study of Bransby and Randolph (1998), soil deformation mechanisms at yield were investigated for a strip footing subjected to combined loadings under undrained conditions using two-dimensional finite element and upper-bound plasticity analyses. Taibat and Carter (2000) investigated patterns of soil movement and the development of plastic zones and failure mechanisms for different combinations of loads and moments using finite element analyses of circular

foundations on the surface of homogenous, purely cohesive soil. Bransby and Yun (2009) followed a similar approach to study the influence of skirt geometry on the deformation mechanism of soil under combined loading. However, a few physical models have been done, let alone run in an increased gravitational field. Jumikis (1961), for instance, has extensively studied the geometry of ruptured surfaces post-failure on sand of a strip footing subjected to moment loads using simple setups in 1g. Running on the same manner are the studies of Teh, et al. (2008) on layers of sand and clay and Hossain and Randolph (2010) on clay, both of which were conducted in centrifuge.

Carrying on from the elasto-plasticity based approach of earlier studies, various load states in *VHM* spaces were constructed by conducting several swipe tests. Results of nine (9) model tests of a strip, surface footing overlying dense sand under an increased gravitational field and driven in the vertical, horizontal and rotational directions are presented. Table 1 shows all the test cases performed with obtained relative densities of the ground and the vertical capacity of each test. Ground deformation was observed in-flight using close-range photography. Soil flow was investigated by employing a fully developed displacement field measuring software based on Particle Image Velocimetry (PIV). This software was developed by White and Take (2002) specifically suited to the analysis of geotechnical tests. Characteristics of ground failures are delineated in terms of progressive formation, propagation of soil flow, and orientation of the ruptured surfaces relative to model footing.

2. EXPERIMENTS AND PROCEDURES

2.1 Test set-up and preparations

The test set-up for all the loading tests is shown in Figure 1. All the loading tests were performed under an increased gravitational field (50g) using the Tokyo Tech Mark III Geotechnical Centrifuge (Figure 2).

A dense ground was modeled using standard Toyoura sand with a final height of 230mm and a plan area of 800x150mm shown in Figure 1(a). It was prepared by air pluviation technique. This technique is commonly employed when uniform dry sand is required. It was carried out by pouring the sand on the model container through a hopper suspended from a hoist, maintaining a consistent pouring height relative to the surface of the model ground. After the desired ground height was completely filled up, the soil surface was smoothened using a flat vacuum leveler. Relevant properties of the sand are provided in Table 2.

On the other hand, the model footing (Figure 1(b)) was constructed from hardened steel and is assumed to be rigid. It has a breadth of B=40mm and length of 150mm. Sand paper was glued on the whole span of the footing base to provide a fully rough bottom interface. This footing was modeled as a surface footing in plain-strain condition. The footing itself weighs 304grams.

All the loads applied to the footing were displacement-controlled at a rate of 0.01mm/s. These loads were imposed by means of a sophisticated loading jack in Figure 1(a) which was developed by Puntrattanasin et al. (2003) and was designed specifically for combined loading of foundations. This apparatus has two vertical screw loading jacks (V. jack 1 and V. jack 2) that can independently apply loads at a maximum stroke of 400mm displacement and a horizontal jack (H. jack) with 250mm stroke capacity.

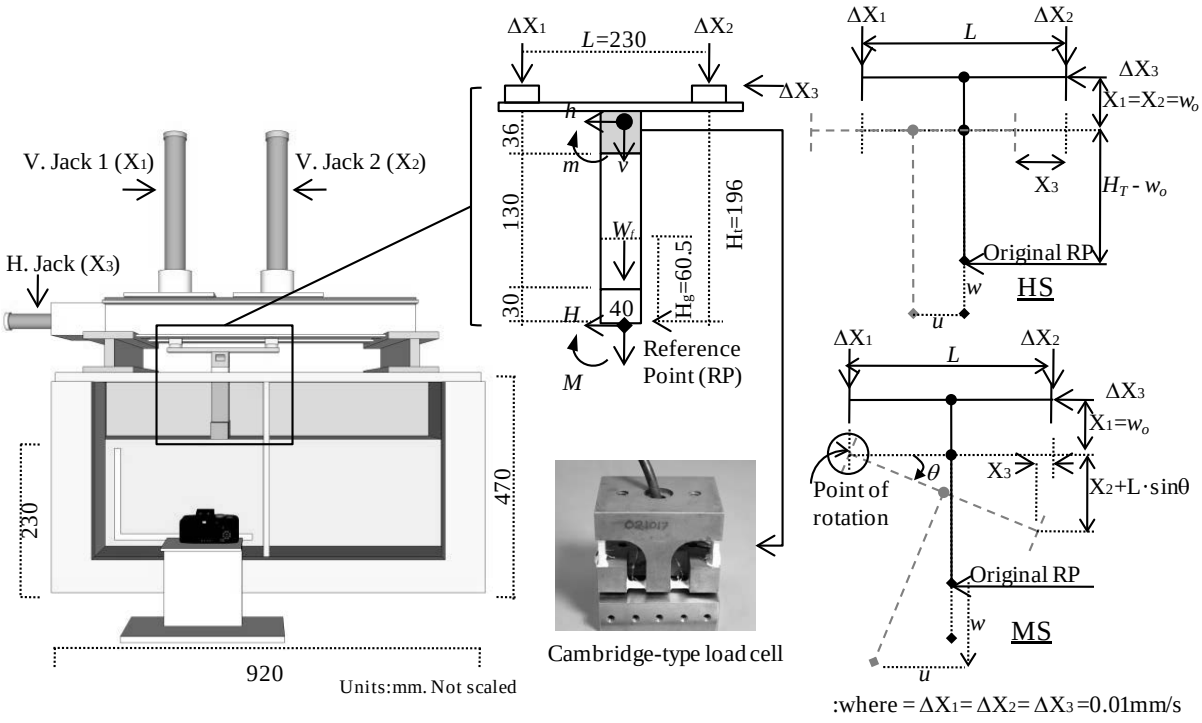
The displacement of the footing base, subsequently called the reference point (RP), in the vertical (w) and horizontal (u) directions as illustrated from Figure 1(c), are given by Equations 1 and 2 as

$$w = 0.5\left(X_1 + X_2\right) + H_t \cos\theta - H_t \quad (1)$$

$$u = X_3 + 0.5\left(L\cos\theta\right) + H_t \sin\theta - 0.5L \quad (2)$$

where X_1, X_2 and X_3 correspond to the displacements directly measured by three long-range Linear Variable Differential Transformers (LVDTs) fixed along V. jack 1, V. jack 2 and H. jack respectively (all in dimensions of *mm*); H_t is the total height of the footing from the load cell to the RP, and L is the span between the two vertical jacks.

The difference in the movement of the two vertical jacks conveniently provides the rotation of the footing θ, and can be expressed as,



$$\sin\theta = \left(X_2 - X_1\right)/L \quad (3)$$

In the presentation of results, footing displacements w and u were normalized by footing width B and θ is expressed in radian.

On the other hand, the actual loads were quantified

Figure 1 Test set-up: (a) Loading jack with model ground and container and PIV set-up, (b) Schematic drawing of model footing with Cambridge-type load cell, and (c) Loading mechanisms of footing system for HS and MS cases.

using a Cambridge-type load cell bolted between the top of the model footing and the loading arm of the jack shown in Figure 1(b). It is constructed out of hardened-tool steel and is capable of 58.3 kN direct stress load, 8.64 kN shear stress load and 0.505 kN-m moment.

Since footing displacements were interpreted from the RP, loads were subsequently superimposed on the same point. Given that all attachments were well-fixed, the loading arm of the jack and the footing system can be assumed to act as one rigid body during the loading, and that superposition of forces from the load cell to the RP can be convenient.

From Figure 1(b) and (c), superposition of forces gives the vertical, horizontal and moment component forces at the RP as,

$$V = -v - W_f \quad (4)$$

$$\boldsymbol{H} = \boldsymbol{h} \quad (5)$$

$$M/B = -v\cos\theta(H_t) + h\cdot\sin\theta(H_t) - m - W_f\cos\theta\cdot(H_g) \quad (6)$$

where *v*, *h*, *m* are vertical, horizontal and moment loads recorded by the load cell with dimensions of *kN*, *kN* and *kN-mm* respectively; W_f is the weight of the footing; and H_g is the height of the center of gravity of the footing where W_f acts upon.

In the presentation of results, component forces *V*, *H* and *M/B* were normalized by the maximum vertical load, V_{max} experienced in a single model test.

A digital camera (Canon Powershot G7) was mounted about 375mm horizontal distance from the inside window of the container to the level of the model ground to record the soil behavior during the loading tests. The camera was automatically set to obtain images every 100 sec. The captured images were analyzed using the GeoPIV software to obtain displacement vectors of soil flow. The principles of analysis employed in the GeoPIV software are detailed more in the paper of White and Take (2002). Note that the PIV set-up and the PIV analysis which used a patch size of 64 pixels with image-to-scale ratio of 0.14mm/pixel, were found to have a system accuracy 0.45 pixel and a precision of 0.002 pixel for any displacement greater than 10 pixels (Cocjin 2010).

2.2 Loading mechanisms

Three cases of pure vertical loading were conducted. A monotonic vertical loading (VM) was carried out as a pilot test. Two cases (VURa and VURb) which involved vertical unloading-reloading excursions were conducted to support the first case, furthermore to investigate the elastic behavior prior to failure. All of the vertical loading events were performed to the full capacity of the loading arm to provide as much data as possible concerning the vertical hardening.

On the other hand, three horizontal swipe model tests (HS) were conducted. In the first two events (HS1 and HS2), multiple horizontal swipes were commenced at various levels of vertical penetration, w_o shown by the dotted footing frame in HS of Figure 1(c). In every horizontal swipe, the vertical displacement was locked (Δw=0) while the footing was translated with constant horizontal displacement Δu until a horizontal peak load was achieved shown by the dashed-line frame in HS of Figure 1(c). After this peak was reached, the footing was driven back horizontally to its original position before further vertical penetration to the next swipe was carried out. After all the swiping events were performed, the footing was loaded vertically until failure to obtain V_{max} of each model test. HS3 provides a case wherein only one horizontal swipe was conducted before the footing was driven vertically to failure. This was so to confirm the similitude of footing behavior for the multiple swipes conducted in the first two horizontal cases. Figure 3(a) shows the normalized displacement trajectories for the HS cases.

Similarly, three (3) rotational swipe events (MS) were also conducted. These tests were performed by penetrating the footing to a particular depth w_o, at which point loading of one of the vertical jacks (V. jack 1) was halted while the other (V. jack 2) was further continued using the same displacement rate. This particular loading mechanism provided a sweep of w which simultaneously increased with footing rotation θ where the point of rotation corresponds to the stagnated location of V.jack 1 before the swiping proceeded (Figure 1(c)). The second vertical jack was loaded continuously until a perceivable peak load can be observed both in the horizontal and moment directions from the data logger; after which, V. jack 2 was retracted to its original position. This mechanism concludes a single rotational swipe event. Multiple swipe events were commenced at different levels of vertical penetration w_o before the footing was vertically loaded to failure. Details of the swiping displacement trajectories (w,θ) for the rotational swipes are given in normalized form in Figure 3(b).

3. RESULTS

3.1 Vertical loads

The normalized vertical load-displacement at the RP for all the loading events is given in Figure 4.

Linear, elastic relationship characterizes the onset of the loading until failure and during unloading-reloading excursions in the cases of purely vertical loading in Figure 4(a). For each case, stress softening was observed at continued penetration shortly after the peak load. A

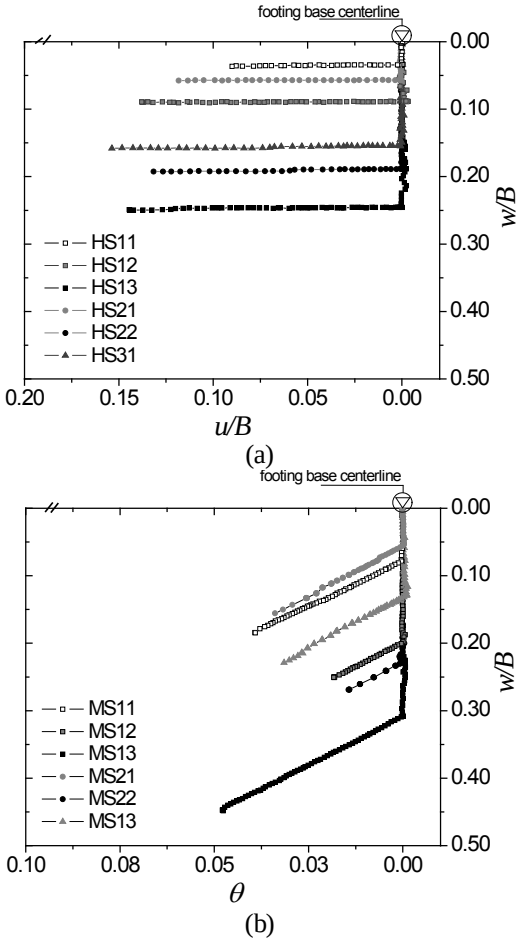

Figure 3 Displacement trajectories for (a) HS and (b) MS.

continued increase in vertical capacity was further seen post-peak, which was also noted in the works of Stuit (1995) in centrifuge involving vertical loading of circular footings on dense sand. He attributed this post-peak hardening to the mobilization of the soil next to the footing which affects a larger area, consequently increasing the recorded bearing capacity.

Conversely, several studies (such as of Nova and Montrasio (1991), Gottardi and Houlsby (1995), and Houlsby and Cassidy (2002)) have proposed expressions called 'hardening laws' which relate the vertical load and plastic vertical penetration of shallow footings. In Figure 4(a), the hardening law expression given by Gottardi and Houlsby (1995) which was derived from set of data tests on a rectangular footing on dense sand, was suitably adjusted and superimposed on the present set of data for comparison. The said expression is given in Equation 7 as,

$$V = \frac{k_p w_p}{1 + \left(\frac{k_p w_{pm}}{V_{\max}} - 2\right)\left(\frac{w_p}{w_{pm}}\right) + \left(\frac{w_p}{w_{pm}}\right)^2} \qquad (7)$$

where V is the vertical load, V_{max} is the vertical capacity equal to unity, w_p is the plastic vertical deformation equivalent to w/B, k_p=5.858 is the initial plastic stiffness derived from the best-fit line, and w_{pm}=0.333 is the value of w_p at V_{max}.

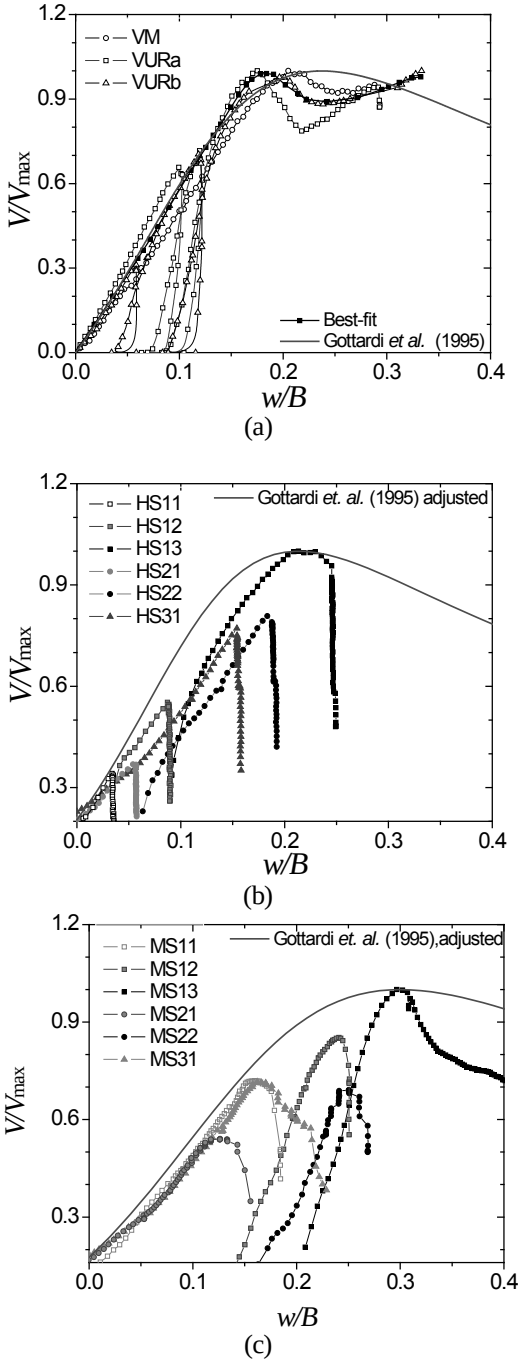

Figure 4 Vertical load-displacement curves of (a) purely vertical loading, (b) HS, and (c) MS.

On the other hand, the behavior of the vertical load during the horizontal and rotational swipes is shown in Figures 4(b) and (c). One swipe event in HS is characterized by a linear increase in vertical load and plastic vertical displacement during the purely vertical loading and an abrupt decrease in vertical stress during swiping at various w_o (Figure 4(b)). In case of HS13, which was loaded to vertical failure before the last swipe, a softening of the vertical stress was observed before it abruptly decreased as the swiping was pursued.

In the case of MS series in Figure 4(c), the rotational displacement was seen to significantly contribute to the increase of the vertical stress level, which increases linearly with vertical penetration, expectedly since footing rotation is largely a function of the vertical displacement (Equation 3). Accordingly, the graph shows that the occurrence of failure in the swiping direction depicts a softening behavior in the vertical stress right after the full mobilization of the vertical footing displacement and components of the footing rotation.

Owing to the type of load cell used in the experiments (Figure 1(b)), purely vertical loading also recorded horizontal and moment load reactions. Figure 5 plots the normalized *V*, *H* and *M/B* generated in the VM, VURa, and VURb cases along with the normalized plastic vertical displacement, *w/B*. In this figure, moment loads were generally seen to increase with vertical loads where *M/B* values at full vertical capacity were in the range of 0.045 to 0.070 of V_{max}. Note however that since the moment load is a function of the footing rotation as given in Equation 6, for an infinitesimal amount of θ during vertical penetration, the vertical load component, *v* directly measured by the load cell diminishes to zero, leaving the generated moment load, *M/B* a function of the moment and horizontal load components, *m* and *h*. In addition, the vertical penetration also generated horizontal loads, *H* in the range of $\pm 0.030 V_{max}$, discriminated solely by the horizontal load component, *h* directly measured by the load cell (Equation 5).

These observations show evidence of appreciable amounts of horizontal and moment loads the footing would experience, which are otherwise ignored in most vertical loading tests. These lateral reactions can be accounted for by the variable effect of soil deformation during the progression of footing penetration. At large embedment, the ground does not only become stiffer but also changes its deformation geometry in order to fully confine the loads imposed on it by the foundation. Such can be deduced from the normalized *wM* plot in Figure 5 where the maximum moment loads were only fully mobilized at footing penetration beyond 15% of the footing width.

3.2 Swipe loads

Six test cases of swipes were conducted, which provided 12 independent displacement trajectories shown in Figure 3. Half of these test cases were carried out by swiping purely in the horizontal direction, and another half was by means of rotating the footing as specified earlier. Each swipe commenced from an arbitrary initial vertical penetration w_o (Figure 1(c)), setting up the corresponding V_o which are provided in Table 1.

Considering the geometry of the model footing and location of the load cell with respect to RP, each swipe case, regardless of displacement trajectory, simultaneously generated both horizontal and moment reactions, which was also shown earlier in the purely vertical cases (Figure 5). In effect, a single swipe provides a defined relationship among the three planar component forces *V*, *H* and *M/B*. However, for convenience in the discussion of swipe loads, all results were grouped according to swiping events and not on directional forces generated, such that a description of footing behavior is specific among all HS only or among all MS only.

Figure 6 shows the normalized vertical and horizontal

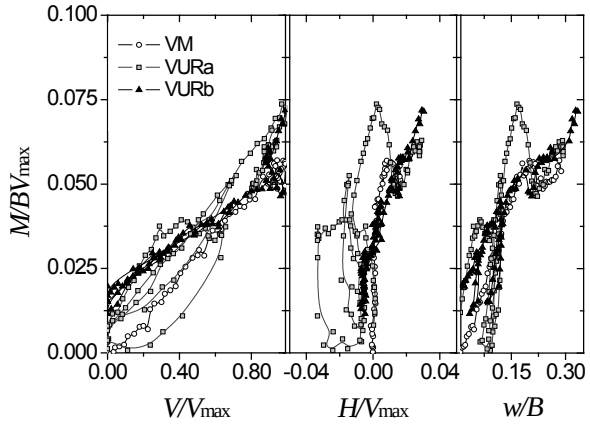

Figure 5 Normalised moment loads with vertical and horizontal loads and vertical penetration of VM, VURa, VURb cases.

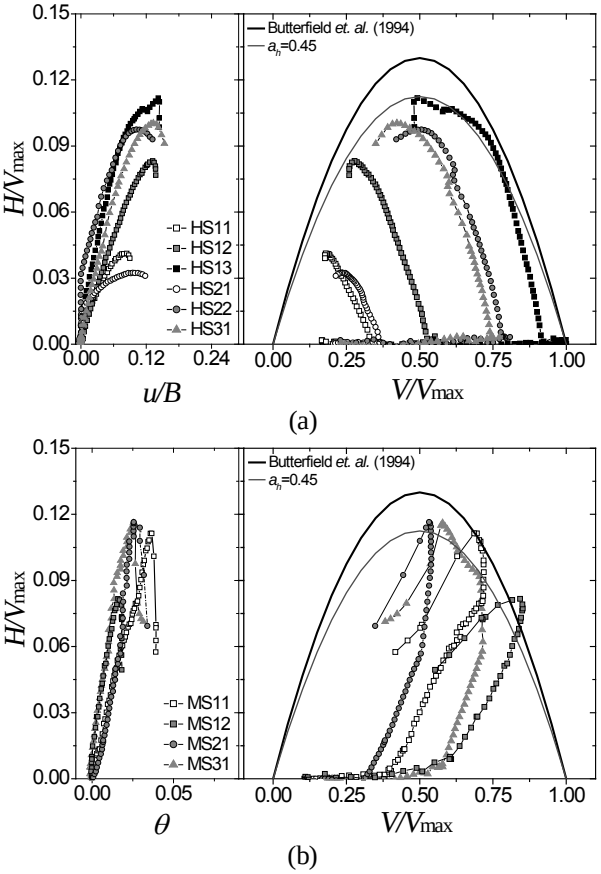

Figure 6 Normalized vertical and horizontal loads with (a) horizontal displacements of HS, and (b) rotational displacements of MS.

loads for HS and MS with respective swiping displacements u/B and θ. From the figures, the horizontal load is seen to increase steeply with horizontal and rotational displacements upon swiping until a maximum horizontal load H_{max} is reached. Horizontal loads consequently dip upon continued horizontal displacement or rotation. This observation clearly manifests the occurrence of plastic footing failure in the horizontal direction on all the swipe cases.

In Figure 6(a), the increase in horizontal loads during the horizontal swiping corresponded to a decrease in vertical loads. The VH load trajectory of HS for a single swipe follows the trajectory of a parabola which commences from V_o until a failure in horizontal direction is reached. Since VH load paths are seen to retract this parabola, it can be said that this parabola bounds the failure zone in the VH load space. Such behavior was observed in several earlier studies such as the numerical simulations of Bransby and Randolph (1998) and Houlsby and Cassidy (2002) and model tests of Nova and Montrasio (1991), Gottardi and Butterfield (1993), Gottardi and Houslby (1995), Gottardi et al. (1999), and Cassidy (2007) on various footing geometries and ground conditions.

Equation 8 provides an approximation to this parabolic shape given in general form as,

$$\left(\frac{H}{V_{\max}}\right) = a_h \frac{V}{V_{\max}}\left(1-\frac{V}{V_{\max}}\right)^{b_h} \qquad (8)$$

where a_h denotes the initial slope of the tangent of the parabola at the origin, and b_h controls the position of the maximum horizontal load for the given V_o, *i.e* the shape of the parabola and is taken equal to 1.

An a_h value of 0.45 fits well in the present set of data. Maximum horizontal capacity, H_{max} occurs at V=0.50·V_{max} where H_{max} is equivalent to 0.11·V_{max}. For purpose of comparison, a parabola with a_h=0.52, as suggested by Butterfield and Gottardi (1994) approximated from results of model tests using rectangular footings over dense sand, was also drawn on the graph. The obvious difference in footing geometry resulted to the observable difference in the sizes of these two parabolas. For instance, in circular footings on dense sand, an a_h value of 0.48 was observed by Gottardi and Butterfield (1993). Circular, spudcans on dense sand pegged an a_h of 0.56 (Dean et al. 1992) on the other hand. Furthermore, some evidence of change in the shape of the parabola can also be seen and is possibly due to the influence of the difference in the vertical hardening experienced prior to each swipe, especially for cases where multiple swipes were conducted.

It can also be deduced from Figure 6(a) that the parabola increases in size with the increase of initial penetration depth w_o, and consequentially of increasing V_o. This observation would suggest that the expansion of the failure surface is dependent on the vertical stress that the footing is carrying before it is subjected to swiping loads.

In contrast, the horizontal loads generated by rotation increase simultaneously with vertical stress commencing from V_o as shown in the VH plot in Figure 6(b). The figure shows that the load path of this particular swipe mechanism radially traverses the VH load space until a point of retraction is reached. In particular, the radial length of the load path from V_o to point of retraction is seen to be dependent on values of V_o, where swipes commencing from smaller V_o take a longer course and those starting from larger V_o take a shorter course. These points of retraction signify that failure in the horizontal direction has been reached. Conclusively, a trace of the two parabolas given earlier in Figure 6(a) following Equation 8 bounded most of these points.

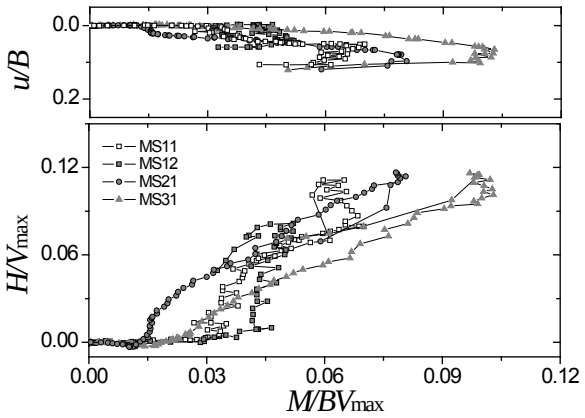

Figure 7 Normalized horizontal and moment loads with horizontal displacement of the RP in MS.

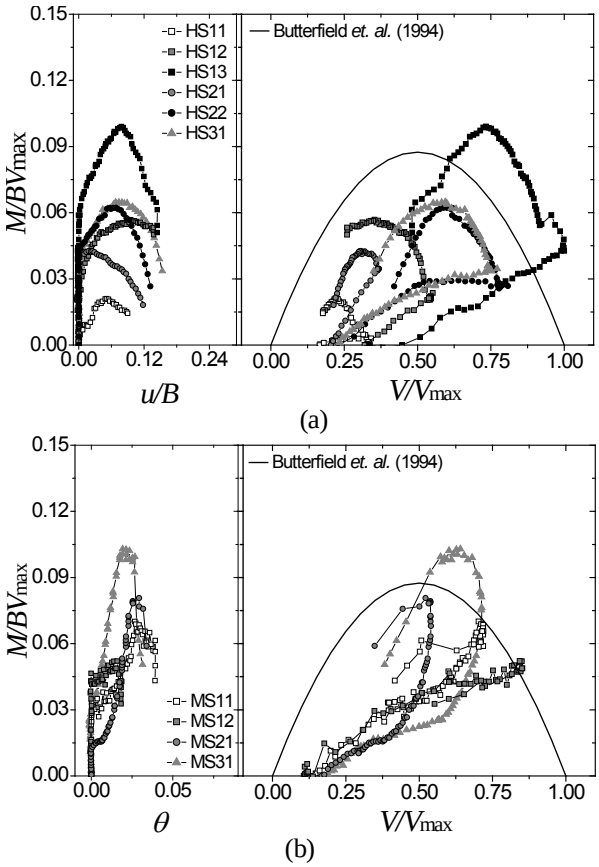

Figure 8 Normalized vertical and moment loads with (a) horizontal displacements of HS, and (b) rotational displacements of MS.

Note that the rotation of the footing also translated the RP horizontally. This horizontal translation of the footing during rotation is plotted in Figure 7 together with the normalized horizontal and moment loads of the MS cases. This graph reveals that large horizontal loads during rotation were experienced at larger horizontal displacements at around $0.10 \cdot B$.

The normalized moment loads for all the swipes are plotted against the normalized vertical loads for HS (Figure 8(a)) with u and MS (Figure 8(b)) with θ.

The amount of moment loads generated during horizontal swipe is seen to be not only generated by the horizontal displacement of the footing. In Figure 8(a), moment loads were already increasing even before the footing was moved horizontally as observed in the *uM* plot. It is revealed in the VM plot of the same figure that this increase in moment corresponded to a linear increase in vertical loads. This brings to light the earlier observation in the vertical loading cases where both horizontal and moment loads were simultaneously generated during vertical penetration (Figure 5). Note, however, that the increase in horizontal load in the HS cases during the footing penetration is found to be insignificant as shown in the abscissa of the VH plot in Figure 6(a). This particular observation would suggest that in the HS case, the increase in moment load, *M/B* during the vertical penetration of the footing is mostly driven by some variables of the vertical load component, which are typically unaccounted for in most vertical loading tests as pointed out earlier. This observation is further supported by Equation 6 where for small values of θ during the vertical penetration, the horizontal component h of the moment load *M/B* subsequently diminishes to zero, leaving the vertical and moment load components, v and m accounting for *M/B*.

Going back to Figure 8(a), it is observed that horizontal translation of the footing increases the moment loads further. However, this increase stops at some point where further horizontal translation only results to a decrease in moment loads. This behavior dictates that plastic moment failure has been reached at these points. The increase in moment loads during horizontal translation corresponded to a decrease in vertical load as observed in the VM plot of the same figure. Since horizontal loads subsequently increase with horizontal displacement (Figure 6(a)), it can be said that the moment loads experienced in the RP is generated simultaneously with horizontal loads. In fact, the generated moment during the horizontal translation is seen to increase linearly with the horizontal load as shown in Figure 9. In this figure, the normalized horizontal and moment loads are plotted with the RP rotation during the horizontal swipe HS. Recalling Equation 6, the calculated moment load at the RP becomes a strong function of the h component even for small amounts of footing rotation which were found to be at around 0.2° (0.0035rad) during the horizontal swipes (Figure 9).

Further comparing Figure 6(a) and Figure 8(a) would tell that all horizontal failure occurred after $0.08 \cdot B$ horizontal displacement while most moment failure have already occurred before this displacement has been reached. This would suggest that for horizontally loaded foundation, moment failure would ensue first before horizontal failure can be reached. This is further exemplified in Figure 9 wherein the horizontal load increases slightly further after the points of retraction of the moment loads, where it eventually goes down with continued decrease in *M/B*. It can then be deduced from these observations that moment failure would govern in the analysis of horizontally loaded foundation.

In Figure 8(b), the moment loads are seen to increase before the footing was set to w_o. When footing rotation was continued further, the moment loads consequently plummeted, signaling the occurrence of plastic footing failure. Considering the VM load paths of the MS cases, it is

seen that moment loads also increase during vertical penetration before swiping, the possible mechanism of which was already explained earlier. This increase in moment is seen linear with the increase in vertical load. The trajectory of the VM load paths changes however once the footing experience rotation. The increase of the VM load path is seen to be stiffer until it reaches moment failure. Upon failure, both moment and vertical loads considerably decrease.

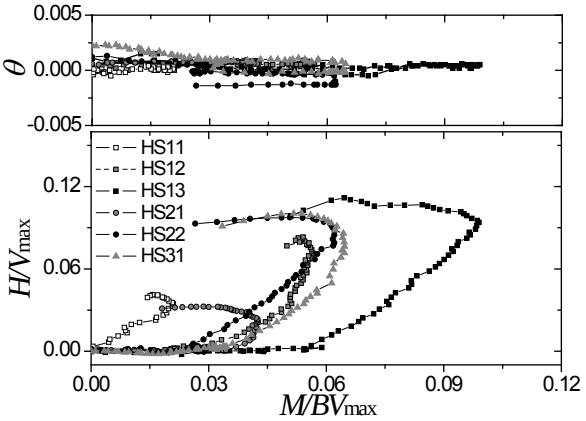

Figure 9 Normalized horizontal and moment loads with rotation of the RP in HS.

In Figure 7, the increase of moment is seen to be linear with the horizontal loads generated during rotation. When failure occurs at maximum rotation, the moment decreases abruptly. Upon closer inspection, it can be observed by comparing the θH in Figure 6(b) and θM in Figure 8(b) that horizontal failures mostly occurred at greater footing rotation for each swipe case. This implies that moment failure occurs first before the footing fails in the horizontal direction during rotation.

In previous studies, the failure defined by VM load paths was mathematically constructed using a parabola. The expression of this particular parabola is given in general form by Equation 9 as,

$$\left(\frac{M}{BV_{\max}}\right) = a_m \frac{V}{V_{\max}}\left(1-\frac{V}{V_{\max}}\right)^{b_m} \qquad (9)$$

where a_m and b_m play the same functions as a_h and b_h given out in Equation 8. The values of a_m for several studies are in the range of 0.35-0.36 (*e.g.* Butterfield and Gottardi (1994) and Gottardi et al. (1999) on rectangular footings on dense sand, and Dean et al. (1992) and Gottardi and Butterfield (1993) on circular footings on dense sand). For comparison, the parabola suggested by Butterfield and Gottardi (1994) with a_m=0.35, was imposed to the VM plots of present set of data in Figure 8. It is found that this particular parabola contains most of the VM load paths of the test cases; however, it provides a conservative approximate to most paths, which can be accounted for by the difference in model footing geometries and loading conditions used in the earlier study.

3.3 Failure mechanisms

Ground behavior was observed in-flight using a digital-camera set up shown in Figure 1(a). Images were captured every 100 secs, which provided the time-lapse for a single analysis in the GeoPIV. Thus, a single analysis only provides the total displacement vector between consecutive images (image *n* and image *n+1*), discriminating potential and actual deformation of earlier analysis observed in earlier images (<image *n*). This was made so in order to more accurately and conveniently superimpose the analysis over the time scale of the loading events thereby giving directly the "current" condition of the soil flow to a particular point in the load plots for a given time frame.

For instance, Figure 10(a) shows the soil flow condition when $V<0.3\cdot V_{max}$ taken from the MS21 case. Conversely, Figure 10(b) reveals the collapse mechanism of the ground after the vertical capacity V_{max} was reached (from VURb case).

In Figure 10(a), the vector values of the soil displacements are defined. It can be observed from the said plot that the region of soil underneath the footing being held in static equilibrium by the vertical load with vector displacements of more than 0.30mm (about 0.75%·*B*) propagates to a maximum span of about 1.0·*B* from the center of the footing, extending to a depth of approximately 1.0·*B* immediately below the RP. The soil flow is generally downward and concentrically in the direction of vertical loading. Eventually, at failure, a ruptured zone develops at both sides of the footing, taking the form of a spitting curved wedge as shown in Figure 10(b). Plastic heaving can be also observed implying that a plastic region was smoothly sheared-off with continued loading. This plastic region can reach to a maximum depth of 2.0·*B* relative to original free surface defined in the figure by the original position of the footing.

Contour plots of the VHM for HS and MS, with VH and VM as corresponding principal axes, are provided in

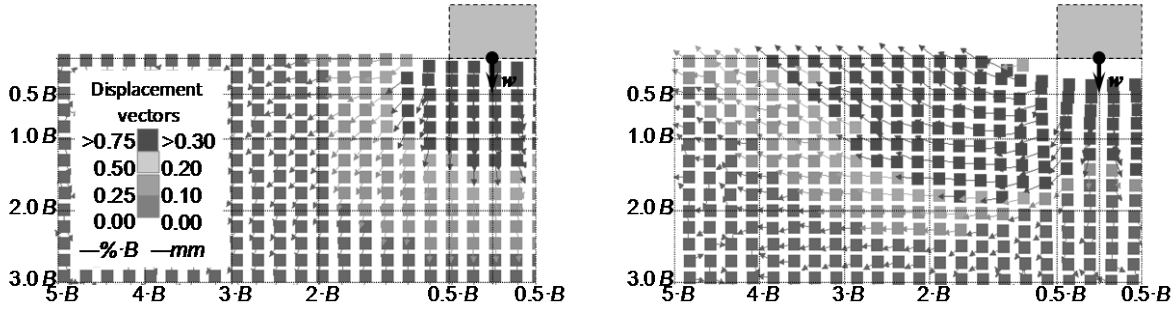

Figure 10 Soil deformation during vertical loading in (a) MS21 for $V<0.3\cdot V_{max}$, before swiping, (b)VURb after vertical failure, V_{max}.

Figures 11(a) and 12(a) respectively. Various points in these load spaces were defined showing specific soil flow conditions, primarily to characterize deformation patterns pre- and post-failure.

Soil deformation before failure in HS is exemplified by points in the HS21 and HS22 swipes in Figures 11(b) and (c).

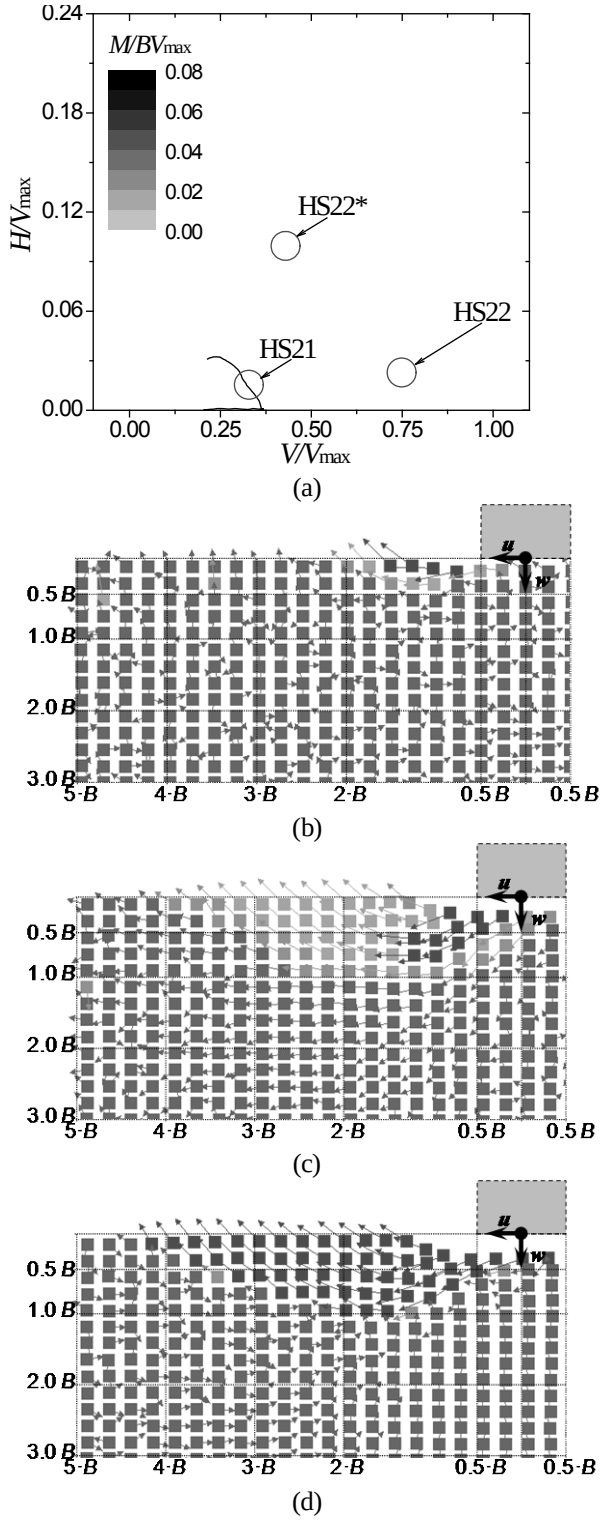

Figure 11 (a) VHM contour plot of HS cases inside parabola a_h=0.45, (b) soil deformation before failure in HS21, (c) soil deformation before failure in HS22, (d) soil deformation after failure in HS22*.

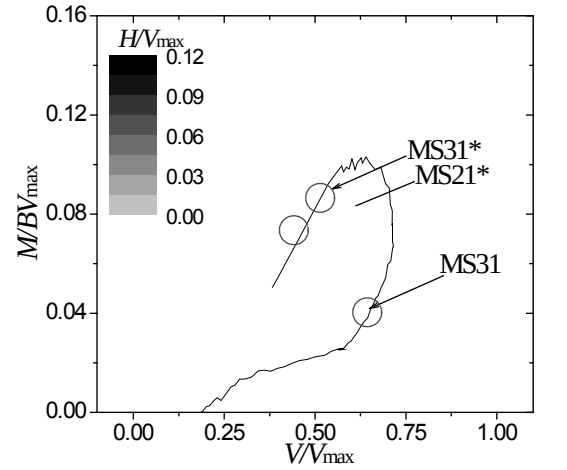
It can be observed that a curved-wedge mass of soil emanating directly below the footing was translated in the direction of the swipe. However, the volume of this translated mass largely depends on the vertical penetration before swipe w_o found to be $0.05 \cdot B$ and $0.2 \cdot B$ for HS21 and HS22 respectively (Figure 4(b)).

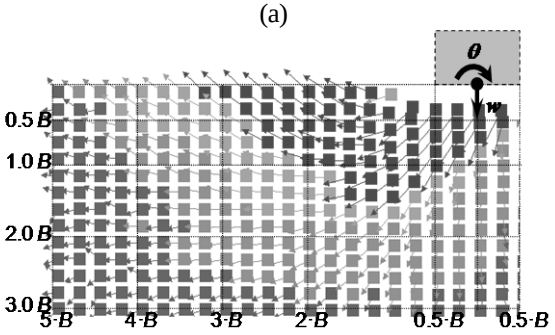
A typical failure mechanism for horizontally loaded foundation is shown in Figure 11(d), taken from HS22*. It is seen that the progression of the curved-wedge mass early on in the swipe eventually demarcated the ruptured surface during failure. This ruptured surface has a span of $4 \cdot B$ from the center of the footing, and a maximum depth of $1.0 \cdot B$ relative to free surface wherein further loading will only smoothly translate the mass to the direction of the heave.

Figure 12 shows the ground behavior of rotationally loaded footing. Before failure, the ground is seen to be mobilized by the resulting rotation (Figure 12(b)), wherein a scooping mechanism is exhibited with vector displacements of $0.75\% \cdot B$ expanding until a depth of $1.5 \cdot B$ relative to free surface. However, at failure, the ruptured surface (Figures 12(c) and (d)), takes the shape of a curved-wedge, similar to the horizontally-loaded ruptured surface in Figure 11(d). Similarly, the depth of this wedge is about $1.0 \cdot B$, spanning a distance of $4.0 \cdot B$ from the center of the footing. This observation would suggest that at plastic failure, the ruptured surface of horizontally and rotationally loaded grounds exhibit an almost similar geometry.



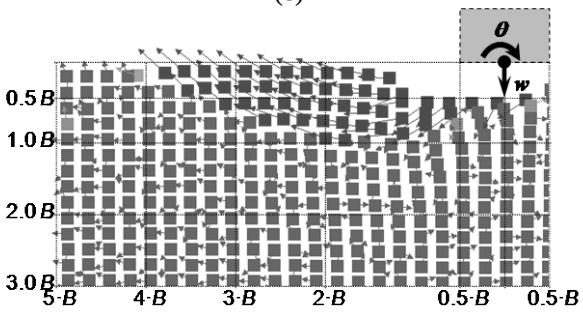
4. CONCLUSIONS

The present study was able to fulfill three major targets: (1) define several independent load paths progressing to failure, (2) define a failure mechanism for the soil-footing system, and (3) superimpose the failure mechanism at different stages of the loading events.



In particular, the study was able to provide evidence of appreciable amounts of horizontal and moment loads which are otherwise ignored in most vertical loading tests. These lateral reactions can be accounted for by the variable effect of soil deformation during the progression of footing penetration, where the ground does not only become stiffer but also changes its deformation geometry in order to fully confine the loads imposed on it by the foundation. This observation imply the substantial effect of footing embedment during vertical penetration beyond $15\% \cdot B$ where at vertical capacity, moment loads in the range of 0.045 to 0.070 of V_{max} and horizontal loads in the range of $\pm 0.030 V_{max}$ were recorded.

It is also found that most horizontal failure occurs at greater plastic displacements compared to moment failure both in the horizontally and rotationally loaded grounds. In particular, maximum moment loads were reached before the horizontal displacement of $0.08 \cdot B$, while horizontal failure occurred at $u > 0.08 \cdot B$. Conversely, the points of maximum moment in the rotation swipe did not correspond to points of maximum horizontal loads. On the contrary, horizontal loads were observed to increase further after a clear moment failure has already been reached. These observations would conclude that moment failure occurs first before the footing fails in the horizontal direction during horizontal and rotational loadings.



Patters of soil movement before failure seem to vary accordingly with the direction of loading, or the current state of loads. The region of soil underneath the footing being held in static equilibrium by the loads acting on the footing largely depends on the amount of initial vertical penetration w_o. However, at full plastic failure, the ruptured surfaces of horizontally and rotationally loaded grounds exhibit an almost similar size and geometry.

Abstract: Collapse or severe damage of structures supported on pile foundations have been observed after many severe earthquakes, especially where the soil conditions consisted of soft deposits characterised by poor mechanical properties (i.e. low values of strength and shear modulus or soil susceptible to liquefaction). The formation of the plastic hinges in the piles at various locations suggest that the bending moments and/or shear forces experienced by them would have exceeded the bending and/or shear capacity of the section. However, many case histories have shown collapses albeit a high margin of safety being effectively applied during design with regard to the classical mechanism of failures, such as the bending and the shear mechanisms. This may suggest that the actual mechanism of failure has not been properly considered. Recently, the buckling instability of piles in liquefiable soils is recognised as a possible failure mechanism. Although the current codes of practice do not explicitly mention this particular issue, the presence of large axial loads may have important consequences, particularly where piles are founded in liquefiable or very soft soils. In such conditions, the axial and lateral loads (from inertia or spreading soil) may also lead to a reduction of the buckling capacity due to the second order non-linear effects, and the piles may fail due to buckling instability. In this paper the role played by the axial loads and its influence on the bending behaviour of piles are investigated.

1. INTRODUCTION

Pile foundations are slender structural elements inserted deep into the ground to support heavily loaded structures such as: bridges, buildings, jetties or oil platforms. Typically, this type of foundations is used when ground is insufficiently strong to support the structure on its own. Often, this condition occurs in seismic-prone zones with loose or medium dense sandy soil. In a saturated condition, these soils are prone to liquefy during medium to strong earthquakes, and undergo significant reduction of their strength and stiffness.

Unfortunately, piles supported structures still collapse and/or show severe damages (see Figure 1 for a case history of bridge collapse in a very recent earthquake), after strong earthquakes, particularly in liquefiable soils. This is despite the fact that large factors of safety are employed in the design. Further discussion in this paper will concentrate on the pile performance in liquefiable soils.

The current understanding of pile failure in liquefiable soils identifies four feasible mechanisms of failure, such as: (a) excessive settlement, (b) bending, (c) shear and (d) buckling. Also combination and the interaction between the above mechanisms can cause failure as well.

Excessive settlements occur when the side friction and the bearing capacity of the pile reduces due to the loss of strength and stiffness of the soil caused by liquefaction. In fact, if the residual bearing capacity is insufficient to carry the vertical load, the foundation may undergo excessive settlement and eventually fail to meet the serviceability criteria. This type of pile failure may not involve any structural damage.

The bending mechanism due to liquefaction induced lateral spreading of the ground is often regarded as the principal cause of pile failure (Hamada 1992, Ishihara 1997, Tokimatsu *et al.* 1998, Goh and O'Rourke 1999, Abdoun and Dobry 2002, Finn and Fujita, 2002).

When the shear capacity of the pile is low, for example for hollow sections, the lateral spreading may cause the pile to fail in shear.

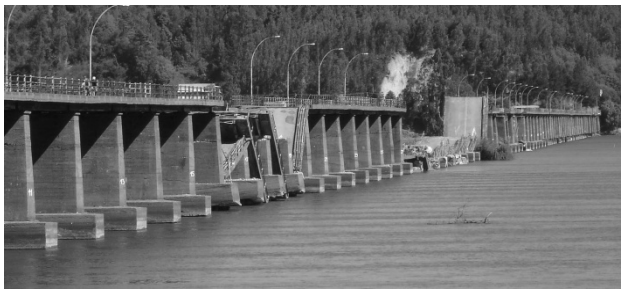

Figure 1. Bio-Bio Bridge damaged during the 2010 Chile earthquake (Courtesy of Daniella Escribano Leiva.).

In contrast to above three failure mechanisms, piles may also fail due to axial instability owing from higher the loss of lateral confinement in liquefied soil (Bhattacharya et al. 2004). This is supported by the fact that many failures of pile foundations in past earthquakes not only occurred in

laterally spreading grounds but also were observed in level grounds where no lateral spreading would be possible.

Buckling mechanism suggests that if the soil liquefies, the pile will lose significant amount of lateral stiffness offered by the surrounding soil and may behave like a long unsupported column with lower buckling capacity, and may buckle due to the presence of axial load from superstructure. While the bending and buckling mechanisms have been studied in detail separately, little has been reported on their interactions (see for example the work done by Dash *et al.* 2009, 2010). It is also important to note that the bending moment in the pile due to lateral loading (e.g., from flow of liquefied soil or inertia) may get amplified in presence of higher axial load. The aim of this paper is to illustrate the effect played by the axial load on the bending response of the pile.

2. CURRENT UNDERSTANDING OF PILE- SOIL INTERACTION

Among four recognised mechanisms of pile failure, two mechanisms generally govern the design of piles in liquefiable soils, which include: bending mechanism and buckling mechanism. The behaviour of pile for these mechanisms is described in detail in the following sections.

2.1 Pile failure based on bending mechanism

In the bending mechanism, piles are considered as beams. The lateral loads on the piles are due to inertial effects from the superstructure and kinematic effects due to ground movement. The pile-soil interaction can be described considering three different phases (Tokimatsu *et al.* 1998), as illustrated in Figure 2.

Phase 1. Prior to the development of pore water pressure, the inertia force from the superstructure may dominate.

Phase 2. Kinematic forces from liquefied soil start acting with increasing pore pressure.

Phase 3. Towards the end of shaking, kinematic forces would dominate and have a significant effect on the pile performance particularly when permanent displacement occurs in laterally spreading soil.

Combination of different phases of loading:

In sloping grounds, the liquefied soil will start to move horizontally, which constrain the pile to deform in the same direction of the slope. It may be assumed that seismic motion has already passed the peak but the shaking may still be persistent with lesser intensity and therefore the inertia force transmitted from the superstructure will be small. Under such loading condition, the maximum bending moment induced by the pile may not occur near the pile head but at a certain depth. Ishihara (1997) noted that during the earthquake, the liquefaction of the soil starts approximately at the time of occurrence of peak ground acceleration. He argues that since the seismic motion has already passed its peak, subsequent shaking will be less intense, so that the lateral inertia force applied by the superstructure will not be significant. Therefore, the effects of inertia of the superstructure on the pile response are considered separately and are not combined with the lateral spreading effects. Hamada (2000) mentioned that permanent displacement of non-liquefied soil overlying the liquefied soil is a governing factor for pile damage. A similar conclusion has also been stated by Berrill *et al.* (2001). Further to this, Tokimatsu et al. (2005) and Tokimatsu and Suzuki (2005) carried out large scale shaking table tests of pile groups in dry and saturated sands and suggested the required conditions and methodology to combine inertial and kinematic loads for piles subjected to seismic loads as follows.

When natural period of structure (T_b) > natural period of ground (T_g):

$$M_p = \sqrt{M_i^2 + M_k^2} \quad (1)$$

When natural period of structure (T_b) < natural period of ground (T_g):

$$M_p = M_i + M_k \quad (2)$$

where, M_p, M_i and M_k are the maximum bending moment, bending moment due to the inertia of the superstructure and bending moment induced by the kinematic interplay (i.e. lateral spreading) respectively.

However, in the literature, it is not clear if the effects due to the inertia and lateral spreading should be analyzed separately or to combine them in order to obtain the maximum bending moment for a field condition.

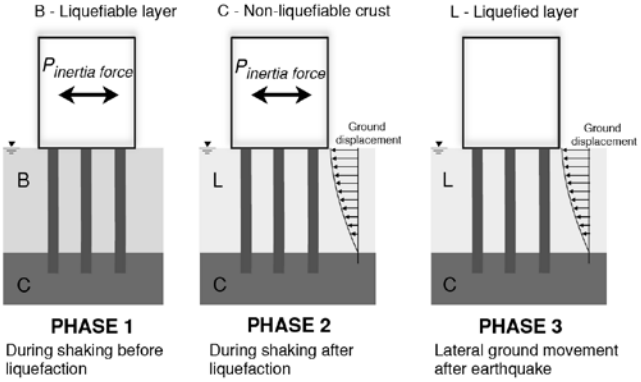

Figure 2. Schematic showing different phases of pile loading based on bending mechanism of pile failure.

2.2 Pile failure based on buckling mechanism

Based on the back-analysis of 14 cases of pile foundation performance and a series of centrifuge tests, Bhattacharya et al. (2004) suggested that the buckling instability may be considered as potential mechanism of pile collapse. As shown in Figure 3, the pile-soil interaction and different phases of loading on pile may be represented by four different stages.

Stage1: Before the earthquake the pile transfers the axial load from superstructure to the supporting soil by 1) shear generated along the surface of the pile due to the soil-pile friction, and 2) point resistance due to the end bearing at the bottom of the pile.

Stage 2: Before the liquefaction the confining pressure around the pile is not expected to decrease substantially. The pile is predominantly loaded by inertia forces generated from the oscillation of the superstructure.

Stage 3: As the shaking continues, in loose to medium dense saturated soils, excess pore pressure develops, and the soil starts to liquefy. With the onset of liquefaction the pile may lose its shaft resistance particularly in the liquefied layer and shed axial loads downwards to mobilize additional base resistance. If the base capacity is exceeded than the axial load demand, settlement failure may occur. If the pile is sufficiently stable at base, it may experience a high slenderness ratio and will be prone to buckling instability.

Stage 4: In sloping ground the pile may also be subjected to additional drag force due to lateral spreading of soil as explained in the previous section, along with the axial load.

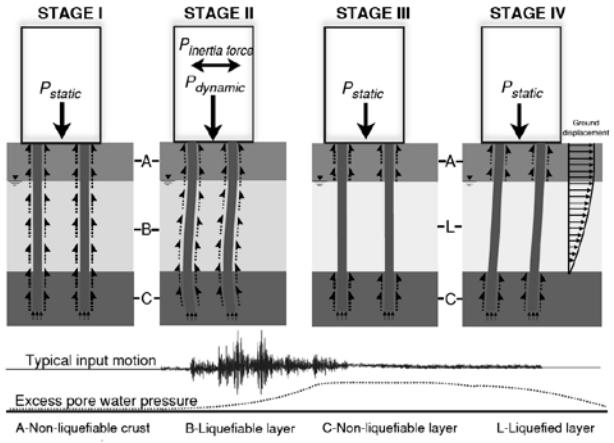

Figure 3. Schematic showing different phases of pile loading based on buckling mechanism of pile failure.

3. EFFECT OF AXIAL LOAD ON BENDING RESPONSE OF THE PILE

In field condition, piles are subjected to both axial and lateral loads during earthquakes, and they should be considered as beam-column elements. During liquefaction the buckling load capacity (P_{cr}) of the pile decreases. Considering the static load of the pile (P) as a constant value throughout, if P_{cr} reaches close to P, the structure can suffer excessive bending due to even a very small amount of lateral loading or imperfection. On the other hand, the lateral deflection or bending moment in pile due to lateral loading is expected to increase with decreasing P_{cr}, (i.e., increasing P/P_{cr} ratio).

The interaction between the axial and lateral load is generally referred to as *P-delta* effect. Stability analysis of elastic column (Timoshenko and Gere, 1961) shows that the lateral deflection (y_0) due to lateral loads is amplified in the presence of axial load (P) producing a final deflection of pile (y) as given in equation (3), which is also plotted in Figure 4.

$$\frac{y}{y_0} = \frac{1}{1-\frac{P}{P_{cr}}} \tag{3}$$

The ratio y/y_0, commonly known as "Buckling Amplification Factor" (BAF), is a function of the critical buckling load, which depends on the boundary conditions of the pile.

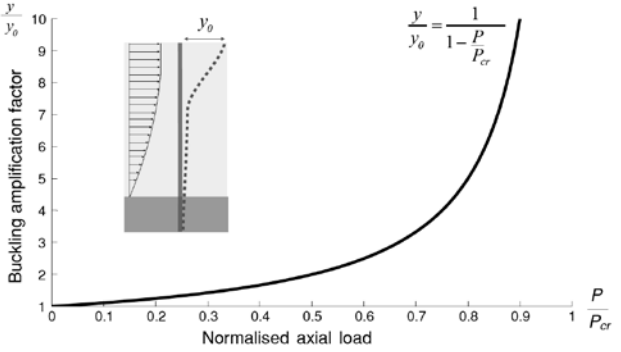

Figure 4. Buckling amplification factor for different ratios of P/P_{cr}.

For piles subjected to lateral spreading the value of y_0, due to the lateral load only, may be assed considering two different methods, namely force and displacement based method. These two approaches are illustrated in more details in the next section, where the effect of axial load is incorporated.

3.1 Numerical model

The inclusion of axial load in bending analysis can be easily implemented in a numerical model, where the lateral and axial loads are considered together. The numerical model for lateral loading of the soil on pile is generally carried out in two different ways such as:

1. force based method
2. displacement based method

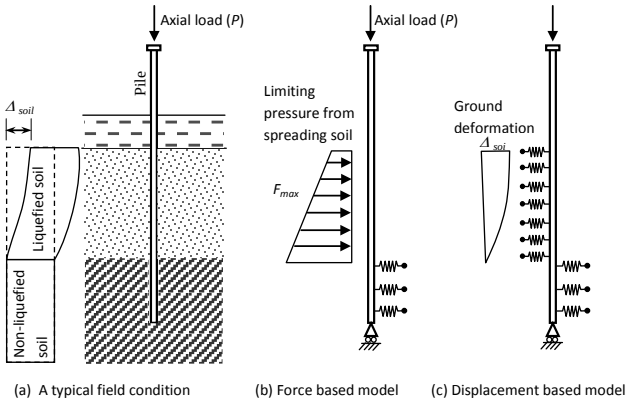

Figure 5. Force and displacement based models of pile-soil interaction in liquefiable soil.

Figure 5 shows these two methods of representing a field condition. In force based method, the force from liquefied soil flow is represented by a limiting pressure (F_{max}) on pile. (see Figure 5b). Figure 5c illustrates displacement based method, where the lateral spreading is modelled by applying

a displacement at the free ends of the soil springs. Typical results of pile response from these two methods with axial load are described in the next section.

3.2 Typical results

Figures 6 shows the effect of the axial load on the bending response of a pile foundation, in terms of normalised pile displacement *y/D* (where *y* is the lateral displacement evaluated considering the effect of axial load) against either Δ_{soil}/D or F/F_{max} depending on the method of analysis (i.e., force based method or displacement based method). Clearly, Figures 6 and 7 show that when the axial load is higher with respect to critical buckling load, the pile head deflection (*y*) and maximum bending moment in pile get larger.

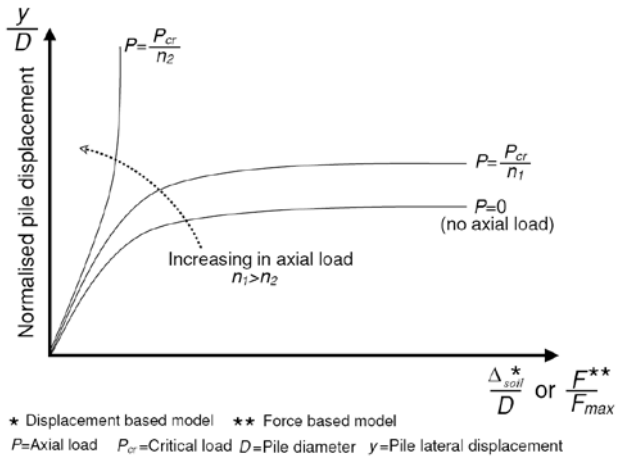

Figure 6. Pile head deflection response due to lateral and axial load.

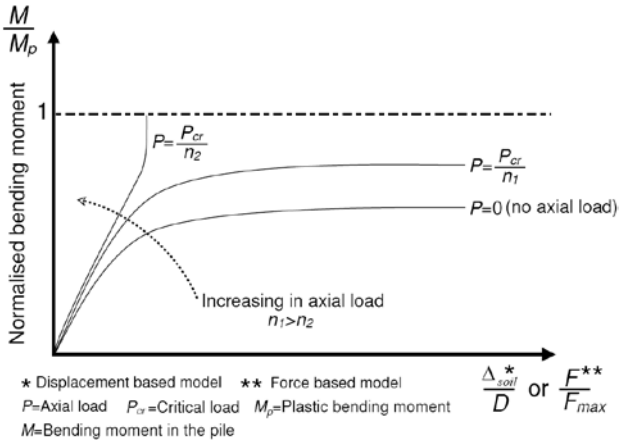

Figure 7. Pile bending moment response due to lateral and axial load.

During liquefaction, as the soil loses its stiffness, the elastic buckling load (P_{cr}) also reduces. Assuming a constant static axial load on pile, this also causes the P/P_{cr} ratio to increase. With the increasing P/P_{cr}, the pile head deflection and bending moment in pile also increase. When this ratio is close to 1, i.e., axial load is close to the buckling load, the bending moment amplification factor becomes very high, which leads the bending moment in pile to reach its plastic moment capacity, M_p, at a lower value of lateral load. The sudden rise in pile head deflection demonstrates the failure of the pile where bending moment reaches M_p and pile continues to deflect without any additional loading. A similar behaviour can also be observed when the axial loaded piles in level liquefied ground subjected to inertia loading.

4. DISCUSSUION ON CURRENT CODES OF PRACTICE

This section reviews the recommendations suggested by the main codes of practice.

- The *Japanese Road Association Guidelines* (JRA, 2002) suggests designing piles against bending failure considering both the inertia and kinematic force due to the lateral spreading. The action of the liquefied soil can be considered as a distribution equals to 30% of the total burden pressure. Figure 8 shows that, if there is also a non-liquefiable crust overlaying the liquefiable layer, its action can be accounted by a passive earth pressure distribution.

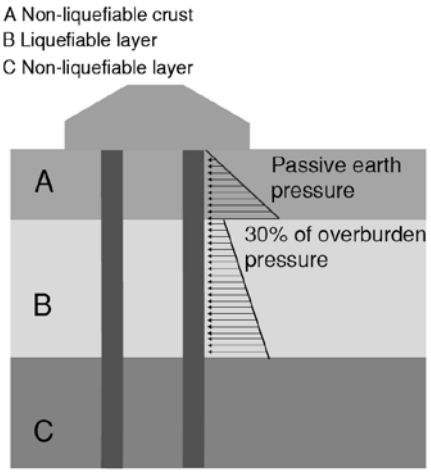

Figure 8. Idealisation of loading for seismic design of pile foundation subjected to lateral spreading as suggested by JRA (2002).

- *Eurocode 8 part 5* (1998) suggests to design considering the bending due to inertia and kinematic loads arising from the deformation of the surrounding soil recommending that piles should be designed to remain elastic. However they admit that the interfaces between layers having different properties should have the capacity to develop plastic hinge. For these calculations the lateral resistance offered by the soil layers susceptible to liquefaction should be ignored.
- Other codes, such as the American code *NEHRP* (2000) and Indian Code *IS-1893* (2000) also focus on the bending mechanism.

5. CONCLUSION

In summary, the current codes of practice treat the piles as beam elements and assumed that the lateral loads from structural inertia and/or soil movement cause bending failure of the piles. In contrast to current practice, present investigation shows that the need of incorporation of axial load can be vital in determining the response of piles in liquefiable soils, and ignoring it during design may be un-conservative.

Abstract: In order to examine the applicability of the three-dimensional finite element method for evaluating pile foundation behavior while soil shows strong nonlinearity, numerical simulations of two soil-pile-structure models subjected to strong shaking were performed. The tests were conducted using the large-scale shaking table at the E-Defense to investigate the response and failure of a nearly full-scale pile-structure system under multi-dimensional loading. It is shown that the numerical analysis can reproduce the behavior of the piles and superstructure as well as those of soil with a reasonable degree of accuracy, suggesting its applicability to soil-pile-structure system subjected to strong 3-D shaking.

1. INTRODUCTION

Most of Japanese metropolises lie on soft ground near seas and large rivers. For this reason, pile foundations are commonly applied for substructures, representing 70~80% of all buildings. Pile foundation is, however, weak in horizontal direction, thus soil and structures tend to be damaged by both inertial force from superstructures and kinematic force from ground displacement during earthquakes with large-scale horizontal shaking. Despite this fact, mechanism of these damages has not been fully understood, due to the lack of data since no observation has ever been made. Furthermore whether or not the three-dimensional nonlinear behavior of piles during earthquakes can be reproduced by numerical analysis has not been studied sufficiently.

In order to obtain sufficient data to establish a design method for pile foundation with failure of piles taken into account, a series of shaking table tests using soil-pile-structure models were performed (MEXT and NIED, 2006; Suzuki et al., 2008; Tokimatsu et al., 2008). The E-Defense shaking table platform and a cylindrical laminar shear box were used for the tests, and a full-scale pile-structure system was subjected to a series of single- or multi-dimensional loading. In cases where large scale loading was applied, subsidence and residual displacement of footing were observed, and data including pile damage process were obtained.

By performing numerical analysis of the abovementioned shaking table tests using three-dimensional finite element method, this paper verifies the validity of the evaluation method on three-dimensional nonlinear behavior of pile foundation structures during earthquakes.

2. SHAKING TABLE TESTS

The E-Defense shaking table platform has a dimension of 15 m length and 20 m width. Photo 1 and Figure 1 show the test model constructed in a cylindrical laminar box 6.5 m high with an inside diameter of 8.0 m. It consists of forty-one stacked ring frames, enabling two-dimensional shear deformation of the inside soil.

A 3x3 steel pile group was used for the tests. The piles were labeled A1 to C3 according to their locations within the

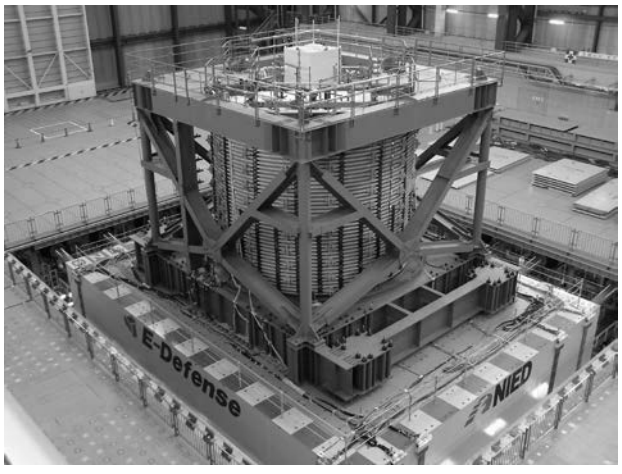

Photo 1 Test Model on Large Shaking Table

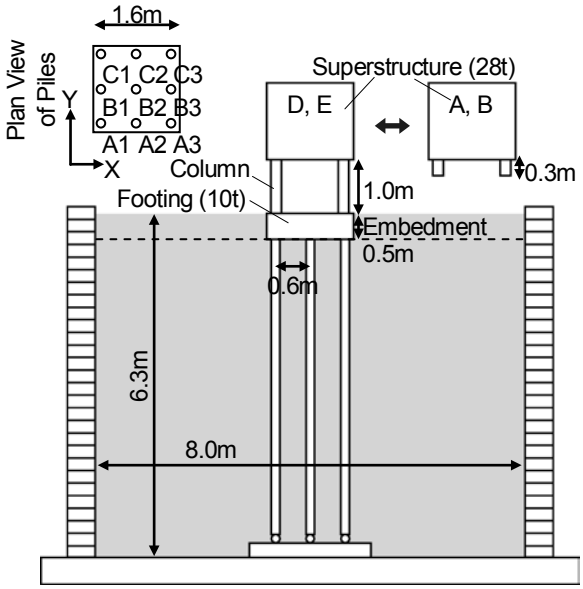

Figure 1 Soil-Pile-Structure Model

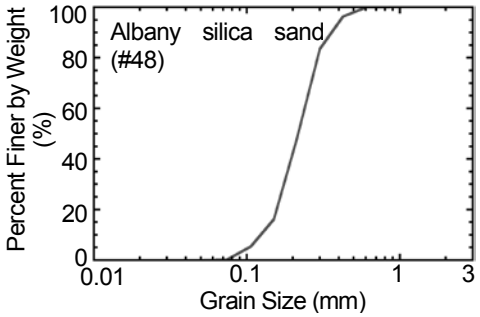

Figure 2 Grain Size Distribution of Albany Sand

pile group, as shown in Figure 1. Each pile had a diameter of 152.4 mm and a wall thickness of 2.0 mm. The piles were set up with a horizontal space of four-pile diameters center to center. Their tips were jointed to the laminar box base with pins and their heads were fixed to the footing of a weight of 10 tons.

Dry Albany sand from Australia was used for preparing the sand deposit. Figure 2 shows the grain size distribution of the sand. The sand had a mean grain size D_{50} of 0.31 mm and a coefficient of uniformity U_c of 2.0. After setting a pile group in the laminar box, the dry sand was air-pluviated and compacted at every 0.275m to a relative density of about 70% to form a uniform sand deposit with a thickness of 6.3m.

As listed in Table 1, a total of five test series named A to E was conducted in alphabetical order, in which the presence of foundation embedment and superstructure, and the natural period of superstructure, as well as the type of input motions, and their component and maximum accelerations were varied.

Table 2 shows the list of shaking conditions of test series. In order to clarify the effect of natural period of superstructure on dynamic behavior of the test model, the tests were conducted under one-, two- or three-dimensional shaking with three types of ground motions, which dominate in different period ranges, with maximum horizontal

Table 1 Test Model Series

	Embedment	Superstructure	Natural period (s)
A	Yes	Yes	0.1
B	Yes	Yes	0.6
C	Yes	No	-
D	Yes	Yes	0.2
E	No	Yes	0.2

Table 2 Shaking Conditions of Test Series

	Maximum input acceleration (m/s^2)			
	JR Takatori		Taft, Tottori	
	XYZ	XY, X, Y	XYZ	XY, X, Y

B	0.3, 0.8			
C	0.3, <u>0.8</u>			
D	0.3, <u>0.8</u>		0.3, 0.8	
E	0.3, <u>0.8</u> 6.0, 8.0	0.3, 0.8	-	

accelerations adjusted to 0.3 m/s^2 and 0.8 m/s^2. Pile strains were within elastic range in all the test series. In addition, in order to investigate the pile destruction process induced by ground motion, additional tests were conducted for series E, under three-dimensional shaking with maximum accelerations at equivalent levels in actual earthquakes. JR Takatori wave was used, with maximum horizontal accelerations at 6.0 m/s^2 and 8.0 m/s^2.

Among the cases conducted with three-dimensional JR Takatori wave, this paper focuses on the ones in test series A, C, D and E with maximum acceleration adjusted to 0.8 m/s^2 (as underlined in Table 2), and reports the results of numerical analysis. None of the piles failed in any of the focused test cases.

3. ANALYTICAL MODEL

Numerical analyses were conducted with a three-dimensional FEM model using analysis code EENA3D developed by TEPCO (Yoshida et al., 2006; Yoshida et al., 2008). Figures 3 and 4 illustrate the analytical model.

The laminar shear box is modeled as solid elements with equivalent mass and adequately small stiffness. The degree of freedom is restrained, so that each ring frame of the shear box may maintain its plane during shear deformation. To take the effect of rocking behavior of the shaking table into account, vertical springs are placed at eight points at the bottom of the box. All analysis cases share the same spring constant.

Figure 4 describes details of piles and footing. Areas of the piles are set as void, and piles are connected to the soil

Internal friction φ (°)	29.5

* σ_v' : Effective overburden pressure (kN/m^2)

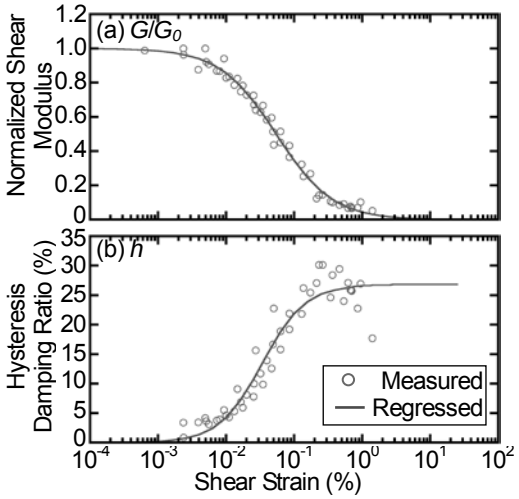

Figure 5 Dynamic Strain Dependency of Soil

with rigid beam elements, maintaining pile sections. Additionally, in order to simulate friction between the piles and the soil, joint elements are inserted between the piles and the soil. Pile head rigidity in the analysis model is 0.86.

Columns are modeled as beam elements. The rigidity of both column ends is set according to footing-superstructure transfer function obtained from the tests.

Specifications and dynamic strain dependency of the soil are explained in Table 3 and Figure 5, respectively. Velocities of P and S waves, V_P and V_S, are obtained by performing regression analysis on the results of PS logging depending on overburden pressure σ'_z. Poisson's ratio ν is calculated from V_P and V_S. As explained in Figure 6, in order not to include engineering judgments in parameter setting, discrete data of G/G_0-γ regression curve shown in Figure 5 are directly inputted to simulate soil's nonlinearity. τ-γ relation is obtained from inputted G/G_0-γdynamic strain dependency curve, also as discrete data. The discrete τ-γ relation is linearly interpolated to define skeleton curve. Cohesion c is set to zero. Internal friction angle φ is obtained from Equation 1;

$$\tau_{max} = \sigma_c \cdot \tan\varphi \tag{1}$$

where σ_c is the consolidation stress; and shear strength τ_{max} is defined by the maximum value of τ-γ skeleton curve. Obtained internal friction angle is used to define the strength of joint elements.

In addition, in this study, the nonlinear model of soil concerning its shear deformation component is defined by

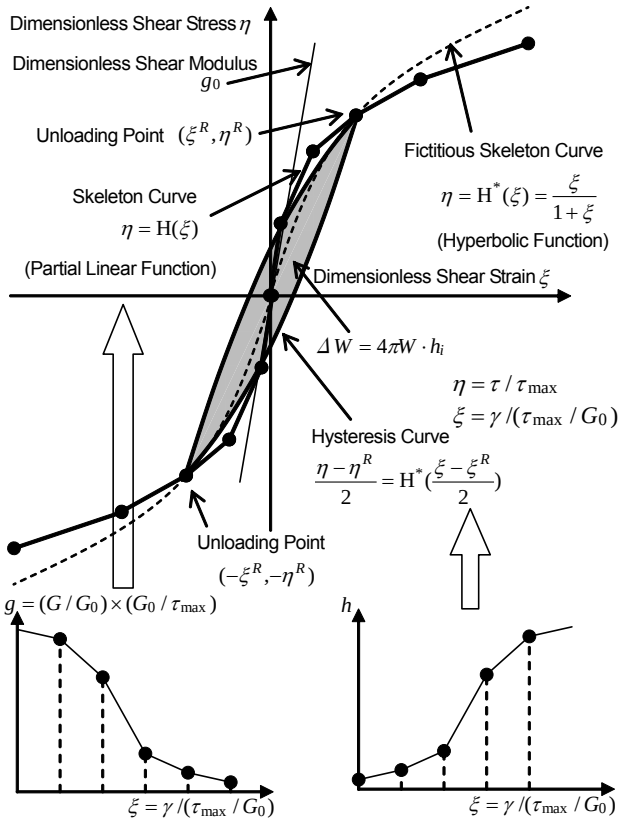

Figure 6 Modeling of Nonlinearity for Shear Strain

the second constant J_2 of deviatoric stress q, based on von Mises' failure criterion. Relation of equivalent stress $\sigma_e(=\sqrt{1/2 \times s_{ij} s_{ij}})$ and equivalent strain $e(=\sqrt{2 \times \varepsilon_{ij} \varepsilon_{ij}})$, which are expressed by root of deviatoric stress q and deviatoric strain ε_s respectively, is defined by stress-strain relation given by Equation 2.

$$\sigma_e = G \cdot e \tag{2}$$

Dynamic strain dependencies (G/G_0-γ, h-γ) are considered in Equation 2. However, since both the equivalent stress σ_e and the equivalent strain e take only positive values, it is impossible to identify whether it is pulsating or alternating. In order to draw hysteresis curve, the radius of yield surface in π plane is given as deviatoric strain e (Yoshida et al., 1993).

Input motion, as shown in Figure 7, is calculated by averaging each component of eight observed records obtained at the bottom of the shear box and the soil. All three components of the input motion are applied simultaneously to the bottom center of the box.

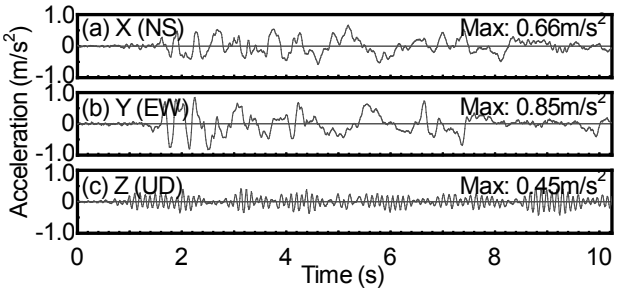

Figure 7 Input Motion (Case E)

4. NUMERICAL ANALYSIS RESULTS

Figures 8-11 show the observed and estimated time histories of accelerations of superstructure, footing and ground surface, as well as time histories of strain of corner pile A1 at pile head (-0.1m) and underground (-1.1m), in all cases. Observed records, as shown in blue lines, show that the accelerations in Y direction tend to be 1.5-2 times larger than those in X direction in all cases.

In Case A, the horizontal acceleration increases in the order of ground surface, footing and superstructure (Figures 8(a)-(c), (f)-(h)). In Case C, which has no superstructure, horizontal accelerations of ground surface and footing have no significant sign of amplification (Figure 9(b)-(c), (g)-(h)). In Cases D and E, the horizontal acceleration increases in the order of footing, ground surface and superstructure. Additionally, the horizontal acceleration of superstructure is larger in Case D, which has embedment in footing portion, rather than in case E, which has no embedment (Figures 10, 11(a)-(c), (f)-(h)). On the other hand, vertical accelerations do not show such a trend of amplification similar to horizontal ones, in any case (Figures 8-11(k)-(m)). Estimated results tend to underestimate slightly the accelerations in Y direction, and underestimate the accelerations in Z direction; however, the overall results are in fairly good agreement with the observed ones.

The bending and axial strains of the piles tend to increase along with the accelerations of upper structures, which suggests that the inertial force has a dominant effect on deforming of piles, and that the axial strains of piles are mainly caused by overturning moment coming from the inertial force (Figures 8-11(d), (e), (i), (j), (n), (o)). In Case C, the inertial force is small and the pile strains are significantly smaller than any other cases (Figure 9(d), (e), (i), (j), (n), (o)). In Cases A and E, bending strains tend to be in opposite phase at pile head and underground (Figures 8, 11(d), (e), (i), (j)), while in Case D, bending strains tend to be in the same phase at pile head and underground (Figure 10(d), (e), (i), (j)). The estimated results from the analyses tend to underestimate the bending strains in Y direction in Case A in comparison with the other cases (Figure 9(i), (j)), and tend to estimate the bending strains at pile head in Case D in the opposite signal (Figure 10(d), (i)); however, the results can reproduce the overall tendencies observed in the tests with a reasonable degree of accuracy.

To discuss the reason of underestimating the vertical accelerations, Figure 12 shows the Fourier amplitudes, calculated from the average of the records obtained at the bottom of the laminar box (Figure 9(a)) and the bottom of the soil (Figure 9(b)), in all cases. The peak value of the Fourier amplitude is significantly larger in soil, which suggests that the vertical input motion level was higher near the center of the test model. This is probably due to elastic deformation of the bottom plate of the laminar box which was caused by the vertical input motion, and such deformation had a considerable effect on the vertical response of the test model, affecting the accuracy of the analyses.

Figures 13-16 show bending strain distributions of three piles, A1, B2 and C3, at the instances when the bending strain takes its peak value at the pile head (cases A, C and E) or underground (case D) in each case. At these instances in all four cases, pile A1 is the leading pile (Figures 13-16(c)) and pile C3 is the trailing pile (Figures 13-16(a)). In Case C, observed bending strain level is low compared to other cases, due to the small inertial force, and has only one peak at pile heads (Figure 14); while in Cases A, D and E, observed bending strain level is high due to the large inertial force, and has a peak underground as well as at pile heads (Figures 13, 15, 16). Case D, compared to Case A, has a taller superstructure, and the rocking mode of the footing is more dominant, so the strain distributions have the same signal at pile heads and underground (Figure 15). Case E, compared to Case D, has no embedment at the footing portion, and the sway mode of the footing is more dominant, so similar to Case A, the strain distributions have opposite signals at pile heads and underground (Figures 13, 16). Additionally, the difference of bending strains between the three piles caused by group pile effect is hardly seen in Case C (Figure 14), while such a difference is significant in Cases A, D and E, where the peak value of bending strain is larger and the depth of inflection point is shallower in the leading

pile than in the trailing pile (Figures 13, 15, 16). Estimated results are in fairly good agreement with observed ones, able to reproduce the difference in bending strains caused by both the difference of model condition and the group pile effect. The analysis has a slightly lower level of accuracy in Case D than other cases, which suggests that the shear mode of pile deforming might have been overestimated in the analyses (Figure 15 (b), (c)).

Overall, it can be confirmed that the estimated results from all cases are able to reproduce the three-dimensional nonlinear behavior of the test models, regardless of the presence and the natural period of the superstructure or the presence of the embedment of the footing.

5. CONCLUSIONS

In order to confirm the applicability of the three-dimensional finite element method for evaluating pile foundation behavior during earthquakes, numerical simulations of four soil-pile-structure models subjected to strong shaking were performed. The tests were conducted using the large-scale shaking table at the E-Defense. It has been shown that the numerical analysis can reproduce the three-dimensional nonlinear behavior of the piles, superstructure and soil with a reasonable degree of accuracy regardless of model condition, as well as the difference in bending strains of piles caused by both the difference of model condition and the group pile effect.

Abstract: The response of coupled soil-pile-structure systems to seismic loading is studied in the frequency domain using two-dimensional (2D) finite element (FE). The soil-pile interaction in 3D is idealized in 2D type using soil-pile interaction springs with hysteretic load displacement relationships. The soil stratum is meshed with quad plane elements. The length of each element is adequately defined according to the anticipated wavelength propagating in the soil. Bilinear one dimensional beam elements with three degrees of freedom per node are used for modeling the pile and the column. Comparisons of the FE results with established results from the literature suggest that the current model can reasonably capture the essential features of soil, pile, and structural responses.

1. INTRODUCTION

Estimation of the seismic response of piles and piles supporting structures, in highly seismic areas such as Japan, has received large attention in recent years. The available procedures of seismic soil-pile-structure interaction (SSPSI) estimation include those based on simplified interactions models such as the beam on dynamic Winkler Foundation approach (Kagawa and Kraft 1980; Allotey and El Naggar 2008), as well as those based on more rigorous FEM (Cai et al. 1995; Rovithis et al. 2009) or BEM (Kattis et al. 1999; Padrón et al. 2007) formulations. These methods utilize either simplified two-step methods that uncouple the structure and foundation portions (Gazetas 1984; Fan et al. 1991) or a fully coupled SSPSI system in a single step (Kaynia and Mohzooni 1996; Rovithis et al. 2009). The coupled 3D FE approach is most representative of the SSPSI system. However, such this method, even if available, have well-known limitations when used in seismic design. Several investigators attempted to propose procedures to simplify the rigorous 3D FE models. For example, Ozutsumi et al. (2003) proposed a method to idealize soil-pile interaction in 3D into the 2D type using soil-pile interaction springs. While the conventional spring elements used in the analysis of soil-pile interactions are embedded in the same plane of the 2D FE analysis domain, the soil-pile interaction spring proposed by Ozutsumi et al. (2003) is a spring that connect free pile elements to 2D meshes of a soil profile with hysteretic load displacement relationships.

The objective of the current paper is to check the capabilities of the 2D FE model, proposed by Ozutsumi et al. (2003), to the analysis of coupled SSPSI in the frequency domain. A 2D effective stress FE analysis, FLIP (Iai et al. 1992), is employed to this end. Although validation of the model is confirmed in the time domain through comparison of the FE results with recorded centrifuge data (Hussien et al. 2010), verification of the model in the frequency domain is necessary. The verification process has been executed assuming elasto-dynamic behavior of the soil and comparing the free-field, pile head, and structure responses with those found using other established approaches.

2. PROBLEM DEFINITION

The SSPSI examined in this study comprises of an end-bearing single pile supporting a single degree of freedom structure founded on a homogeneous dry sand layer of thickness (L) over rigid rock as shown in figure 1.

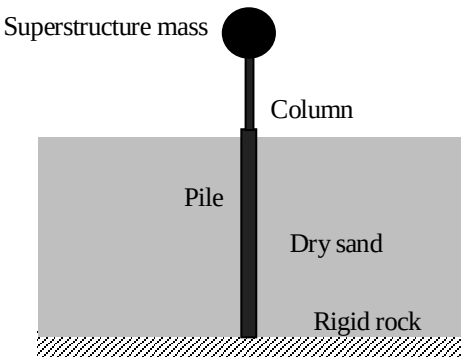

Figure 1 A schematic view of the system under investigation

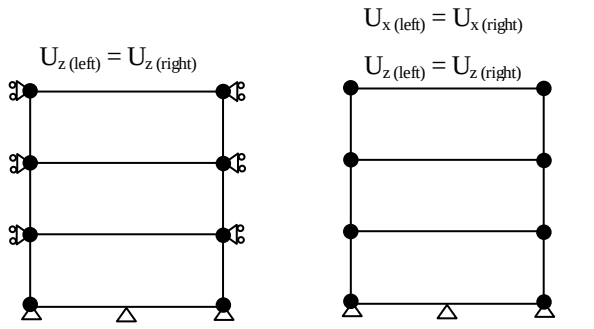
3. FINITE ELEMENTS AND PARAMETERS IDENTIFICATION

The soil stratum was meshed with quad plane elements. The length of each element was adequately defined according to the anticipated wavelength propagating in the soil. The maximum element size was less than one-fifth to one-eighth the shortest wavelength to ensure accuracy.

The thickness, shear wave velocity, Poisson's ratio, mass density, and hysteretic damping ratio of the dry sand layer are, respectively:

L = 30 m; V_s = 200 m/s; υ_s = 0.4; ρ_s = 1500 kg/m^3; β_s= 5%.

The pile column system was modeled with 20 one dimensional (1D) beam elements. Each node of the pile was connected to the soil mesh with soil-pile spring element. More details on the soil-pile spring could be found in Ozutsumi et al. (2003) . The pile tip is assumed to be pinned and has a circular cross-section of diameter D_p = 1.5 m, length L_p = 30 m (equal to the thickness of the soil stratum L), the pile slendrness ratio (L_p/D_p) = 20, Young's modulus E_p = 65 GPa , Piosson's ratio υ_p = 0.3, and mass density ρ_p = 2500 kg/m^3.



The structural mass (M) and height (H_{st}) were assumed to be equal to 100 Mg and 10 m, respectively and the ratio EI_{st}/EI_p = 0.06 , 0.66, and 1.85 leading to a fundamental frequency $f_{st,fixed}$ = 1.67, 5.0, and 8.4 Hz, respectively. The fixed-base frequency of the structure is equal to the first (f_1), second (f_2), and third (f_3) natural frequencies of the soil layer, respectively.

The wave parameter σ (Veletsos et al. 1974):

$$\sigma = \frac{V_s}{f_{st.fixed}.H_{st}} \qquad (1)$$

which is may be looked upon as a measure of the relative stiffness of the soil and the structure. When V_s and H_{st} are selected to be constants and equal to 200 m/s^2 and 10 m, respectively, σ is inversely proportional to $f_{st.fixed}$. $1/\sigma$ is equal to 0.083, 0.25, and 0.42 corresponding to $f_{st,fixed}$ = 1.67, 5.0, and 8.4 Hz, respectively.

The FE analyses were performed in two steps. In the first step (self-weight analysis), the *in situ* stresses were initialized in the soil due to the own weight of the soil. Properties of pile, pile-soil interaction spring, and structure were set to be zero during this stage of analysis. During the second stage of analysis (seismic response analysis), the actual properties of soil, pile, pile-soil spring, and structure were assigned. Two different boundary conditions were assigned to the model in the two stages of analysis. For the first stage, all nodes on the lateral boundaries are restrained from moving in horizontal direction while vertical displacements of the nodes having the same height were assigned same displacement as shown in Fig. 2(a). For the second stage, not only vertical displacements of nodes having the same height were set to be equal but horizontal displacements were set also as shown in Fig. 2(b) to prevent spurious wave reflections at the boundaries.

(a) Self-weight analysis (b) Seismic response analysis

Figure 2 Boundary condition of the problem model

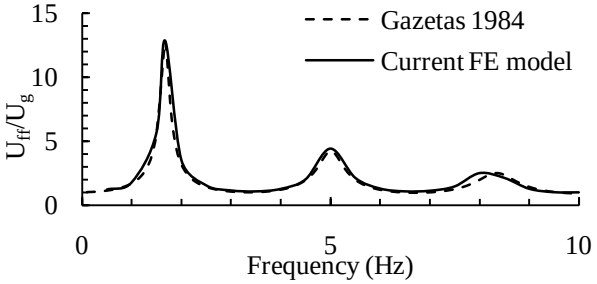


Figure 3 Verification of the free-field amplification

The input motion is specified at bedrock level in the form of a harmonic horizontal displacement $U_g(t) = U_g.\exp(i2\pi ft)$, where U_g = amplitude of the input bedrock displacement; f = frequency of excitation; $i^2 = -1$.

4. FREE FIELD MOTION

Elastic response time histories for free-field are derived at different frequencies of excitations. From these time histories, the amplitude of steady-state response is noted and normalized with respect to the amplitude of input bedrock motion. In figure 3, amplification of the soil stratum obtained using the present 2D FE method is compared with that obtained using a simple 1D free-field analysis (in the frequency domain, Gazetas 1984) at different frequencies of excitation. Amplification for 1D analysis is given by:

$$\frac{U_{ff}}{U_g} = \frac{1}{\cos(qL)} \quad \text{where} \quad q = \frac{2\pi f}{V_s\sqrt{(1+2i\beta_s)}} \qquad (2)$$

where U_{ff} = amplitude of free-field ground displacement. The comparison shows that there is an excellent agreement between the current FE method and free-field analysis conducted by Gazetas 1984 for all frequencies range covered in figure 3.

5. KINEMATIC SOIL-PILE ANALYSIS

A seismic S-wave propagating vertically in a soil layer without any foundation causes only horizontal displacements in the free-field soil. A cylindrical pile tends

to diffract the incident seisnic waves, modifying the free-field soil motion, so that the horizontal displacement of the pile head, U_p, will be different from the free-field surface motion U_{ff}, and a rotation ϕ_p of the pile head will take place. This type of interaction between piles and soils is called kinematic interaction. This kinematic effect is usually asessed in terms of the kinematic interaction factors I_u and I_ϕ, which are defined, respectively, as the maximum translation and rotation of the pile head normalized by the corresponding maximum displacement of the free field soil surface as:

$$I_u = \frac{U_p}{U_{ff}} \quad \text{and} \quad I_\phi = \frac{\phi_p \cdot D_p}{U_{ff}} \tag{3}$$

The kinematic interaction factors obtained by this study were compared to established results from the literature (Fan and Gazetas 1991, Rovithis et al. 2009). The kinematic response of the soil-pile system was examined for the typical pile proprties ($L_p/D_p = 20$, $E_p/E_s = 1000$). Both fixed and free conditions at pile head were considered.

In the particular case of a fixed-head pile, the analytical solution for I_u is given by the expression (Makris and Gazetas 1992):

$$I_u = \Gamma = \frac{k + iwc}{E_p I_p (q^4 + 4\lambda^4)} \tag{4}$$

which was obtained through a properly calibarated dynamic Winkler model. The corresponding kinematic interaction factores for a free head pile are (Nikolaou et al. 2001):

$$I_u = \Gamma\left[1 + \frac{1}{2}\left(\frac{q}{\lambda}\right)^2\right] \tag{5}$$

$$I_\phi = \Gamma \frac{q^2 D_p}{\lambda} \tag{6}$$

in the above equations, (k+iwc) denotes the so-called dynamic impedance of the Winkler bed, with w being the cyclic vibrational frequency and *i* the imaginary unity; $q = w/V_s$ is the wave number of the harmonic SH waves in the soil; λ is the well-known Winkler wave number:

$$\lambda = \left\{\frac{k + iwc - mw^2}{4E_p I_p}\right\}^{\frac{1}{4}} \tag{7}$$

Based on the comparative results shown in figure 4, it is established that the adopted FE model captures well the variation of kinematic pile response in wide range of frequency.

6. KINEMATIC PILE BENDING MOMENT

As well known in linear analysis, all computed stress and strain quantities are proportional to the excitation intensity, expressed by the the amplitude of the bedrock acceleration $\ddot{U}_g = w^2 U_g$. The pile bending moments were normalized to the amplitude of bedrock acceleration (Kavvadas and Gazetas 1993, Rovithis et al. 2009)

$$M_{nor} = \frac{M}{\rho_p D_p^4 \ddot{U}_g} \tag{8}$$

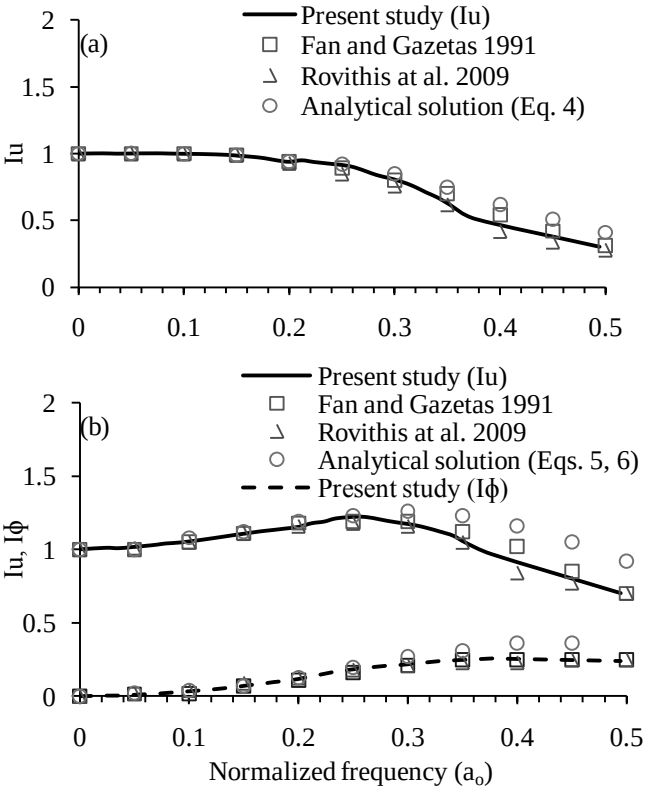

Figure 4 Kinematic soil-pile interaction for : (a) fixed head and (b) free head conditions

Figure 5 presents the distribution of amplitudes of normalized steady state bending moments for the free and fixed pile head conditions at the first two fundamental frequencies of the soil deposit f_1 and f_2 calculated using the present FE method compared to those obtained by Rovithis et al. 2009 (3D FE analysis) with the same soil and pile condtions. Figure 5 implies that the current FE analysis reasonably reproduced normalized pile bending moment agree well previous established ones by Rovithis et al. 2009 for different fundamental frequencies of the soil.

7. DYNAMIC CHARACTERISTICS OF THE SOIL-PILE-STRUCTURE SYSTEM

In this step, a concentrated mass attached to the structural column is introduced to the model. The verification process in this stage focuses on evaluating the effective natural (f_{SSI}). The effective natural frequency (f_{SSI}) of the coupled system is defined, according to Rovithis et al. 2009, as the frequency at which the ratio (U_s/U_{ff}) is maximized, where U_s is the structure mass displacement. Verification was performed by comparing the effective

period of the system (T_{SSI}) calculated using the current FE model at different values of parameter 1/σ with the available analytical solutions as well as 3D FE analysis by Rovithis et al. 2009. The available analytical procedures includes:

- Solution by Veletsos and Meek (1974):

$$T_{SSI} = T_{st,\,fixed}\sqrt{1+\frac{k_{st}}{K_x}\left(1+\frac{K_x H_{st}^2}{K_\theta}\right)} \qquad (9)$$

where $T_{st,\,fixed}$ and K_{st} represent the fixed-base natural period and stiffness of the structure. K_x and K_θ denote the frequency-dependent stiffness in translational and rocking oscillations, respectively.

- Rigorous analytical solution by Maravas et al. (2007):

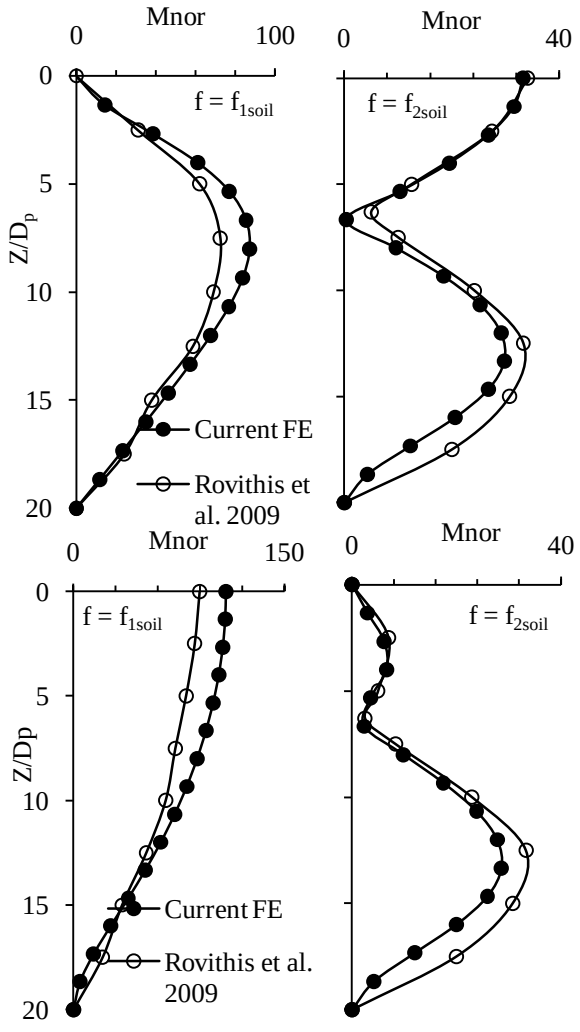

Figure 5 Normalized steady state bending moments at the first two fundamental frequencies of the soil deposits: (a) free head pile; (b) fixed head pile

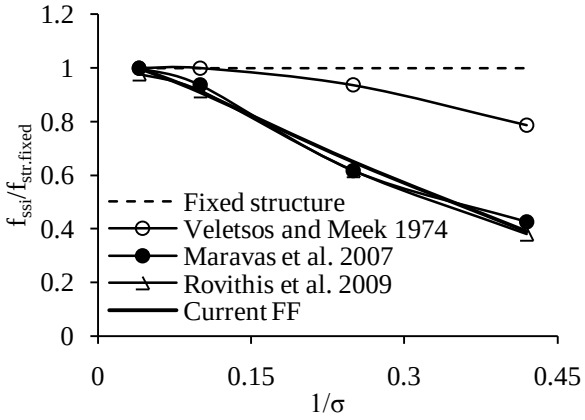

Figure 6 Ratio of the effective natural frequency of the system to the structural fixed-base frequency against parameter 1/σ

$$T_{SSI} = T_{st,\,fixed}\sqrt{\frac{k_{str}}{k_x}\left(\frac{1+4\zeta^2}{1+4\zeta_x^2}\right)+\frac{k_{str}H_{str}^2}{k_\theta}\left(\frac{1+4\zeta^2}{1+4\zeta_\theta^2}\right)+\left(\frac{1+4\zeta^2}{1+4\zeta_{str}^2}\right)} \qquad (10)$$

where ζ_{str} and ζ represent the damping ratio of the fixed-base and flexibly supported structure, respectively, andζ_x, ζ_θ the damping ratios in swaying and rocking of the foundation.

Comparison of the current FE model results against the aforementioned equations as well as results obtained by Rovithis et al. 2009 is illustrated in figure 6, where the ratio of the effective natural frequency of the system to the natural frequency of the fixed-base structure ($f_{SSI}/F_{str.fixed}$) is plotted against the flexibility parameter (1/σ). The very good agreement between the numerical results and both the rigorous analytical solution of Maravas et al. (2007) and the 3D analysis of Rovithis et al. 2009 is evident, confirming the accuracy of the FE model.

8. CONCLUSIONS

In this paper, applicability of the simplified FE model, proposed by Ozutsumi et al. (2003), to the analysis of SSPSI in the frequency domain is examined. The verification process has been executed assuming elasto-dynamic behavior of the soil and comparing the results obtained using the simplified FE model with those found using other established results from the literature. Based on the comparative results in the paper, it is established that It has been shown that this procedure can be used successfully for a provision of the response of a single pile to inertial loading caused by the lateral forces imposed on the over structure and kinematic loading caused by the soil developed during an earthquake.

Abstract: The bearing capacity of pile has been evaluated based on static vertical loading test. However, external forces acting on pile are not only static loads but also dynamic loads such as earthquake loads. In cases of large earthquake, dynamic loads dominate the design considerations. Although loading rate dependency on soil behavior and bearing capacity of pile has been known, there exist little studies and quantitative evaluation methods on bearing capacity of pile considering loading rate have not been proposed yet. The purpose of this study is to investigate the effects of loading rate on sand behavior and bearing capacity of pile for seismic design of pile. The issue to be investigated in this study is the effect of loading rate on sand behavior and bearing capacity of pile. Triaxial compression tests and model loading tests under a centrifuge acceleration field varying loading rate were conducted. The paper summarizes the results of triaxial compression tests and model loading tests.

1. INTRODUCTION

The bearing capacity of pile has been evaluated based on static vertical loading test. However, external forces acting on pile are not only static loads but also dynamic loads like earthquake loads. In cases of large earthquake, dynamic loads dominate the design considerations. Although loading rate dependency on soil behavior and bearing capacity of pile has been known, there exist little studies and quantitative evaluation methods on bearing capacity of pile considering loading rate have not been proposed yet.

Figure 1 illustrates the effects of loading rate on soil behavior, indicating that both soil strength and deformation modulus increase as loading rate increases. Pile loading test such as static loading test is generally used to examine the bearing capacity of piles and soil testing methods such as unconfirmed and triaxial compression tests are used to obtain the soil strength and deformation characteristics. Figure 2 shows typical ranges of loading rate for different loading methods as well as possible maximum vertical velocity during earthquake. The range of maximum velocity during earthquake is almost several kine-several tens kine from observed velocity in the vertical direction as shown in Table 1. Assuming the rocking motion of superstructure during earthquake, the maximum velocity that may occur during rocking motion was calculated as in the order of 20kine. Compared to the possible maximum vertical velocities during earthquake with the loading rates of soil test and investigation method for pile, there is a considerable difference of loading rate. This fact implies that it is necessary to examine the bearing capacity with soil parameters considering loading rate.

From these backgrounds, the purpose of this study is to investigate the effects of loading rate on soil behavior as well as bearing capacity of pile for seismic design of pile.

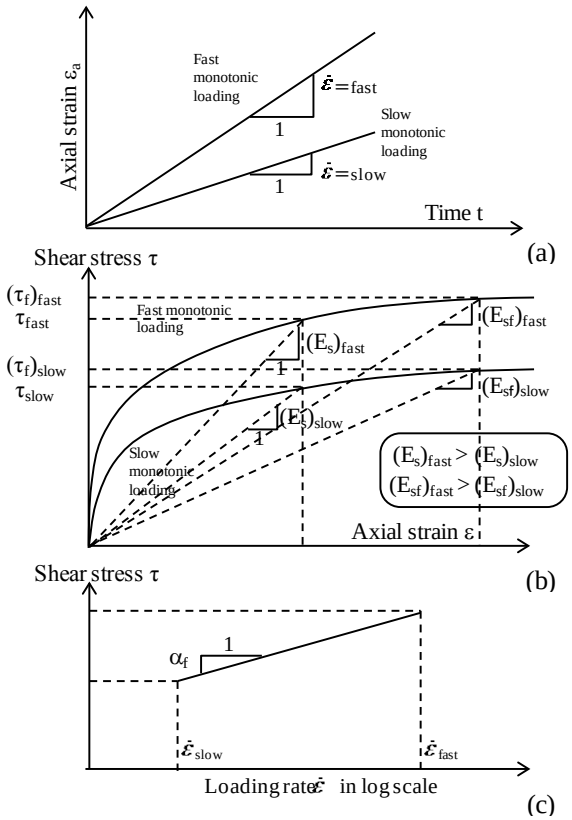

Figure 1 General trend observed in compression test: (a) Axial strain vs. time, (b) Shear stress vs. axial strain, (c) Shear stress vs. loading rate

This paper firstly reviews the effects of loading rate on soil behavior and bearing capacity of foundations, secondly describes the triaxial compression tests with varying loading rate to examine the effect of loading rate on sand behavior, and finally discusses the model loading tests with varying loading rate to confirm the effect of loading rate on bearing capacity of pile.

2. REVIEW OF PREVIOUS STUDY

2.1 Soil Strength and Deformation Characteristics

There are a number of studies using triaxial compression tests. The paper by Casagrande and Shannon (1948) provided the data of strength increase obtained from vacuum triaxial tests on a dry dense sand specimen under a vacuum pressure of 29kPa, showing about 10% increase over the loading rate from 0.00063kine to 63kine with a considerable scatter of maximum principal ratio at failure for higher loading rates. Seed and Lundgren (1954) conducted drained and undrained triaxial compression tests on saturated sand at confining pressures (196kPa) with three loading rates; static tests, slow transient tests and rapid transient tests, of which the time to reach maximum load was 10-15 min (approximately corresponds to 0.002kine), approximately 4 sec (0.375kine) and 0.02 sec(75kine), respectively. They concluded that the strength of dense saturated sand under transient loading conditions is greater than that for normal rates of loading due to (1) the effects of dilatancy combined with lack of drainage and (2) the effects of the rate of deformation.

Pore pressure measurements were made by Whitman and Hearly (1962) who performed undrained traixial tests on saturated sands under a confining pressure of 98kPa and showed the data of pore water pressure change during compression tests. The stress-strain curves for dense saturated sand for two different loading rates (0.003kine and 300kine) showed that in both cases the negative pore water generates with shearing, associated with a sharp increase in deviator stress and no significant effect is observed with respect to loading rate.

Lee et al. (1969) pointed out the significance of confining pressure on the effect of loading rate by performing drained (dry sand) and undrained tests on dense and loose sands at three different confining pressures (98, 588 and 1470kPa) with strain rates varying from 0.00003kine to 25kine. They observed the noticeable greater transient increase of about 20% for dense sands at high confining pressures.

2.2 Loading Rate Effects on Bearing Capacity

Model tests on footings or piles have been also used for the study of the effects of loading rate on bearing capacity of foundations. Vesic et al. (1965) mentioned that their earlier model loading tests performed a series of vertical loading tests for a circular footing on dry or submerged sand using a wide range of loading rates from 0.0002kine to 2kine. The relative density of the model ground is from 75% to 81%. Their results of ultimate bearing capacity with loading rate

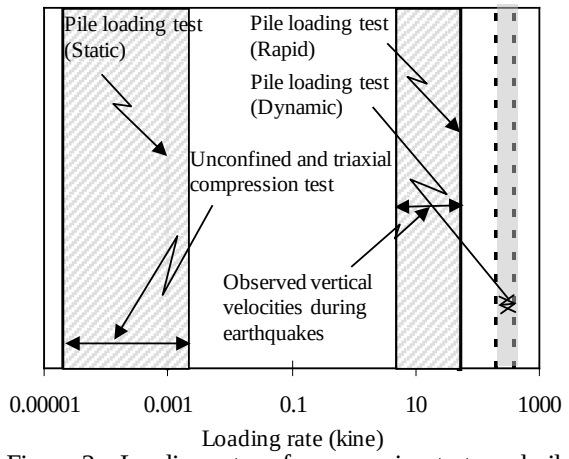

Figure 2 Loading rates of compression tests and pile loading tests

Table 1 Maximum velocities observed in recent earthquakes

Year	Earthquake	Observation point	Maximum velocity (kine)	
			Vertical	Horizontal
1979	Hyogo-ken Nanbu	Kobe marine observatory	51	110
1995	Hyogo-ken Nanbu	JR Takatori	40	90
2004	Niigata Chuetsu	Ojiya	31	98

indicates that the bearing capacity first decreases as loading rate increases up to the loading rate of 0.04kine, but for more rapid loading rate there is a steady increase of bearing capacity. Senanayake (1973) conducted loading tests on shallow circular and square footings on dry dense sand and obtained a steadily increasing trend of bearing capacity with increasing loading rate without any drop. The loading rates are in the ranger of 0.00005kine – 50kine. Konagai et al. (1994) performed model loading tests of a circular surface footing on submerged sand at three different speeds: 0.0017, 0.017, and 0.17kine. Although the trend of variation of bearing capacity seem not conclusive, they stated that their experiments qualitatively confirmed the variation of bearing capacity with loading velocity observed by Vesic et al.

Huy et al. (2005) carried out pile loading tests in unsaturated sand in a calibration chamber, using a CPT cone as a model pile. Model ground was prepared by the cycle of fluidization, vibration and drainage. The loading tests consist of four stages: constant rate test of 2kine, constant rate test of 0.1kine, dynamic test with 25kine and static constant rate test of 0.1kine. The dynamic tests showed an increase in base resistance of 4% and an increase of local shaft resistance of 6%, compared with those of the static test.

Centrifuge cone penetration tests in sand at five European centrifuge centers reported by Bolton et al. (1999) confirmed that small, and generally negligible, effects were observed in dry sand by increasing the penetration rate from 0.25 kine to 2kine. Takemura and Kouda (2000) gathered the similar centrifuge data of cone testing with the penetration rate of 0.017kine to 0.27kine and stated that no apparent difference was observed within this range.

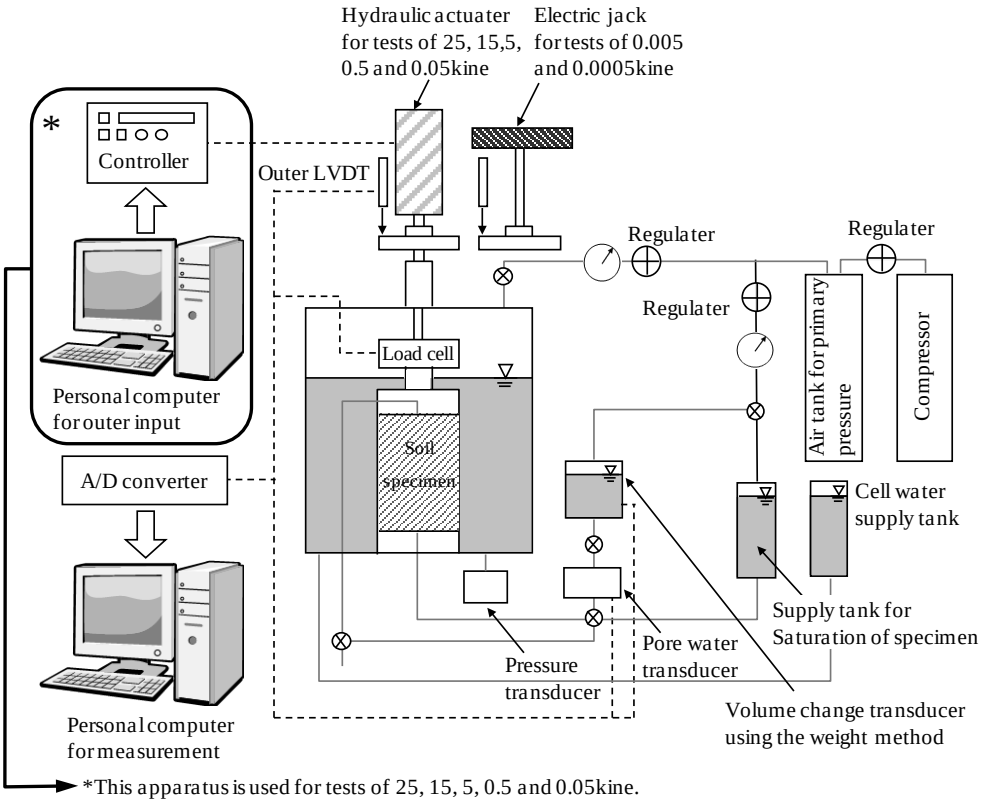

Figure 3 Basic components of triaxial apparatus

3. TRIAXIAL COMPRESSION TESTS

3.1 Test Apparatus, Soils Tested and Test Program

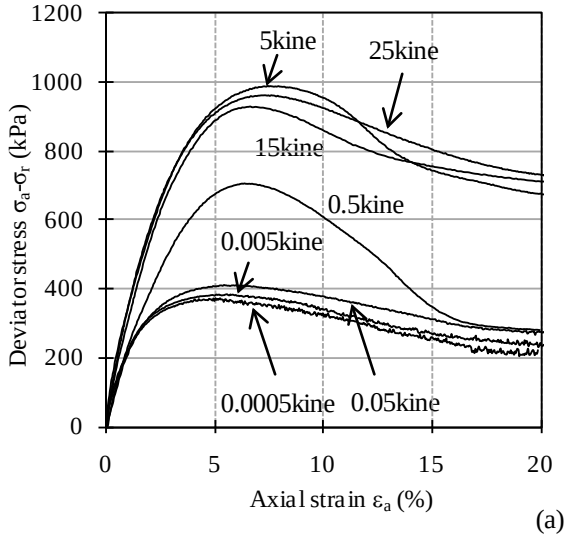
Two different loading systems as shown in Fig. 3 were used in this study to control the loading rate accurately as possible; an electric gear triaxial apparatus for slower loading rate tests and a hydraulic triaxial apparatus for higher loading rate tests. The entire system is closed-loop-controlled by a microcomputer utilizing an analogue-to-digital converter and a stepping motor controller operated by a custom made control program. Load is measured by a load cell, displacement by an LVDT, and cell and pore pressures by pressure transducers mounted on the bottom of the triaxial cell. Drainage is allowed at the top and bottom surfaces of a sand specimen and the pore water pressure measurements are made at the bottom of the specimen. All signals from the instrumentation are conditioned through amplifiers and active filters before entering the microcomputer.

Differential pressure transducers are commonly used for volumetric strain measurement in drained tests with normal loading rates. A newly made volumetric change transducer was used in this study to improve the accuracy of volumetric strain measurement, in particular for higher loading rates. The volumetric change transducer measures the weight of the pore water drained from the specimen,.

The soil used for all tests in this study was Toyoura sand and the material properties are shown in Table 2.

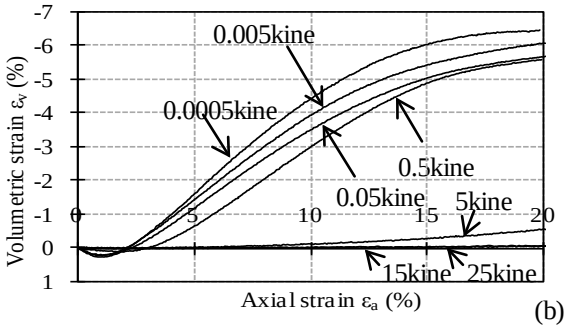
Five series of the tests were performed. Series 1 to 4 used saturated sand specimen and Series 5 dry sand specimen. Specimens with the target relative density of 80% were prepared by air-pluviation method. The coefficient of permeability of the specimen of 80% relative density measured by constant head tests was in the range of 1.0×10^{-2} to 2.0×10^{-2} (cm/sec).

Table 2 Material Properties of Toyoura sand



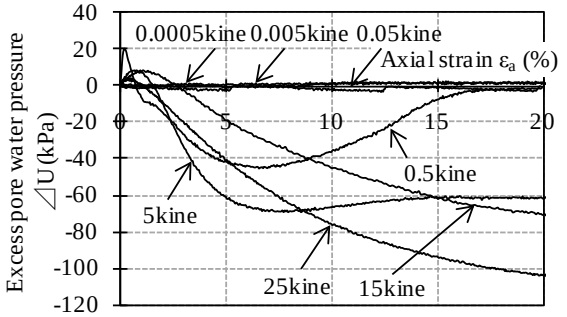
Specific gravity of soil particle: Gs	2.645
Mean grain size: D_{50} (mm)	0.19
30% diameter on the grain size diagram: D_{30}(mm)	0.16
Effective grain size: D_{10} (mm)	0.14
Uniformity coefficient: Uc	1.56
Coefficient of curvature: Uc'	0.95
Maximum void ratio: e_{max}	0.99
Minimum void ratio: e_{min}	0.62

Table 3 Test program



Series	Saturated or dry	Drained condition	Confining pressure (kPa)	Loading rate (kine)	Target relative density (%)
1	Saturated	Drained	100	0.0005,0.005 0.05,5 15,25	80
2			500		
3		Undrained	100		
4			500		
5	Dry	Drained	100		

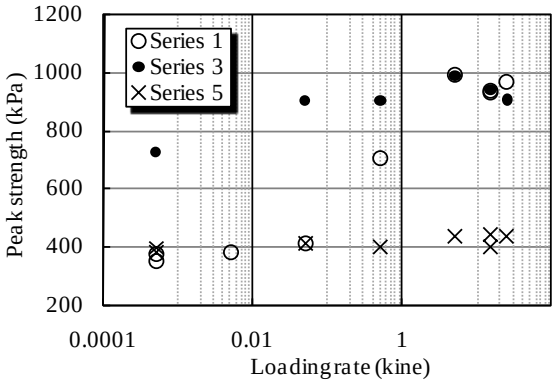
The specimens were saturated using the CO_2 method for the specimens of Series 1 to 4 and a back pressure of 98kPa was then applied. The B-value was checked for each specimen at a low confining pressure before the test commenced. A minimum value of B=0.95 was obtained to ensure the full saturation of the specimen.



The test program is shown in Table 3. All the tests were

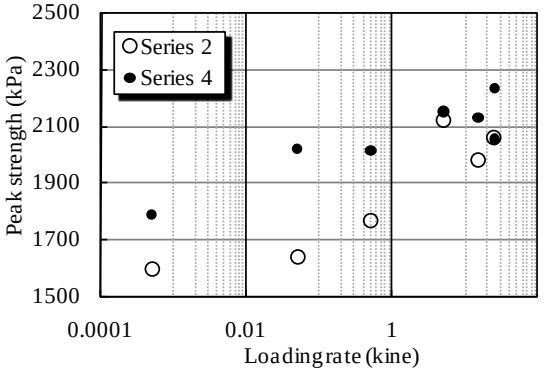
(a)

(b)



(c)

Figure 4 Results of Series 1:
(a) Deviator stress vs. axial strain
(b) Volumetric strain vs. axial strain
(c) Excess pore water pressure vs. axial strain



conducted to drained and undrained conditions under the confining pressures of 100 and 500kPa. 'Drained' means here that the valve of drainage line is kept open during the test, which does not ensure that there is no excess pore water pressure within the entire specimen. It may be appropriate therefore to call 'partially drained'.

3.2 Test Results

Figures 4(a), (b) and (c) show the results of Series 1 of partially drained test on saturated sand; deviator stress, volumetric strain and excess pore water pressure vs. axial strain, respectively. Figure 4(a) confirms the findings; sand exhibits stiffer response and higher shear strength when the sand sample is subjected to faster loading rate, and the peak

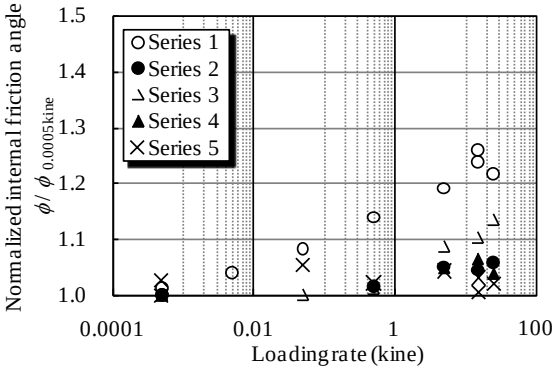

Figure 6 Relationships between normalized internal friction angle at peak stress ratio and loading rate

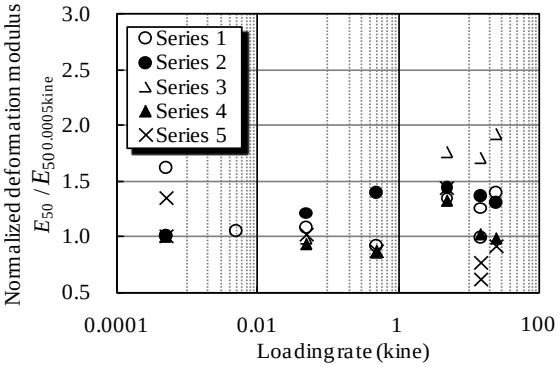

Figure 7 Relationships between normalized deformation modulus and loading rate

strength defined at the deviator stress maximum increases when the loading rate increases. Deviator stress vs. axial

strain relationships in Fig. 4(a) can be classified into two groups; one is the curves of 5kine to 25kine, the other is 0.0005kine to 0.05kine. The curves of 0.5kine lies in between the two groups. Relationships between volumetric strain vs. axial strain in Fig. 4(b) suggests that the first group can be considered as 'undrained' test, since there is no, or negligible volumetric strain throughout the test. The second group can be regarded as fully drained test, since there is no, or negligible excess pore water pressure generation during the test as is seen in Fig. 4(c). The effect of the loading rate on deformation of the specimen is seen in the volumetric strain vs. axial strain curve. It is seen from Fig. 4(b) that the slower the loading rate , the larger the volumetric strain.

The peak strength defined by the maximum deviator stress is plotted against loading rate in logarithmic scale in Fig. 5(a) for Series 1, 3 and 5 with a confining pressure of 100kPa and for Series 2 and 4 with a confining pressure of 500kPa in Fig. 5(b). The rates of increase over the range of 0.05kine to 25kine in terms of one-logarithmic cycle are 5% for Series 5 and 10% for Series 3, respectively. Series 1 of saturated sand under partially drained condition shows a sudden increase of the peak strength from 0.05kine and the peak strength approaches to that under undrained condition at the loading rate of 15kine. This observation is also true for the data of Series 2. This sudden change in peak compressive strength is mainly due to the relative magnitude between the loading rate and the rate of dissipation, and partly due to the change in mode of deformation. The internal friction angle at the maximum stress ratio was calculated by Eq. (1).

$$\phi = \sin^{-1}\left(\frac{\sigma_a - \sigma_r}{\sigma_a + \sigma_r}\right)_{\max} \qquad (1)$$

Plotted in Fig.6 is the internal friction angle at the maximum stress ratio normalized by that at the slowest loading rate of 0.0005kine against the loading rate for various conditions. The figure implies that the mobilized internal friction angle under 25kine is as much as 1.25 times larger than that obtained from triaxial compression tests with the recommended loading rate such as 0.00005kine.

Figure 7 plots deformation modulus E_{50} against loading rate. The deformation modulus E_{50} is normalized by the deformation modulus E_{50} at the loading rate of 0.0005kine. Here, the deformation modulus was estimated using Eq. (2).

$$E_{50} = \frac{(\sigma_a - \sigma_r)_{\max}}{2\varepsilon} \qquad (2)$$

As was illustrated in Fig. 7, the deformation modulus E_{50} becomes larger when the loading rate is higher, except Series 5 of dry sand under partial drained conditions.

3.3 Summary of Triaxial Compression Tests

The purpose of this investigation was to examine the effect of loading rate on sand behavior by conducting a series of triaxial compression tests with a varying loading rate of 0.0005kine to 25kine. The following findings were obtained from triaxial compression tests varying loading rate.

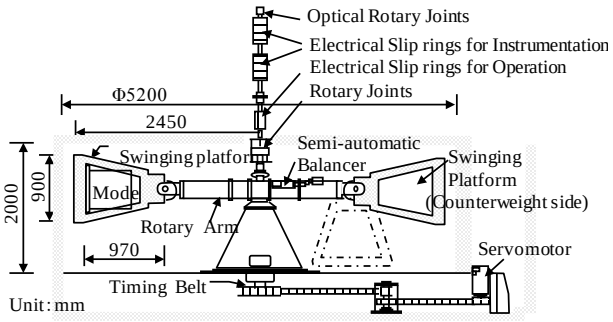

Figure 8 Tokyo Tech Mark 3 Centrifuge apparatus

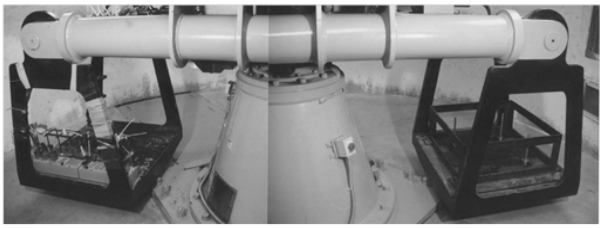

Photo 1 Tokyo Tech Mark 3 Centrifuge apparatus

1) The failure strength and the stiffness of dense sand generally become higher / stiffer when the loading rate is higher.
2) Deviator stress vs. axial strain relationships in partially drained tests were clearly classified into two groups. The soil exhibits undrained behavior when a loading rate is faster than 5kine, while the soil shows no appreciable difference in behavior when the loading rate is slower than 0.05kine.
3) The internal friction angle and the deformation modulus increase with the increase in loading rate. The internal friction angle and the deformation modulus with the loading rate of 25kine may become, respectively, 10-50%, 30-150% larger than those obtained in the compression tests with the recommended loading rate for triaxial tests.

4. CENTRIFUGE MODEL LOAD TESTS

4.1 Test Apparatus, Soil Tested and Test Program

The Tokyo Institute of Technology Mark 3 Centrifuge (Tokyo Tech Mark 3 Centrifuge) was used for the model test described in this paper. This centrifuge is a beam type centrifuge having a pair of parallel arms that hold platforms on which the model container and a weight for counterbalance are mounted as shown in Fig. 8 and Photo 1. Radius of rotation is 2.45m, which is the distance from the rotating shaft to the platform base. The surface of swinging platform is always normal to the resultant acceleration of the centrifuge acceleration, nG, and earth's gravity. Specifications of the centrifuge are summarized in Table 4.

For data acquisitions, two types of signal transmission methods are used. One is classical electrical slip ring. Transducers are connected to the slip rings through a junction box and signals are transferred to amplifiers on the laboratory floor. The other is an optical rotary joint. Transducers are amplified there and then are converted to digital signals by A/D converters. Gains and the other conditions of the signal conditioners can be controlled by a

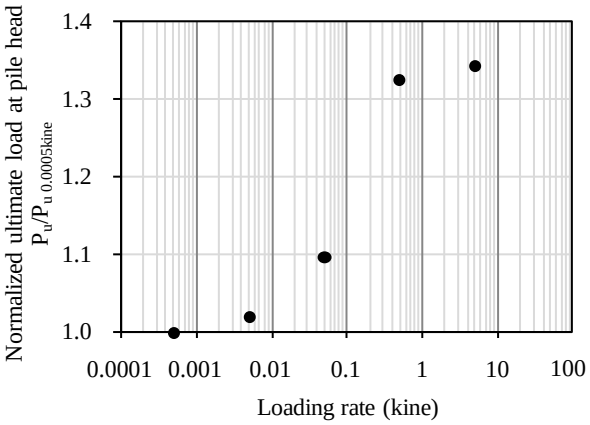

Figure 11 Relationships between normalized ultimate load at pile head and loading rate

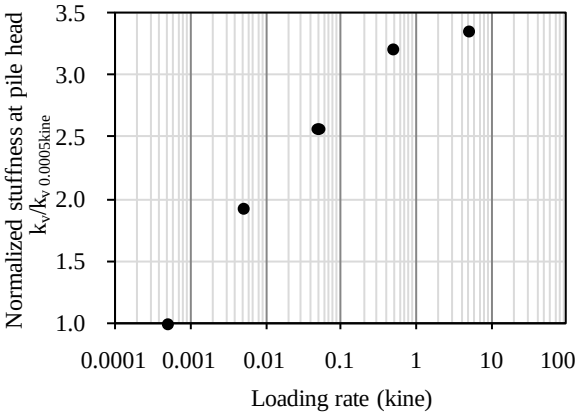

Figure 12 Relationships between normalized stiffness at pile head and loading rate

PC on the laboratory floor. The digital signals are transferred to a PC on the laboratory floor through the optical rotary joint.

The schematic view of test apparatus is shown in Fig. 9. The dimensions of container made by steel were width B=500mm, height h=600mm and length l=200mm. The model pile was steel cylindrical pipe of 20mm in diameter, 200mm in length and 5mm in thickness. The surface of model pile was considered to be smooth. The strain gauges were mounted inside of the model pile to measure the strain of model pile, and the earth pressure transducer was mounted on the tip of model pile to examine the resistance at the pile tip. Earth pressure transducers and accelerometers were embedded in the model ground. The loading was carried out by a hydraulic actuator. The hydraulic actuator was rigidly jointed with the model pile. The ranges of loading rate are 0.0005kine to 25kine by this actuator. The model ground was prepared by air-pluviation method using Toyoura sand to achieve a relative density of Dr=80%. All the tests were conducted under 50 G.

4.2 Test Results

Figure 10 presents the relationships between load at pile head and vertical displacement normalized by the pile diameter, δ/D. These loading tests were carried out in dry

dense sand varying loading rate in the range of 0.0005-5kine. The load at pile head and stiffness generally become higher / stiffer when the loading rate is high.

Figure 11 indicates the relationships between the load at pile head normalized by that at the slowest loading rate and loading rate. The definition of ultimate load at pile head is the measured maximum load at pile head. The data indicates that the load at pile head increases as the loading rate increases. Compared to the results at the slowest loading case and that at the highest loading case, the increment of the load at pile head is almost as large as 30%.

The relationships between the coefficient of subgrade reaction normalized by that at the slowest loading rate and loading rate are plotted in Fig. 12. The coefficient of subgrade reaction is calculated by load increment and displacement increment in the relationships between load and displacement at pile head. The normalized coefficient of subgrade reaction shows the large value when the loading rate is high. Thus, the stiffness at pile head increases as the loading rate is high.

The bearing capacity of pile may be calculated based on the bearing capacity formula as shown Eqs. (3)~(5).

$$Q = Q_s + Q_b \qquad (3)$$

$$Q_b = A_b(cN_c + \gamma DN_q S_q + \gamma BN_\gamma S_\gamma) \qquad (4)$$

$$Q_s = A_s(K_0 \gamma z \tan\phi) \qquad (5)$$

Where,

$N_c = (N_q - 1)$

$N_q = \exp(\pi \tan\phi)\tan^2(45° + \phi/2)$

$N_\gamma \approx 2(N_q + 1)\tan\phi$

S_c, S_q, S_γ: Shape factor, c: Cohesion,
γ: Unit weight of soil, D: Embedded length
B: Pile diameter
K_0: Coefficient of earth pressure at rest, $K_0 = 1 - \sin\phi$
z: Depth measured from the ground surface

The increase in the internal friction angle will directly lead to an increase in the value of the bearing capacity factors for N_q, N_γ used for end bearing capacity, as well as shaft friction. The vertical ultimate bearing capacity of pile was evaluated for the same conditions of model loading test. The internal friction angle ϕ=40deg. obtained from the triaxial compression tests of Series 5 was used for calculation of the ultimate bearing capacity. The relations of the calculated values of bearing capacity normalized by that at the slowest loading rate and loading rate with experimental values are plotted in Fig. 13. Here, the legend of Fig. 13 means that 'Exp.' and 'Cal.' are experimental value and calculated value, respectively. The trend indicates that the normalized calculated ultimate bearing capacity agrees almost with the experimental value. Thus, it is said that the increment of bearing capacity due to the effect of loading rate corresponds with the increment of calculated bearing capacity using bearing capacity formula as shown Eqs. (3)~(5) and the increment of internal friction angle.

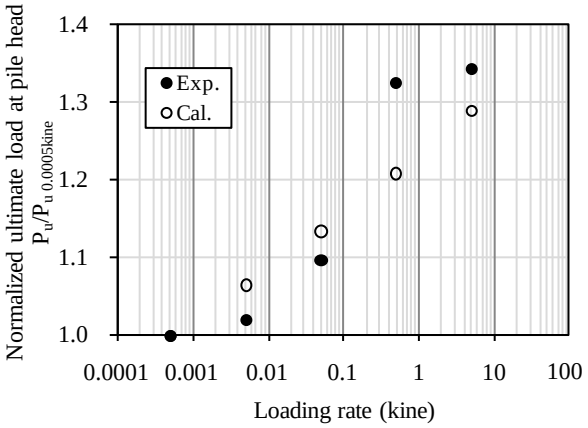

Figure 13 Relationships between normalized ultimate load at pile head by calculation and loading rate with experimental value

4.3 Summary of Model Loading Tests

The purpose of model loading tests is to confirm the effect of loading rate on bearing capacity of pile by conducting a series of centrifuge model tests. The following findings were obtained.

(1) The ultimate bearing capacity and the stiffness at pile head become higher / stiffer when the loading rate is higher.

(2) The ultimate bearing capacity and the coefficient of subgrade reaction at pile head increase as the loading rate increases. The ultimate bearing capacity and the coefficient of subgrade reaction at pile head with the loading rate of 5kine may become, respectively, 35%, 330%, larger than these obtained in the slowest loading cases.

(3) It is concluded that the increment of calculated bearing capacity of pile using bearing capacity formula and the internal friction angle obtained from the results of triaxial compression test on Series 5 agrees almost with the increment of experimental value.

5. CONCLUSIONS

The purposes of this study were to experimentally examine the effect of loading rate on sand behavior by a conducting a series of triaxial compression tests with varying loading rate of 0.0005kine to 25kine and to confirm the effect of loading rate on bearing capacity of pile by conducting a series of model loading tests at centrifuge acceleration field with varying loading rate in the range of 0.0005kine to 5kine. The following findings were obtained;

(1) The effect of loading rate on soil strength and bearing capacity of pile was confirmed clearly. Both soil strength and bearing capacity of pile increase as the loading rate increases.

(2) The effect of loading rate on stiffness of sand and coefficient of subgrade reaction was also examined clearly. Both stiffness of sand and coefficient of subgrade reaction at pile head become higher when the loading rate is high.

Abstract: It is widely accepted that tunnels have high seismic stability because of a confining effect from surrounding ground. However, tunnel structures have experienced serious damages during past huge earthquakes. Although the need for seismic performance of tunnels is emphasized in specifications for tunnels, it is required to understand detailed mechanisms on interaction between the tunnel and the ground. There are many uncertain factors which affect the soil-structure interaction, e.g., arch action of ground, deformation of ground with tunnel and tunnel cover. The arch action of the ground is expected to occur due to stress releasing of the surrounding ground during construction process of the mountain tunnel, and it might be changed by earthquake-induced ground deformation. In order to investigate the pseudo-static response of the urban mountain tunnel in lightly consolidated sandy ground and effect of stress releasing, centrifuge model tests were carried out in this study. In conclusion, following results were obtained. Firstly, due to the arch action, initial bending moments exerted in case with stress releasing are quite small. Secondly, the deterioration of the arch action takes place due to shear deformation of ground. Thirdly, the pseudo-static response before and after deterioration of the arch action are significantly different.

1. INTRODUCTION

Recently, the number of construction of urban tunnels has been increasing because of intensive use of urban areas. In order to reduce construction cost of the urban tunnels, mountain tunnelling methods have extended its application to the urban area in relatively soft ground (e.g. lightly consolidated or unconsolidated sandy ground) at shallow depth.

Underground structures were considered having high seismic stability because of a confining effect from surrounding ground (Kawashima 1994). However, tunnel structures have experienced serious damages in the 1995 Hyogo-Ken Nanbu Earthquake (Asakura et al. 1996), and consequently the design codes for tunnels were revised (e.g. JSCE 1996). The revised specifications recommend taking into account the soil-structure interactions by proper methods, such as the seismic displacement method. This method is a kind of pseudo-static approach in which seismically-induced ground deformation is statically applied to the tunnel structure through the soil springs. This soil-structure interaction is affected by many factors, e.g., stress conditions of soil, tunnel cover depths, deformation of ground together with tunnel structure, surface condition of tunnel and lining structures, thus, there are many uncertainties in the application of the seismic displacement method. Although the need for seismic performance of the urban tunnels is emphasized in JSCE standard specifications for tunnels (JSCE 2008), it is required to understand detailed mechanisms on the soil-structure interaction under various conditions.

Arch action of the ground above the mountain tunnel is expected to occur due to ground deformation during unlined construction process of the moutain tunnel, i.e. stress releasing of the ground is generated, and the earth pressures acting on the tunnel lining are much smaller than that by the shield tunnelling method. According to previous studies (Shibayama et al. 2010), the experimental results showed that the earth pressure acting on tunnel in sand changes due to deterioration of the arch action which is caused by the shear deformation of the ground. However, in the experimental study (Shibayama et al. 2010), at the initial state, actual stress releasing during construction process of the mountain tunnels, are not represented.

In this study, active type shear tests in a centrifuge were carried out to understand the detailed pseudo-static seismic response of the urban mountain tunnel embedded in lightly consolidated sandy ground, and the effect of the stress releasing around the tunnel. In particular, difference of the pseudo-static response of the tunnel structure before and after deterioration of the arch action is discussed.

2. CENTRIFUGE MODEL TEST

2.1 Introduction

Seismic stability of the tunnel structure is usually evaluated by the seismic displacement method. This method evaluates structural forces exerted on the tunnel by applying the shear deformation of surrounding ground to the tunnel structure in a pseudo-static approach, because the effect of inertia force acting to the underground structure can be neglected as compared with superstructures. Figure 1 shows an active type shear box used in this study. The seismic displacement method was experimentally reproduced by using this shear box. Validity of the experimental method for a rectangular tunnel constructed in sand has been confirmed by the previous study (Shibayama et al. 2009). In this study, pseudo-static responses of the urban mountain tunnel were investigated by the experimental simulation of the seismic displacement method using the active type shear box in a centrifuge.

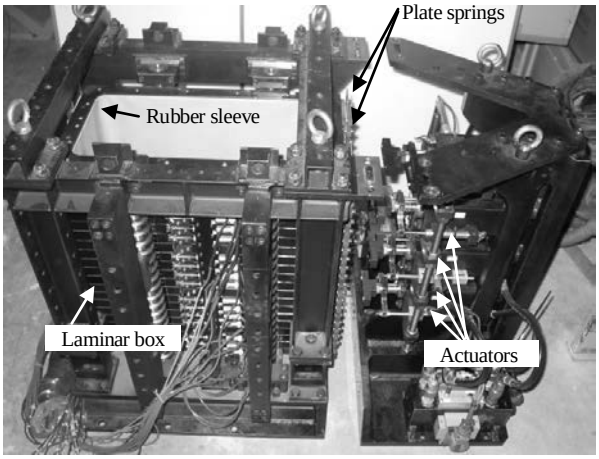

Figure 1 Active type shear box

Table 1 Specifications of active type shear box

Maximum centrifuge acceleration		100g
Actuator	Number	4
	Stroke	±20mm
	Force capacity (20.5MPa oil pressure)	25.8kN (outward) 18.0kN(inward)
	Peak velocity	133mm/sec
Laminar box	Dimensions (inner)	W 452mm B 202mm H 524mm
	Number of laminae	20+fixed one

2.2 Test and model description

The active type shear box comprises two parts; a laminar box and actuators, as shown in Fig. 1. The laminar box consists of 20 stacked 24mm laminae with a roller bearing support and one fixed lamina at the base of the box. The shear deformation of the laminar box was imposed by four hydraulic actuators connected to the four laminae at specific elevations. Horizontal displacements of the other laminae were transmitted through four linked sets of 0.6mm plate springs. A rectangular shape rubber sleeve was placed on the inner wall of the box to prevent the soil particles from getting into the gaps of the laminae. Thin stainless vertical sheets and a horizontal sheet of 0.2mm thickness with rough surface were fixed to both the inner end walls and the base of the box, respectively. These sheets are used for mobilizing the shear stresses on the inner boundary when the box is sheared. The specifications of the active type shear box are summarized in Table 1.

Assuming horseshoe-shaped mountain tunnel in the lightly consolidated sandy ground, an aluminium model tunnel was used for the model tests, as is shown in Figure 2. The model lining has a diameter of 100mm, a height of 75mm and a thickness of 2mm with smooth surface, which approximately corresponds to a 5m diameter tunnel with an unreinforced concrete lining of 300mm thickness in the prototype scale under centrifugal acceleration of 50g.

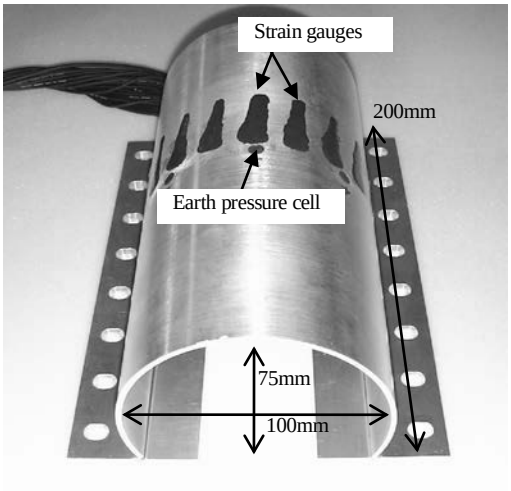

Figure 2 Horseshoe-shaped model tunnel

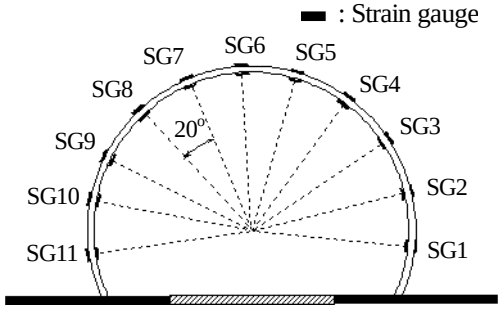

Figure 3 Positions of strain gauges

In total, 22 strain gauges were attached on both outer and inner surface of the model tunnel in pairs to measure sectional forces (especially, bending moment in this paper) exerted on the model tunnel. Figure 3 illustrates the positions of the strain gauges attached to the model tunnel.

Figure 4 illustrates a schematic diagram of model setups for the tests. Assuming lightly consolidated sandy ground, cemented sand was used for the model ground. The cemented sand is comprised of a mixture of silica sand

No. 6 (G_s=2.64, D_{50}=0.51mm, Uc=1.74, e_{max}=0.922, e_{min}=0.565 and ϕ=41deg.), cement, admixtures and water. The material properties of the cemented sand are summarized in Table 2. In order to investigate, an effect of stress releasing on pseudo-static response of the tunnel, two cases of the tests were conducted. In case with the stress releasing (i.e. with SR case), the model ground was constructed to have a certain gap, δ=3mm in radial direction, between tunnel and excavated ground at 1g field as shown in Figure 4. During increasing centrifugal acceleration up to 50g, the excavated ground was deformed by this certain gap. Due to this allowed ground deformation, appropriate initial stress condition, is created. On the other hand, in case without stress releasing (without SR case), there is no gap (i.e. δ=0mm) as shown in Figure 4. According to experimental comparisons between these two cases, the effects of the stress releasing are discussed.

In this kinds of the tests, a tunnel cover (H_c) and diameter (D) ratio is one of important parameter, as the depth controls the stress condition of the tunnel surroundings, including formation of the arch action above the tunnel due to the stress releasing. Generally, depth of the urban tunnels is relatively shallow, it normally has the cover of a several times of the tunnel diameter. Thus, the covers of the model grounds, H_c, were selected to be 300mm which corresponds to a tunnel cover-diameter ratio, H_c/D of 3.

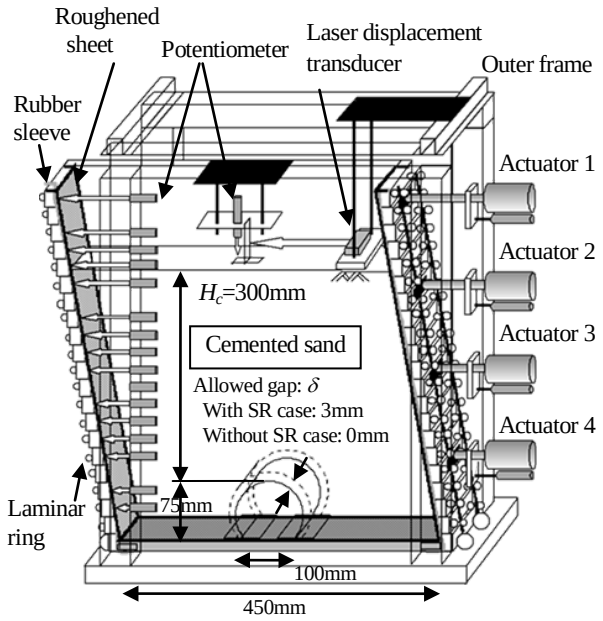

Figure 4 Model setup

Table 2 Material properties of cemented sand

Figure 5 shows typical examples of the input horizontal displacement distributions measured by potentiometers attached to the each laminar ring, when positive and negative certain values of horizontal displacements were applied from the actuators. The measured distributions have almost linear distributions with depth. Thus, input nominal shear strain, γ, is defined by the gradient of the

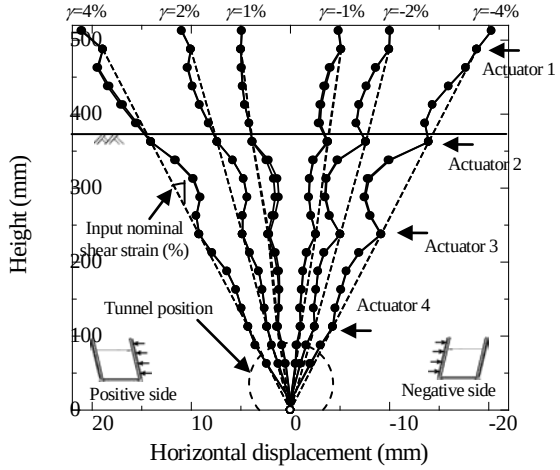

Figure 5 Distributions of horizontal displacement

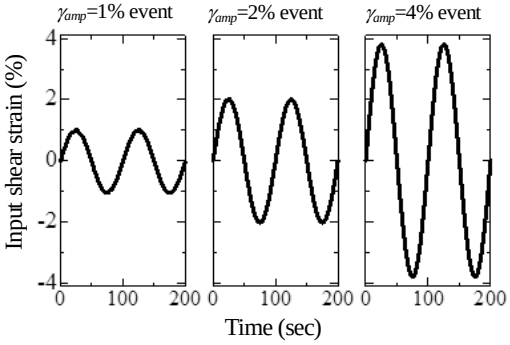

Figure 6 Shear strain history

intended distribution of the input horizontal displacements, as shown in Figure 5.

Time histories the input nominal shear strain are shown in Figure 6. The two cycles sinusoidal nominal shear strain for the amplitudes, γ_{amp}, of 1%, 2% and 4% respectively, were imposed on the model ground continuously under centrifugal acceleration of 50g. An each cycle of the nominal shear strain was applied in 100sec.

3. NUMERICAL CALCULATION

As well as, the centrifuge model tests, FE push over analyses were carried out using the FEM code, PLAXIS 2D Ver. 9.02. Figure 7 illustrates FE mesh configuration and loaded horizontal displacements used in the analyses. As shown in the figure, the calculation mesh has 22.5m wide and 18.75m height in the prototype scale, which is composed by 1450 fifteen-noded triangular two-dimensional plane strain elements and 38 five-noded elastic beam elements. The input horizontal displacements were

statically imposed on the side boundaries of the model ground, which have linear distributions with depth, as shown in Figure 7. The values of the input horizontal displacements at the ground surface are 0.188m, which correspond to the nominal shear strain of 1%. During the whole analyses, displacements were restricted in both direction along the bottom mesh boundary, and horizontal displacements were restricted along the side boundaries, as illustrated in Figure 7. The tunnel structure is modelled as elastic beam elements with appropriate interface elements, and for all analyses it was assumed to behave in a linear elastic manner. The Mohr-Coulomb (MC) model was employed to simulate the soil behaviour in all the FE analyses. The MC model is elasto-plastic model which involves five strength parameters, i.e. Young's modulus, E and Poisson's ratio, ν for soil elasticity; friction angle, ϕ and cohesion, c for soil plasticity and ψ as an angle of dilatancy. Material properties of the tunnel and ground models are summarized in Table 3 and 4, respectively.

When the shear deformation of ground is imposed, considerable static stresses were acting on the tunnel due to overburden pressure and the construction process. Hence, prior to the shear deformation loadings, static analyses of excavated processes were undertaken to establish the initial stresses acting on the tunnel. Starting from a green-field profile, the excavation of the tunnels causes stress relief in the ground. To model this excavation process, concept of the so-called β-method is used. The idea is that the initial stress, p_0, acting around the location where the tunnel is to be constructed is divided into a part (1-β) p_0 that is applied to the unsupported tunnel and a part of βp_0 that is applied to the supported tunnel. Instead of the b value a load contribution ratio (LCR) is used in FE analyses. In fact, when the ground at the tunnel position is excavated, an initial out-of-balance force occurs that is comparable with the initial force, p_0. In the beginning of calculation, this force is fully applied to the ground and it will be stepwise decreased. Then, the calculation has been done until certain value of the LCR is produced, and the out-of-balance force is imposed on tunnel structure. After that, horizontal displacements are imposed on the model ground. As parameter which controls amount of stress releasing, a load contribution ratio (LCR) is used. Varying the parameter, LCR, several cases are calculated. Figure 8 indicates calculated characteristic curve, which is relationship between calculated earth pressure and vertical convergence at the tunnel crown after the static calculations. In the figure, the values of the earth pressures and convergences are normalized by the value of the calculated earth pressure in LCR100% case and the tunnel diameter, respectively. Totally 11 case of the calculation were conducted varying the LCR from 15% to 100%, as shown in Figure 8. In the next section, results of the cases with the LCR 100% and 30% will be discussed, which corresponding the test case without and with stress releasing. As references values, the case with the LRC 15% will also be compared, in which the arch action of the ground almost fully mobilized without the collapse of the surrounding ground.

4. RESULTS AND DISCUSSION

Figure 9 shows initial distributions of measured bending moments for the both with and without stress releasing cases before the shear deformations of the ground were imposed. The cases with and without are indicated by open circles and squares, respectively. In the figure, calculated distributions were also plotted, in which cases with LCR of 100% (as a real line), 30% (a broken line) and 15% (a thin dashed line) are included. The positive bending moment is defined as the case for the inner surface of the tunnel lining suffers tension force. As shown in Figure 9, small amounts of positive and negative bending moments were exerted in the case with stress releasing compared with the without stress releasing, which is probably due to a formation of the arch action of the ground caused by the stress releasing. As mentioned previously, calculated results with LRC of 100% and 30% could be considered as the test cases without and with stress releasing, respectively. And case with LRC=15% is considered as case in which the arch action of the ground is fully mobilized without collapse during the excavation process. As well as the test results, the calculated bending moments of the LCR=30% and 15% are quite small compared with the case of LCR=100% in which the arch action is not considered. Although actual values are slightly different between the measured and calculated results, the calculated bending moment distributions are practically similar to these of the model tests.

Figure 10 shows variations of the bending moment measured at the tunnel crown, the right spring line and mid-part between them in the both tests for with and without stress releasing in the model tests. In Figure 10, solid and broken lines indicate the cases of with and without stress releasing, respectively, and dashed lines show the input shear strain. Cyclic variations of the bending moment at the crown and right spring line are smaller than that at the mid-part. At the crown and spring line, initial values of bending moment of the case of with stress releasing are quite small, as previously mentioned. Then during shearing, the bending moments are increase and approach to these of the case without stress releasing, during shearing.

Figure 11 shows the bending moments measured before and after γ_{amp}=1% shearing event for the both cases with stress releasing and without stress releasing, and Figure 12 shows the bending moments measured before and after γ_{amp}=4% event in the both cases, without stress releasing and with stress releasing. The terms 'before' and 'after' in the figures correspond to the test elapsed time of 0 second and 200 seconds respectively in Figure 6. In these figures, the calculated distributions are also included. In the case of with stress releasing, the bending moments before the first (γ_{amp}=1%) shearing (which has been already introduced in Figure 9 as initial values) are much smaller than those after shearing, and the bending moments at near the crown increase and in side parts decrease after 1% shearing, as shown in Figure 11 (b). Firstly, before γ_{amp}=1% shearing, the measured values are almost the similar to the calculated

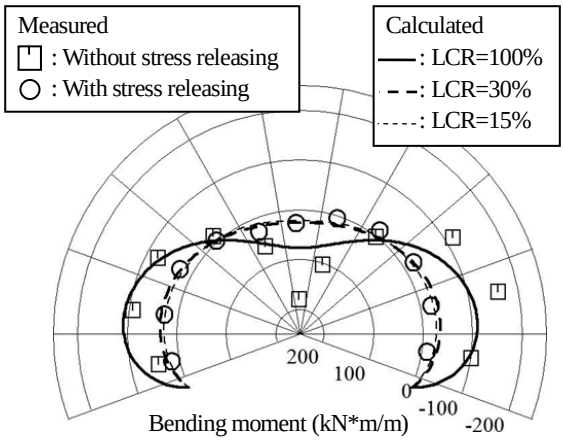

Figure 9 Initial bending moment distributions

distributions with LCR=30% or15%, then after shearing,

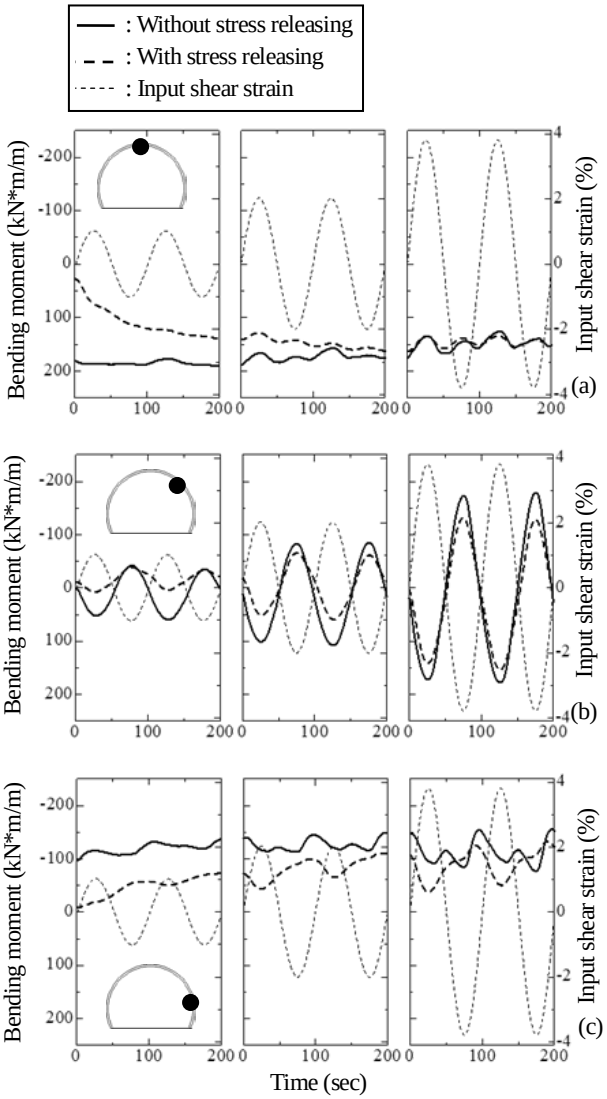

Figure 10 Variation of bending moment (a) at crown (b) at right mid-part and (c) at right spring line

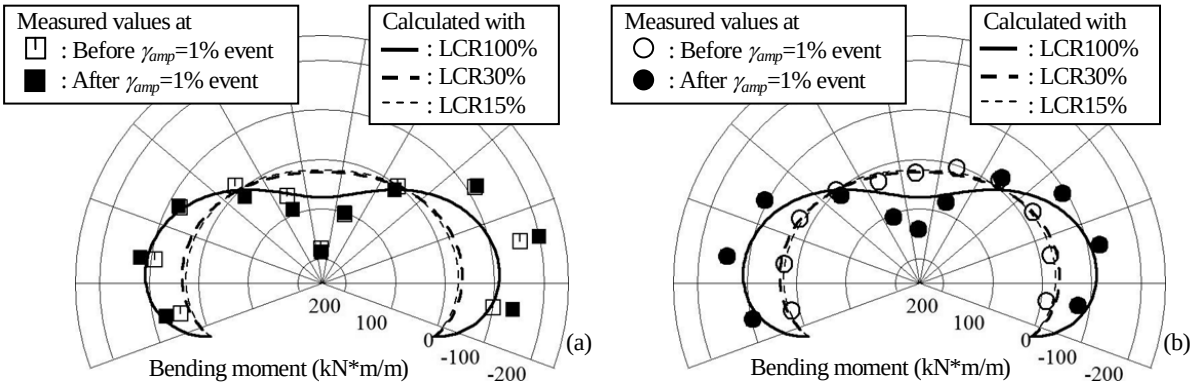

Figure 11 Bending moments measured before and after γ_{amp}=1% event
(a) Without stress releasing and (b) With stress releasing

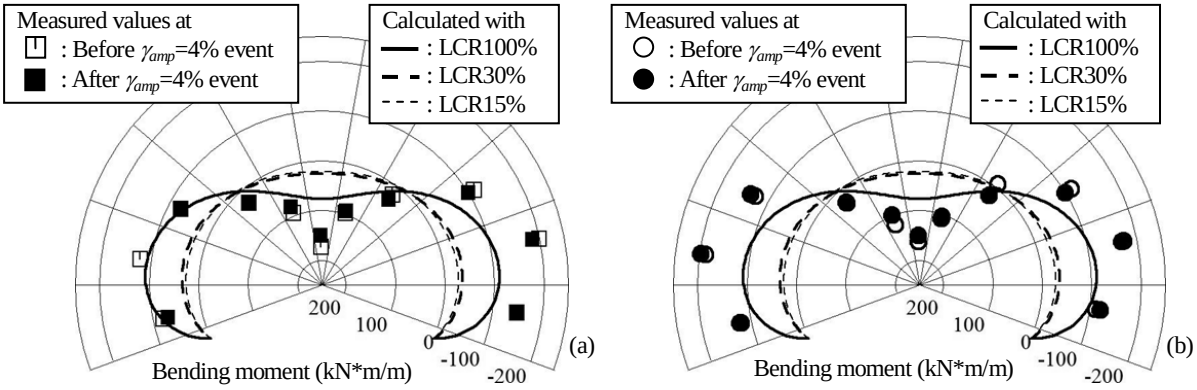

Figure 12 Bending moments measured before and after γ_{amp}=4% event
(a) Without stress releasing and (b) With stress releasing

these are almost the same values of the calculated distribution of LCR=100%. On the other hand, in the case of without stress releasing, 1% shear strain, the moment distributions before and after shearing show almost no change (Figure 11 (a)). Probably, this can be explained by the formation of arch action of the cemented sand above the tunnel with stress releasing during centrifugal acceleration up to 50G, and deterioration of the arch action takes place due to shearing. In Figures 12 (a) and (b), distributions of bending moment before and after 4% shearing show no change in the both cases of with stress releasing and without stress releasing and distributions of the cases of with stress releasing and without stress releasing are almost the same, because the ground of the case with stress releasing has already been subjected to 1% and 2% shear strain cycles and arch action diminished by shearing.

Figure 13 shows comparison between bending moment distributions at after γ_{amp}=4% shearing event of the case without and with stress releasing. In the figure, the calculated distributions were also plotted. As compared with initial values shown in Figure 9, after several shearing event, slightly large amount of bending moments are exerted in the case with stress releasing with respect to the case without stress releasing. This experimental fact might suggest that after the arch action has been deteriorated due to shear deformation of the ground, the larger bending moments exerted in the tunnel with the stress releasing during the excavation process.

In order to understand the effect of the initial condition change on the pseudo-static response of the bending moments due to the shear deformation on the ground, the absolute and incremental values of the bending moments were compared. Figure 14 (a) shows the distributions of the absolute values of the bending moments exerted on the tunnel when the input nominal shear strain γ=1% in the first cycle of the γ_{amp}=1%, 2% and 4% shearing events for the

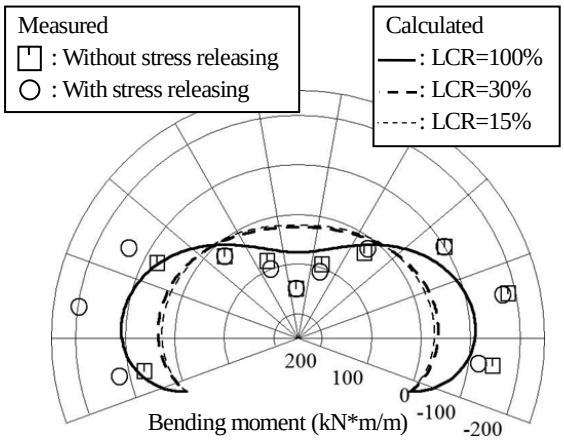

Figure 13 Comparison between bending moment distributions of without and with stress releasing

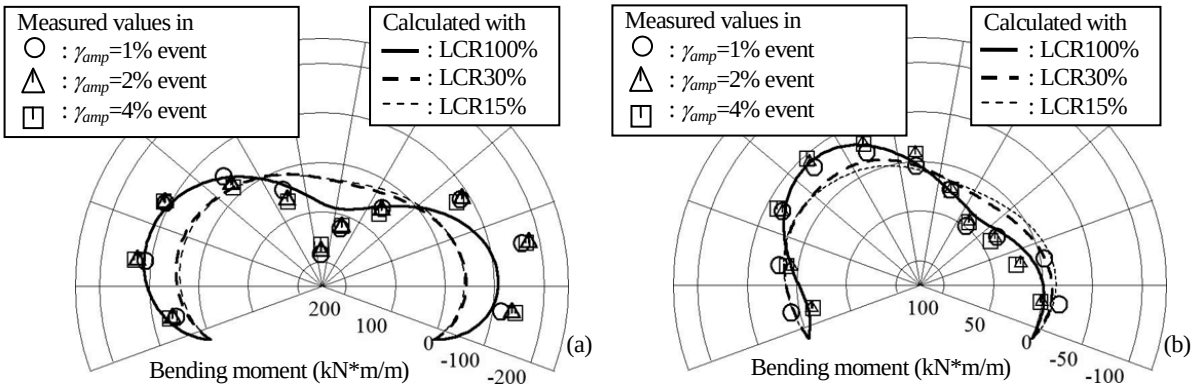

Figure 14 Bending moments measured when γ=1% shear strains imposed for without stress releasing case (a) Absolute values and (b) Incremental values

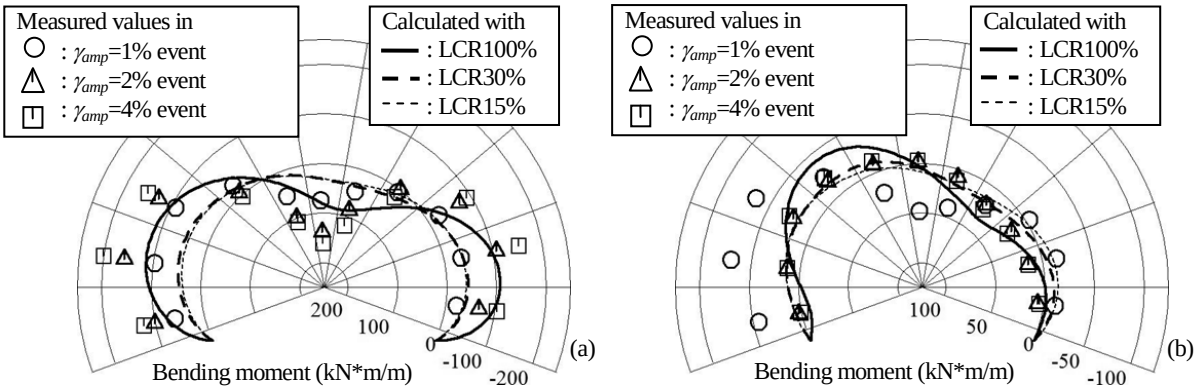

Figure 15 Bending moments measured when γ=1% shear strains imposed for with stress releasing case (a) Absolute values and (b) Incremental values

without stress releasing. Figure 14 (b) indicates distributions of incremental value of the bending moments measured from the beginning of the each shearing events to the same point of Figure 14 (a). In the Figures, the calculated values of the bending moments with the LCR=100%, 30% and 15% were also plotted as a real, a broken and a thin dashed lines, respectively. The previous experiments (Yamada et al. 2002 and Izawa et al. 2006) indicated that sectional forces at the tunnel corners are remarkable when the pseudo-static shear deformation of the ground was imposed on the model tunnel. The present data shown in Figure 14 also support the previous experimental observations. As shown in Figure 14, the absolute and incremental values of pseudo-static responses of bending moments are almost the same. It might be suggested that for the case without stress releasing, if the same values of the ground shear deformations are imposed, the same values of the bending moment responses will be exerted. And it should be noted that the FE analyses well-predict the pseudo-static response for without stress releasing case, because the absolute and incremental experimental values are practically similar to the calculated values. Figure 15 indicates these distributions for the case with stress releasing. As compared with the case without stress releasing, for the with stress releasing, absolute values of the bending moment responses increase from first shearing (γ_{amp}=1%) to final shearing event (γ_{amp}=4%), as shown in Figure 15 (a). This might be explained by the deterioration of the arch action. On the other hand, the larger incremental values of the bending moment are exerted in the γ_{amp}=1% event compared with these in other events, which also related to the deterioration. After the deterioration, the incremental values of γ_{amp}=2% and 4% are almost the same, and practically similar to the calculated results of LCR30%. It can be said that larger values of the bending moment responses will appear after the arch action is deteriorated. After the deterioration, the seismic increments of the bending moments are almost the same if the same values of the ground shear deformations are imposed, however large amount of the absolute bending moments are slightly different after several shear deformation is applied. It might be indicated that prediction of the initial stress condition is quite important.

Figures 16 (a) and (b) show the absolute and incremental values of the bending moments measured when the maximum shear strain was first applied in cyclic shearing 4% in the cases of with and without stress releasing which corresponding to elapsed time of 25 seconds in Figure 6. In Figure 16 (a), for the with stress releasing case, larger values of the bending moments are exerted in left hand side compared with the without stress releasing case. While in Figure 16 (b), incremental values of the bending moments are almost the same between the both with and without stress releasing cases. It might be expected that once the

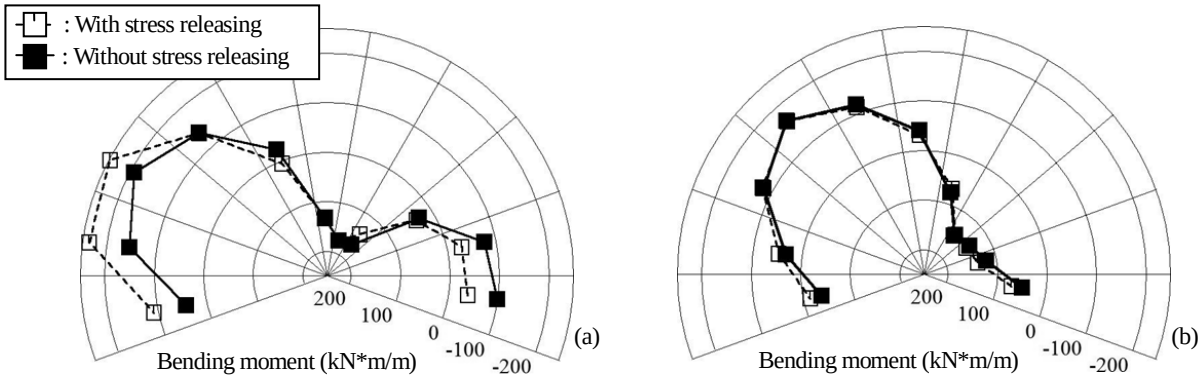

Figure 16 Experimental comparison between bending moments of without and with stress releasing when γ=4% shear strains (a) Absolute values and (b) Incremental values

arch action is deteriorated by the ground shear deformation, larger bending moment exerted in the tunnel.

5. CONCLUSIONS

This paper presented some results of active type shear box tests in a centrifuge by modelling the horse-shoe shaped aluminium tunnel in lightly consolidated sandy ground, as well as FEM analysis, in which construction process of the mountain tunnel is represented. The objective of this study is to investigate, the effects of stress releasing which is expected to occur during the construction process of the tunnel, on pseudo-static response of the tunnel. Following findings are obtained,

1) At initial state, the stress releasing reduces bending moments exerted in the tunnel lining close to zero due to the formation of the arch action of the ground, before shear deformation is imposed.
2) The arch action formed by stress releasing deteriorated by seismically-induced shear deformation of ground. According to the deterioration of the arch action, bending moments exerted in tunnel lining increase.
3) The pseudo-static bending moment responses before and after deterioration of the arch action are different. After the deterioration larger values of bending moments are exerted.
4) After the deterioration, the FE analyses well-predict pseudo-static increment of bending moments. However, to appropriately evaluate seismic performance of tunnel, appropriate initial stress condition due to construction process should be represented.

Abstract: In an earthquake, tunnels passing through liquefiable soil deposits are susceptible to floatation due to their lower unit weight as compared to the surrounding saturated soil. Centrifuge tests have been carried out to investigate such floatation failure of shallow tunnels. Conventionally, the floatation of a buoyant tunnel in an ideal "viscous" liquefied soil may be deemed to displace vertically up to the surface. However, the presence of a rigid tunnel may lead to a reduction in excess pore pressure due to soil dilation from the soil-structure interaction. This paper presents the cyclic in-plane movement of the floating tunnel derived from instrumentation and the Particle Imaging Velocimetry (PIV) technique. The coupled influence of the cyclic movement of the tunnel on the acceleration and excess pore pressure measured at the springing depth of the tunnel during the floatation process are discussed.

1. INTRODUCTION

Underground infrastructure has been a widespread alternative in redeveloping urban spaces to ease congestion pressure arising from land scarcity. This underground infrastructure has often served as vital lifelines for transport, utility and storage purposes. They include subway train and highway tunnels, gas and water pipelines, and fuel storage tanks. However, in the event of an earthquake, the functionality of these lifelines could be put in question especially in soils susceptible to liquefaction.

Historical earthquake events such as the 1906 San Francisco earthquake (Youd and Hoose, 1976), 1964 Niigata earthquake (Seed, 1970), 1964 Alaska earthquake (Hall and O'Rourke, 1991), 1994 Northridge earthquake (Bardet and Davis, 1999), 1995 Great Hanshin earthquake (Okimura et al., 2006), 2003 Tokachi-oki earthquake (Towhata, 2008), 2004 and 2007 Chuetsu earthquakes (Tobita et al., 2009 and Ghayamghamian et al., 2007), 2009 Padang earthquake (Chian et al., 2010a), and the 2010 Chile earthquake (GEER, 2010) have proven the damage susceptibility of underground structures. In the case of tunnels, they usually serve as transportation facilities which may pose a high degree of risk in terms of human losses should they fail during an earthquake. Blocked or damaged transportation routes may also interfere with the ability of emergency personnel to respond promptly to immediate crisis.

Given the evidence of extensive geotechnical failures of lifelines in many earthquake-hit cities, there exists a need to conduct in-depth research to better understand and mitigate such seismic risk which could bring cities to a standstill following a major earthquake event. Centrifuge tests were conducted to provide a detailed understanding of the seismic response of floating tunnels in liquefied soil deposits.

2. LIQUEFACTION INDUCED FLOATATION OF BURIED STRUCTURES

Buried structures are generally subjected to a buoyant force due to their lower submerged unit weight than the surrounding soil. Conversely, the overlying weight and shear strength of the overlying soil inhibits the floatation. In the event of liquefaction, the soil loses most of its shear strength and the tunnel as shown in Figure 1 may float if the effective buoyant force (F_B) is greater than the combined resisting forces from the overlying soil weight (F_{WS}) and the soil's shear contribution (F_{SP}) as expressed below in Eq. (1):

$$F_B > F_{WS} + F_{SP} \quad (1)$$

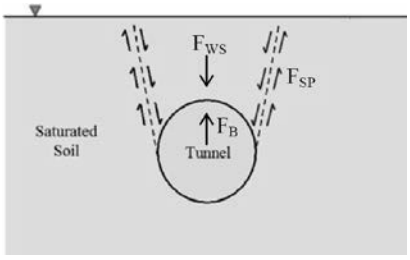

Figure 1 Force components acting on pipe in static condition (Chian and Madabhushi, 2010a)

Schmidt and Hashah (1999) proposed that the floatation of a tunnel requires the following conditions: 1) partial or full liquefaction of the surrounding soil, 2) structure must be buoyant in the liquefied soil mass, 3) nothing holds the structure from floating, and 4) the liquefied material must have mobility and be able to flow as the structure rises. In Figure 2, as the tunnel experiences uplift, the liquefied soil moves underneath the displaced tunnel, further lifting it up

(Hashah et al., 2001). This infers that liquefied soil is free-flowing and capable of filling the void left underneath the displaced tunnel. Based on this assumption, liquefied soil may be deemed as an ideal viscous fluid.

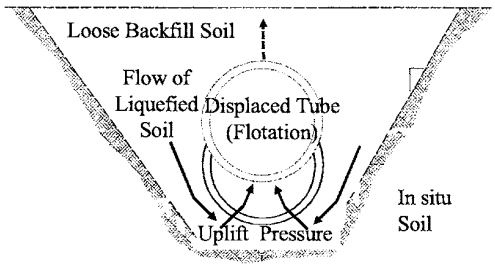

Figure 2 Backfill liquefaction and tube floatation (Schmidt and Hashash, 1999)
