This idea of classifying liquefied soil as a viscous fluid have been pursued by many researchers earlier and have concluded that liquefied soil behaves like a viscous non-Newtonian fluid through pulling bar and sinking ball tests at 1g (Kawakami et al., 1994; Miyajima et al., 1995; Hamada and Wakamatsu, 1998; and Hwang et al., 2006).

3. EXPERIMENTAL SETUP

3.1 Centrifuge Modelling

Soil is a highly non-linear material. It is therefore essential to replicate identical stress and strain conditions in laboratory tests as in the prototype scale. Geotechnical centrifuge modelling achieves these conditions with the use of high centrifugal acceleration to scale up the model. A scaled model is made to correspond with the prototype at the pre-determined centrifuge g-level. As a result, a 1:*N* scale model experiences the same stress and strain conditions as the prototype when subjected to a centrifugal acceleration of *N* times earth's gravity A set of scaling laws for other parameters can be derived as shown in Table 1 (Schofield, 1981).

The model tunnel and pipe were buried in sand models prepared to the relative density (D_R) of 65% with the dry pluviation method using the automatic sand pourer and the accompanying design charts by Chian et al. (2010b). The layout of the tunnel, pipe and instruments are illustrated in Figure 3. Mouldable Duxseal was placed on the sides of the container to minimise reflecting incident stress waves (Steedman and Madabhushi, 1991). The material properties of Hostun sand used in the model are described in Table 2.

Based on centrifuge scaling laws, the 75 mm and 21.25 mm diameter model pipes represent a tunnel and a large diameter pipe with diameters of 5m and 1.42m at prototype scale in a 66.7g test respectively. These pipes were buried at a shallow depth of 1.1 times of their diameter to ascertain the difference in their floatation response with respect to their buried depth. A draw-wire potentiometer was attached to the crown of each pipe to measure its uplift response.

After sand pouring was completed, the models were saturated using the computerised system developed by Stringer and Madabhushi (2009). High viscous methyl cellulose fluid (66.7 cSt) prepared with a mixture of Hydroxypropyl methylcellulose (HPMC) powder and water based on the weight concentration by Stewart et al. (1998) was used as pore fluid to satisfy dynamic centrifuge scaling laws as indicated in Table 1. The saturated model was then loaded onto the 10m diameter beam centrifuge for testing. During the test, earthquakes were fired in-flight using the Stored Angular Momentum (SAM) earthquake actuator devised by Madabhushi et al. (1998).

Table 1 Centrifuge scaling laws

Parameter	Model/ Prototype	Units
General (slow events)		
Length	1/N	m
Area	$1/N^2$	m^2
Volume	$1/N^3$	m^3
Mass	$1/N^3$	$Nm^{-1}s$
Stress	1	Nm^{-2}
Strain	1	-

3.2 PIV Technique

The Particle Image Velocimetry (PIV) is an optical means to visualise flow dynamics in fluids seeded with tracer particles. It is used to obtain instantaneous velocity measurements and related properties in fluids. This concept was adapted to suit geotechnical applications, using a texture-based image processing technique developed by White et al. (2001) as shown in Figure 4.

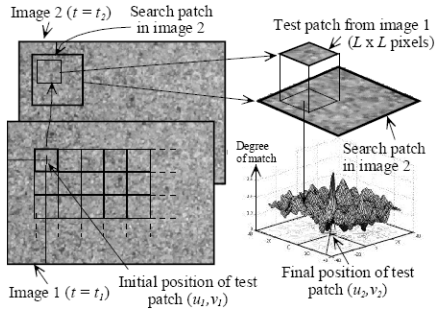

Figure 4 Principles of PIV analysis in geotechnical applications (White et al., 2001)

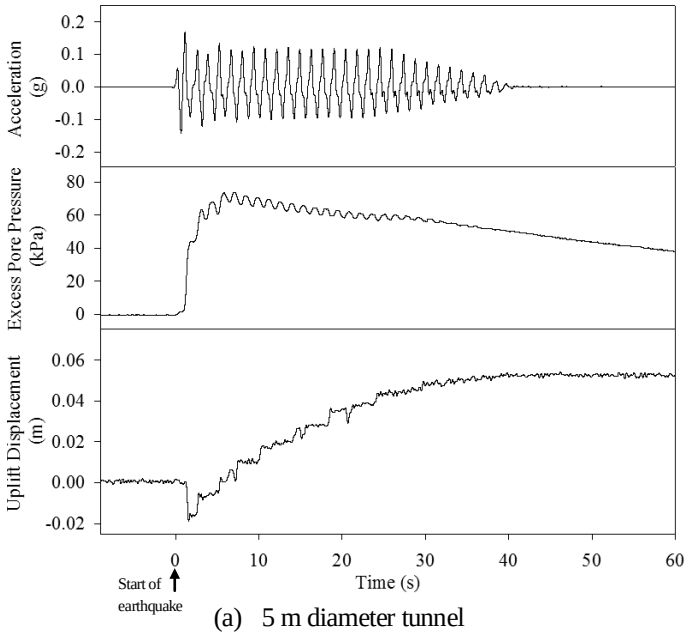
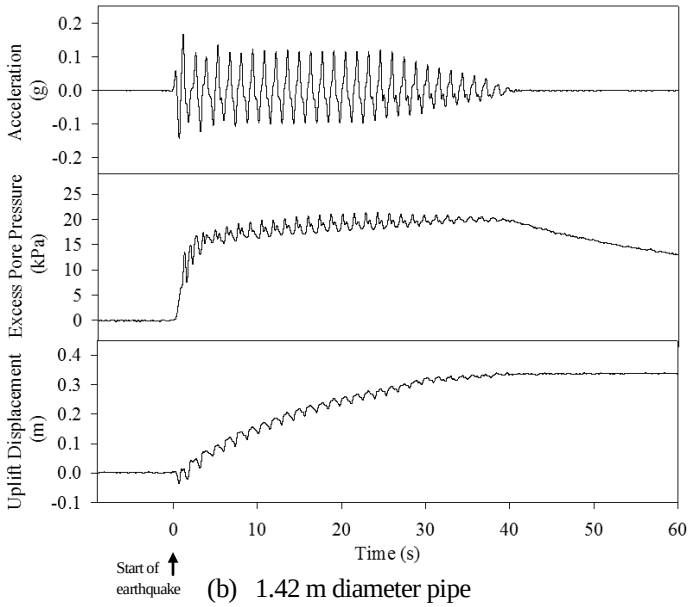


Natural sand has its own texture in the form of different coloured grains. In the case of sands with little texture, the texture can be enhanced with the addition of coloured grains of identical or coarser sand. Based on the unique texture of each patch of soil at the plane of a clear window of Perspex wall of the model box, the deformation of soil can be examined by tracking the movement of these patches from one image to another. Detailed information on the development and performance of the image processing algorithms are described by White et al (2003).

In static tests, the movement of soil grains is slow and progressive. Hence, conventional high resolution cameras were usually used to capture multiple image frames at 3 to 5 second intervals. In the case of earthquake tests, the soil movement is highly influenced by the phase of the earthquake cycle which requires the capturing of large numbers of image frames in each cycle. A typical earthquake of 1 Hz would require a shake frequency of *N* Hz in a dynamic centrifuge test due to scaling law as indicated in Table 1. Hence, a high speed camera is necessary to obtain sufficient image frames to depict the development of soil movement with increasing number of loading cycles. A Phantom v5.0 camera capable of taking 1000 image frames per second was therefore used in these dynamic centrifuge tests.



4. BEHAVIOUR OF LIQUEFIED SOIL AROUND A TUNNEL

4.1 Excess Pore Pressure Generation

The uplift of pipe in a liquefied soil may be deemed to be mainly driven by the buoyancy of the pipe. This is accompanied by the loss of shear strength of the soil due to excess pore pressure generation which encourages floatation. Hence, a high degree of liquefaction has to be present to allow the pipe to float easily. Figure 5 shows that significant liquefaction has been achieved at the springing depths of the tunnel and pipe during the earthquake. At this stage, the shear strength of the soil was reduced significantly, resulting in the floatation of tunnel, as evident in the uplift displacement readings shown in the same figure. This is in agreement with the literature in Section 2.

(a) 5 m diameter tunnel

(b) 1.42 m diameter pipe

Figure 5 Plots of acceleration (‘*A*’), excess pore pressure (‘*B*’ and ‘*D*’), and uplift displacement (‘*C*’ and ‘*E*’) of tunnel and pipe, in prototype scale

4.2 Soil Deformation during Tunnel Floatation

PIV analysis in dynamic centrifuge testing has shown to be capable of providing reliable measurements on the progress of soil deformation and uplift displacement of tunnels (Chian and Madabhushi, 2010b). Figure 6 shows the development of the soil deformation mechanism during the floatation of the tunnel, which tends to develop into a circular flow around a circular buried structure, where the soil lifted by the structure gradually replaces the soil which has moved into the displaced void beneath the buoyant structure.

The uplift displacement of the pipe was significantly greater than the tunnel. This is due to the lower confining stress at shallow soil depth, which leads to the high mobility of soil near the surface (Chian and Madabhushi, 2011). This is evident from the large displacement of soil grains near the surface as observed in Figure 6.

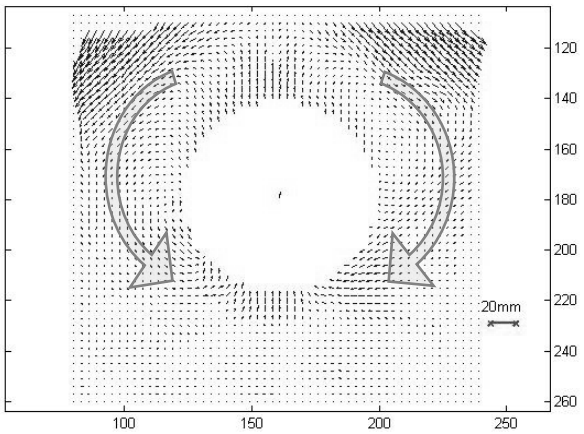


Figure 6 Cumulative displacement vectors of soil and tunnel during the earthquake

4.3 Cyclic Response of Tunnel during Floatation

The hypothetical response of a buoyant object in a viscous fluid is expected to float smoothly towards the soil surface alike to the falling ball viscometer or a sinking ball in liquefied soil test adopted in the measurement of viscosity of liquefied soil. The difference between them is that the former floats rather than sink in the case for the latter. According to Stoke's law as adopted in the sinking ball tests, the viscosity of a fluid can be estimated by the forces of equilibrium acting on a 1-D sinking object as shown in Figure 7 and Eq. (2).

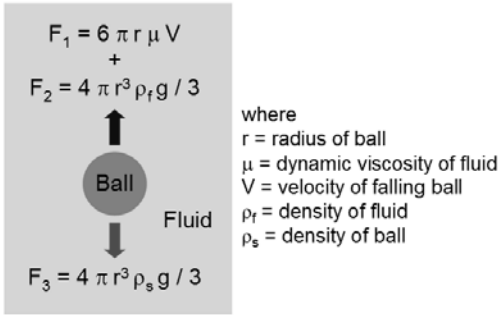

Figure 7 Forces acting on a sinking ball in equilibrium

$$\mu = \frac{2r^2(\rho_s - \rho_f)g}{9V} \quad (2)$$

Detailed movement of the tunnel during the earthquake was investigated with the use of instrumentation attached to the tunnel as well as employing the PIV technique. The vertical movement of the tunnel is obtained from the draw-wire potentiometer or the PIV analysis, while the horizontal movement acquired from the PIV analysis or estimation from the double integration of the acceleration readings from the accelerometers attached on the tunnel. Figure 8 illustrates the cyclic movement of the tunnel during its floatation in prototype scale. The variation between the two sources of measurement is mainly due to the dimensional scaling from model scale to prototype scale. In model scale, the mean differences are merely 0.12mm and 0.22mm in the horizontal and vertical displacements respectively. This indicates the consistency of readings obtained.

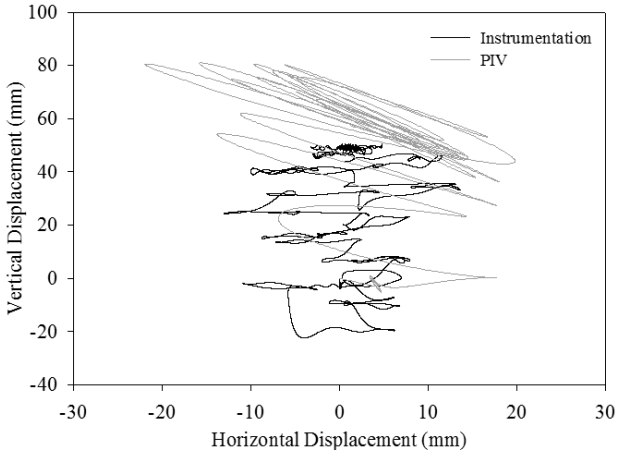

Figure 8 Cyclic movement of tunnel in liquefied soil during floatation, in prototype scale

Centrifuge tests showed the floatation of tunnels in liquefied soil do not follow the same response as the descending sphere in the sinking ball test. Rather than floating directly to the soil surface, the tunnel was observed to also displace horizontally during the earthquake as it floats. This suggests that the liquefied soil may not behave like an ideal viscous fluid in this case due to the interaction between the soil and the oscillating tunnel.

4.4 Soil-Structure Interaction

From the above findings, it is evident that the transition of saturated soil to a liquefied state may cause a buoyant tunnel to float due to the reduction in shear strength and the increased mobility of the liquefied soil. On the other hand, both factors could be altered due to the coupled soil-structure interaction. The liquefied state of the soil influences the buoyant tunnel to float. At the same time, the movement of the tunnel (vertically and horizontally) exerts pressure to the surrounding soil, leading to a partial recovery of the soil's shear strength. This is evident from the reduction in excess

pore pressure as shown in Figure 9. This led to the soil displacing in a wide loop around the tunnel (see Figure 6), unlike the monotonic uplift of structure in upheaval buckling which showed narrow loops of soil movement with high displacement nearer to the structure as shown in Figure 10.

Despite a high excess pore pressure generated, it was observed that the excess pore pressure was dissipating quickly during the earthquake at 3m away from the tunnel face as shown in Figure 9. This indicates that pore fluid is migrating towards the tunnel due to the hydraulic gradient difference as excess pore pressure is relatively lower near the tunnel face at the same soil depth.

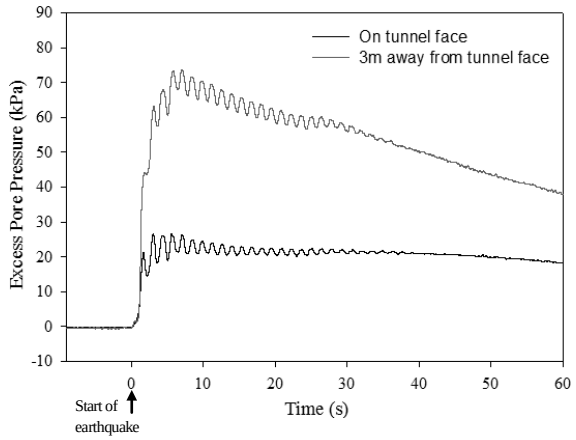

Figure 9 Excess pore pressures at the springing depth of tunnel (*'B'* and *'F'*), in prototype scale

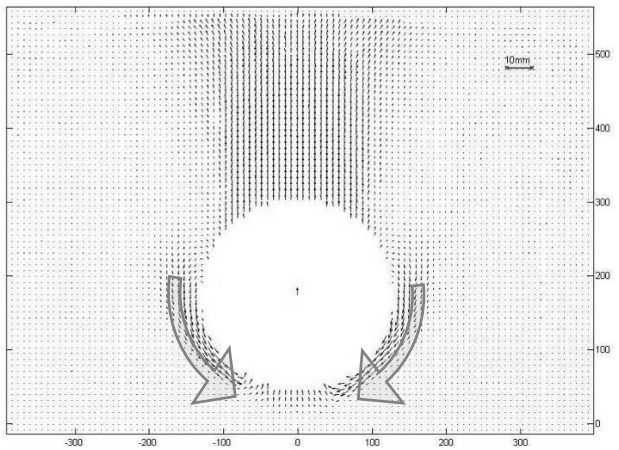

Figure 10 Cumulative displacement vectors of soil and buried structure due to monotonic uplift (Chian et al., 2011)

The accelerations measured on the tunnel face were smaller than those measured 3m from the tunnel face despite being located at the same soil depth as shown in Figure 11. This suggests that the tunnel is getting isolated from earthquake shaking. Pore fluid migration towards the tunnel may be causing a reduction in effective stress locally around the tunnel, thereby isolating it from earthquake shaking. As such, seismic considerations based on free field acceleration may lead to a more conservative analysis on the response of the tunnel.

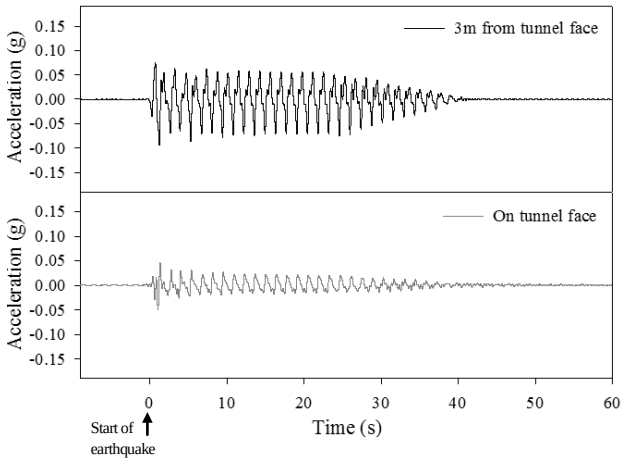

FIGURE 11 Accelerations at the springing depth of tunnel (*'G'* and *'H'*), in prototype scale

5. CONCLUSION

The floatation of tunnel in liquefied soil does not follow the continuous uplift displacement of a typical buoyant object in a viscous fluid. Instead, the tunnel cycles horizontally as it displaces vertically upwards to the soil surface. This indicates that liquefied soil does not behave identical to an ideal viscous fluid in the presence of a rigid tunnel. The cyclic movement of the tunnel, both vertically and horizontally, induces external stresses in the soil around it, thereby leading to partial recovery of shear strength as the soil dilates. This in turn resists floatation of tunnel to occur. The reduction in excess pore pressure near the tunnel also encourages pore fluid migration from the free field. The coupled soil-structure interaction also attenuates the soil's acceleration significantly.

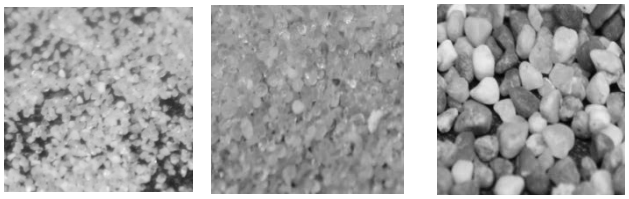
Abstract: Elastic wave measurement techniques are becoming reliable methods for studying materials properties. Several methods have been developed in last three decades. Among the various methods of elastic wave measurement techniques in laboratory, recently developed Disk Transducer method and Trigger Accelerometer method are employed in this study. Disk transducer is flat shaped piezo-ceramic transducer installed in the center of the top cap and pedestal on triaxial apparatus which is able to measure both compression and shear wave on a single speciemen.The maximum stiffness moduli (G_{max} or E_{max}) measurement at very small strain level on three granular materials, Toyoura sand, Silica sand and Hime gravel employing Disk Transducer method and Trigger accelerometer method are conducted. The dynamically measured results are compared with the statically measured results applying small strain cyclic loadings. Poisson's ratio (ν) reflects the lateral deformational characteristics. It is one of the prominent characteristics of materials on analysis of deformation behavior. Simultaneous measurements of the compression and shear wave made possible to compute the Poisson's ratio (ν). The Poisson's ratio (ν) derived by wave measurement was computed in each stress levels on previously mentioned three geo-materials. The specimens were prepared by pouring the material through the air with controlling height for all cases and the compression and shear waves were measured from the lower pressure level (50kPa) to the higher pressure level (400kPa). The stiffness moduli are found approximately similar by both elastic wave measurement methods with the statically derived stiffness. The Poison's ratio is evaluated by both methods which are higher than statically determined value and the effect of stress level on Poison's ratio is examined.

1. INTRODUCTION:

Elastic wave measurements for studying the soil properties are being used in laboratory and field extensively during last few decades. The thoroughly studies of the propagated elastic waves are quite informative to investigate the soil properties. Several researchers have attempted to develop a reliable method for propagating elastic waves and its applications on science and engineering fields. One of the prominent applications is to evaluate the maximum stiffness moduli, mainly shear moduli of the geomaterials.The tangent moduli at very small strain level (within strain level 0.001%) is known as the small strain stiffness moduli which is assumed to be elastic, recoverable and independent of strain level and equivalent one determined measuring elastic waves through the material (Richart et al., 1970, Jardine et al., 1986, Burland 1989; Tatsouka and Shibuya 1992, Arroyo et al., 2003). Several laboratory techniques of measuring elastic wave measurements are being used in geotechnical laboratories. It is assumed that the Shirley and Hampton is pioneer, who developed the Bender Element transducer at first (1978). After its invention, it was extensively used in the various testing apparatuses like consolidometer or odometer (Jamiolkowski et at., 1995, Lee et al., 2010), triaxial apparatus (Viggiani and Atkinson, 1995; Jovicic et al., 1996; Hwang et al., 1998), Shear apparatus (Mulmi, S., 2008). Another method of measuring propagated waves in the specimen was proposed in the University of Tokyo around 2000 which is known as Trigger Accelerometer method (Ahn Dan and Koseki, 2002). In this method, a pair of triggers is firmly installed on the top cap which excites according to the function set on the function generator (various types of signal in terms of wavelet form and frequency can be excited as required). A pair of accelerometers (receiver sensors) is fixed on the surface of the specimen with known distance apart which senses the propagating signals in the specimen. Recently, the flat and disk shaped piezo electric transducer "Disk Transducer" has been developed in the Institute of Industrial Science, The University of Tokyo (Suwal and Kuwano, 2010). In spite of huge popularity, Bender element is not applicable to measure both compression and shear wave in a single specimen, where the later both methods are applicable to measure both compression and shear waves in a single specimen. Few researchers tried to measure both elastic waves combining bender element and compression plate on triaxial apparatus (Brignoli at al., 1996, Lee at



al.,2010,).Recently Bender-extender was developed which is used to measure both compression and Shear waves (Leong et al.,2009, Kumar and Madhusudhan., 2010).

The measurement of both compression and shear waves on single specimen make possible to evaluate the lateral deformation property (poisson's ratio) of the geomaterials dynamically. The effects of relative density and confining pressure on poisson's ratio was investigated in dry sands using Bender –extender and the variability of poisson's ratio was confirmed (Kumar and Madhusudhan., 2010). This study computed the small strain stiffness moduli as well as poisson's ratio by both Trigger accelerometer method and Disk Transducer method including static method on Toyoura sand, silica sand and Hime gravel and the outputs are compared among those methods. The statically derived poisson's ratios for Toyoura sand and Hime gravel are considered as 0.17 and 0.2 (reffering Hoque et al., 1996 and De Silva et al., 2004) in this study.

2. MATERIALS AND TESTING EQUIPMENTS:

2.1. MATERIAL USED:

Three sorts of granular geomaterials, Toyoura sand, Silica sand and Hime gravel, of varying grain size 0.2 mm to 2 mm were tested in study. Toyoura sand is fine-grained, uniformly graded sand, originated from Toyoura Beach area of Yamaguchi prefecture, Japan. Silica sand is one of the popular varieties of sand in the world. Silica sand is produced by degradation of quartz. The quartz crystals are broken down into small grains as Silica sand. The grain size of Silica sand varies from fine to coarse. In this study, Silica sand having mean diameter, D_{50}, 0.45mm was used. Hime gravel is poorly sorted, and the grain shape is angular. It was taken from Hime River, Otari, Kitaazumi, Nagano prefecture, Japan. It is derived from sandstone, chert, granite, sill, quartz etc. The pictures of these materials are shown in Figure 1 (A. Toyoura sand, B. Hime gravel and C. Silica sand). Physical properties including specific gravity, maximum and minimum void ratio, mean diameter and gradation curves are shown in Table 1 and Figure 2 respectively.

a. Toyoura sand b. Silica sand c. Hime gravel

Figure 1. Picture of used materials

2.2 . EQUIPMENTS:

The triaxial apparatus having facility to equip transducers/sensors for wave measurement was employed in this study. Broadly they are categorized as;

A. TRIAXIAL COMPRESSION TESTING MACHINE:

Small size, gear driven and strain controlled triaxial apparatus, as shown in Figure 3 was used for performing experiments. The axial loading system consists of an AC servomotor and a reduction gear system, electro-magnetic clutches and brakes. Stress and strain are precisely controlled by high speed computer.

Table 1. Physical and mechanical properties of tested materials

PHYSICAL AND MECHANICAL PROPERTIES	Toyoura sand	SILICA SAND	Hime gravel
Specific gravity, G_s	2.62	2.64	2.65
Maximum void ratio, e_{max}	0.946	0.787	0.709
Minimum void ratio, e_{min}	0.637	0.538	0.480
Mean Diameter, D_{50} (mm)	0.19	0.45	1.72

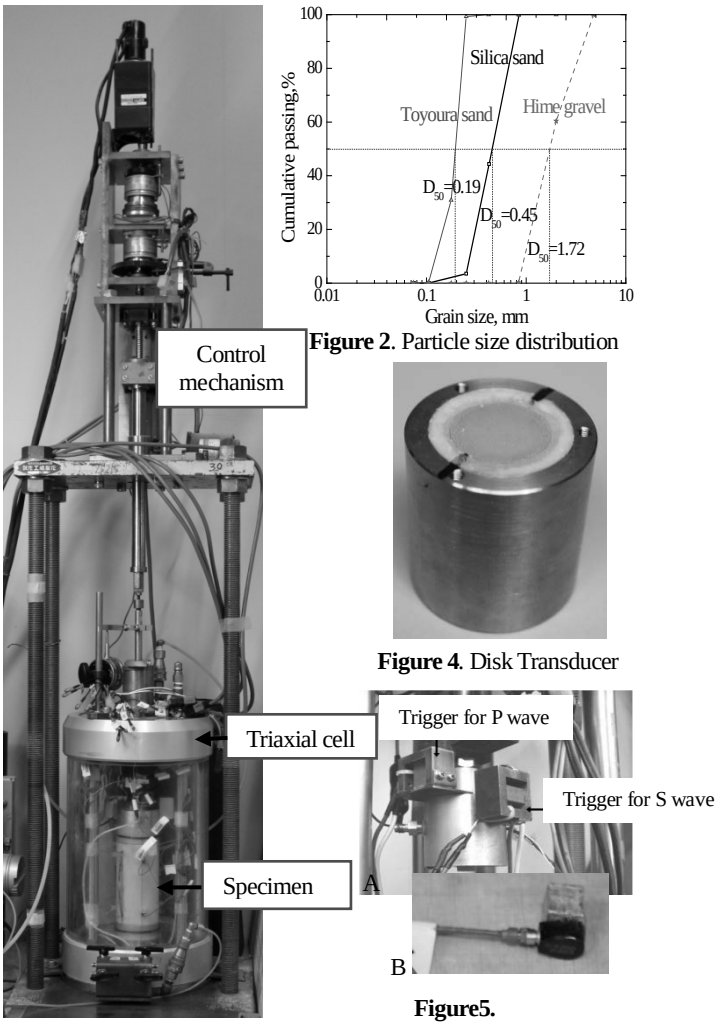


Figure 2. Particle size distribution

Figure 4. Disk Transducer

Figure 3.Triaxial apparatus

Figure5.
A. Triggers B. Accelerometer

B. TRANSDUCERS AND SENSORS:

Two techniques of wave measurement, Disk Transducer method and Trigger Accelerometer method, were applied in this study. The Disk transducer has been recently developed in this study. P-type element and S-type elements are referred for piezo-ceramic element enabling to generate P and S wave on the application of electric voltage. Disk shaped Φ20 mm with thickness 2 mm P-type and thickness 5 mm S-type piezo ceramic elements were used and firmly stuck forming PS-element. Then, it was assembled on metal housing as shown in figure 4 and embedded in top cap and pedestal. The Trigger Accelerometer method was developed

in the University of Tokyo (AnhDan and Kosesi, 2002).The picture of Triggers and Accelerometer are shown in Figure 5.

C. WAVE MEASUREMENT EQUIPMENTS:

Signal for transmitting wave was generated by a digital automatic function generator manufactured by "Tektronix Co. Ltd.". It can produce a maximum peak to peak voltage of 10 V and is capable of producing twelve kinds of different waveforms at frequency ranges of 0.001Hz to 25MHz. An amplifier, NF-HAS 4014 was used to amplify the input signal generated by the function generator before feeding it into the transducer. The oscilloscope HIOKI 8860-50 MEMORY HiCORDER was used to record and display waveforms of the transmitted and received signals.

3. SPECIMEN PREPARATION, TESTING PROCEDUCRES AND ANALYSIS:

3.1 SPECIMEN PREPARATION AND TESTING PROCEDURES:

Specimens of 75 mm in diameter and 150 mm in height were used for all tests. The specimen was prepared by air pluviation technique. The materials were poured through air keeping constant height of pouring to maintain constant density throughout the specimen. Lower pouring height was adopted for erecting loose specimen and higher for dense specimen. In this study, the loose specimens were prepared keeping falling height 20 cm and 80 cm height was maintained while preparing dense specimens. At first, the specimens were set up at an isotropic stress state of 25 kPa, and then the stress was increased to 50, 100, 200 and 400kPa in normally consolidated phase. For over consolidated phase, stress level was descended from 400 kPa to 50 kPa as shown in Figure 6. Specimen was kept in each stress state for sufficient time period to dissipate the creep effect. 11 cyclic loadings with peak to peak strain amplitude of 0.001% were applied in vertical direction and another creep stage was maintained for conducting wave measurement.

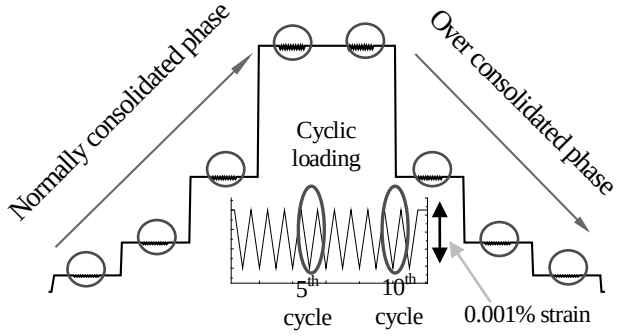

Figure 6. Loading history of experiment

3.2 ANALYSIS PROCEDURES:

Generally, two sorts of analysis were executed namely static and dynamic. Static means result was computed by relation of deformation and stress during small strain cyclic loadings. Deformation was measured by local deformation transducers (LDTs) developed by Goto et al (1991), which can measure local strain in higher accuracy and free from bedding errors. Cyclic (static) Young's modulus (E_{cyc}) was derived by fitting a straight line on the stress-strain plot. The stress-strain relation of 5th cycle and 10th cycle were utilized to evaluate E_{cyc}. The typical plot of stress strain relation is shown in Figure 7. The average results of 0.001% strain amplitude were obtained at each stress state. This stiffness is named as the statically measured stiffness modulus in this study. Stiffness calculated by wave measurement is called as the dynamically measured stiffness modulus. Stiffness was derived by relating stiffness, density and velocity of propagating wave. The Disk Transducers were centrally installed in the top cap and pedestal where as the Accelerometers were fixed on the lateral surface of the specimen. The nature of the wave propagation was schematically shown in figure 8 (a. Disk Transducer method, b. Trigger Accelerometer method). The confining pressure (stress level or cell pressure) employed during experiments varies from 50 kPa to 400 kPa. The cell pressure is applied to simulate (reproduce) the real field condition. It is considered that the cell pressure is working as the confinement in the real field and the propagated waves through the specimen are analyzed as constrained involving no lateral deformation perpendicular to the direction of propagation whether they are measured by centrally installed transducers or sensors fixed at lateral surface. Applying such higher stresses at small specimen (Φ=75mm and 150mm height), the variation on the degree of confinement at center of specimen and surface of specimen is very small and neglected in this study. Constrained vertical modulus (M) could be achieved by Equation (1). The constrained modulus was then converted to the unconstrained modulus using the Equation (2).

$$M = \rho . V_P^2 \tag{1}$$

$$E = \frac{M(1-2\nu)(1+\nu)}{(1-\nu)} \tag{2}$$

$$G = \rho . Vs^2 \tag{3}$$

$$G = \frac{E}{2(1+\nu)} \tag{4}$$

$$\nu = \frac{(0.5V_p^2 - V_s^2)}{V_p^2 - V_s^2} \tag{5}$$

$$f(e) = \frac{(2.17-e)^2}{1+e} \tag{6}$$

[Where, V_p is compression wave velocity, V_s is shear wave velocity, ρ is unit mass of specimen, E is the Young's Modulus ,G is the shear Modulus, e is the void ratio of specimen and ν is the Poisson ratio.]

The dynamically obtained shear moduli are computed measuring shear waves directly as the Equation (3). The relation of Young's modulus and Shear modulus is established by Equation (4) which is used for both static method applying small strain cyclic loadings and wave

measurement methods. One of the benefits of measuring both compression and shear wave in an identical specimen is it permit to evaluate the Poisson's ratio through wave measurement technique directly. Combining the Equations (1), (2) and (3), the Equation of Poisson's ratio in terms of velocity of compression and shear wave is derived (Equation (5)). The densities of specimens were different in tests, so, the void ratio function proposed by Hardin and Richart (1963) was used to eliminate the effects of various densities (void ratio) of specimens. Among the various void ratio functions, Equation (6) proposed for granular materials is used in this study.

a. SIGNAL INTERPRETATIONS:

The output signals generated by receiver transducer are directly fed to the oscilloscope in Disk Transducer method. Any amplifier, signal modifier and filters were not adopted in between receiver transducer and oscilloscope. So, the recorded data were found sometime containing system compliances. It was tried to remove employing Low pass filter. The frequency of the system noise was determined prior to the feeding the signal in the transmitter transducer. The system noises were found to be in the ranges of 22 kHz to 25 kHz. Then the signals were modified as the signals were allowed passing which contains lower frequencies than this. The typical plots of the input, output (recorded) and filtered signals in time series were shown in Figure 9 (P-type) and Figure 10 (S-type) respectively..

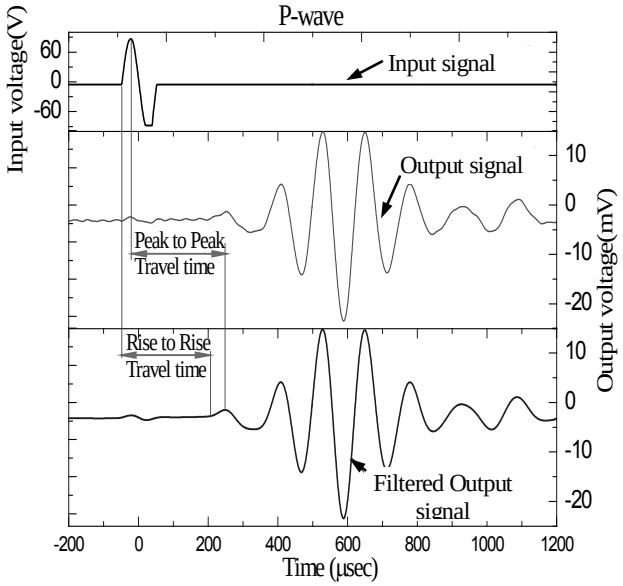

Figure 9: Definition of Travel time for compression wave

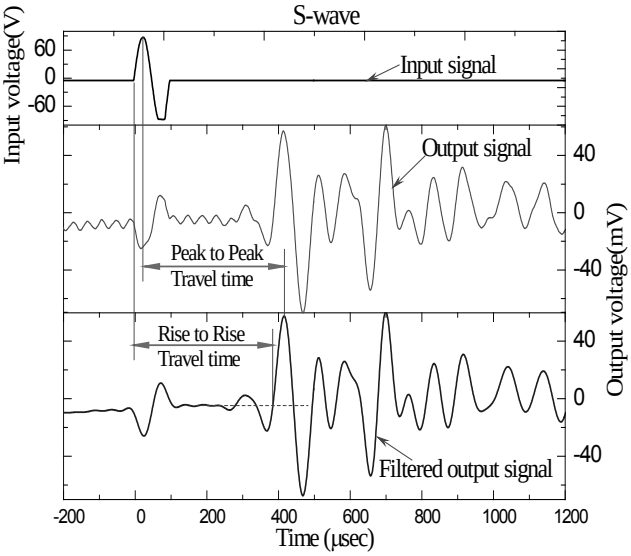

Figure 10:Defination of travel time for shear wave

The compression waves are evaluated as the first sense (deflection) of the signal on time domain series is the real arrival of the compression waves. Figure 9 shows the typical compression wave achieved on this study. The travel time are dealt considering the time gap between the rising of the

input signal to the rising of output signal (T_{rtr}) and the peak of the input signal to the peak of the output signal (T_{ptp}) which are clearly defined on the Figure 9. Interpretation of the shear waves is not still clear and several opinions are presented by various researchers about interpretation techniques. Many studies showed that the first deflection of the shear wave signal may not correspond to the arrival of the shear wave (Mancuso and Vinale, 1988). Disturbances and reflected compression wave travels in the speed of compression wave are arrived at first which create ambiguity on determination of the real shear wave arrival. In single sinusoidal excitation, the rising to rising travel time is defined as the distance from the rising of input signal to the first zero crossing point on the time domain series of the output signal following the recommendation by Jovocic (1996). This zero baseline correction is imposed to minimize the effect of the near field. The criteria employing to determine the travel times based on rise to rise of signals and peak to peak of signals are displayed on Figure 10. The charge amplifier was adopted in Trigger Accelerometer method. So, well informative waveforms are obtained directly. The travel time was determined considering rise of signal at upper Accelerometer to rise of signal at lower Accelerometer

Table 2: List of tests

Test no.	Material	Transducer used	Specimen condition	Relative density (%)	Input Voltage (V)	Input wave	Input frequency range (kHz)
1	Toyoura sand	DT& TA	Dry	56	± 93	sine	2.0 – 30.0
2	Toyoura sand	DT& TA	Dry	92	± 93	sine	2.0 - 30.0
3	Hime gravel	DT& TA	Dry	68	± 93	sine	2.0 – 20.0
4	Hime gravel	DT& TA	Dry	88	± 93	sine	2.0 – 20.0
5	Silica sand	DT& TA	Dry	78	± 93	sine	2.0 – 30.0
6	Silica sand	DT& TA	Dry	99	± 93	sine	2.0 – 30.0

4.0 TEST RESULTS AND DISCUSSIONS

Basically sands are classified according to grain sizes as fine sand (0.125-0.25 mm), medium sand (0.25- 0.5 mm) and coarse sand (0.5-1mm). The material having grain size around 2 mm is called very coarse sand or fine gravel (The international sand collector society, AASTO, USDA, USC). The tested materials, Toyoura sand represents the fine grain material, Silica sand represents the medium grain material and Hime gravel stands for the coarse grain material. The information of the tests is listed on Table 2, in which, the information related to wave measurement is expressed in respect to Disk Transducer method. The wave measurements were conducted inputting the signal of low frequency to higher frequency. Among these frequencies, the waveforms and results of dominant frequency (the frequency at which optimized outputs are achieved) is found out and the analysis is made based on the output of that input frequency.

The tests were performed in loose and dense condition. The input frequency 15.6 kHz was found to be good to propagate elastic waves through Disk Transducers (analyzed by FFT-Fast Fourier Transformation) on toyoura sand specimen. The received signals by P-type receiver while exciting through P-type transmitter elements at various stress level are shown in Figure 11. A single sinusoidal wave of 15.6 kHz was fed through function generator and the received wave was stacked for 100-200 times and the average response was recorded on oscilloscope. The recorded waves were proceeded applying low pass filter and then they are appeared as shown in Figure 11. The waveforms obtained at lower to higher stress levels are displayed from top to bottom and the input signal is shown in lowest of them. In this plot, the signals are plotted in time domain series (microsecond), the input signal is presented in volt and outputs are in milivolt. As discussed in previous, the travel time is determined in each stress level according to rise to rise of signals and peak to peak of signals. Similar waveforms were obtained on the other materials also. The Typical Shear waveforms obtained on Hime gravel are shown in figure 12. The output signals achieved on various stress level are plotted on time domain series which are resulted inputting a single sinusoidal wave of frequency 10.0 kHz. The Waveforms obtained on toyoura sand by Trigger Accelerometer method are shown in figure 13. The Compression waveform at lower stress level and the Shear waveform at higher stress level are shown Figure 13 A. and 13 B. respectively.

4.1 **STIFFNESS MODULI:** The stiffness moludi of the materials are the major parameters used in engineering applications. Currently the facilities of precise measurement of deformation are possible in laboratory. This study employed the LDT for measuring very small scaled deformations. Based on the stress-strain relation during small strain cyclic loadings, statically the young's moduli are calculated and converted into the shear moduli. Dynamically based on wave measurement, the stiffness moduli are determined. The stiffness moduli (Young's and Shear) are determined in both Disk Transducer method and Trigger Accelerometer method. Specimens having lower void and higher void (dense and loose) were tested on this study. The direct comparison of outputs of tests from various density is meaningless due to the outputs are highly influenced by the specimen's density. The stiffness moduli are significantly affected by the density or void ratio of the specimen in granular materials. It needs to nullify for comparing the results of various densities. Many researchers are using the void ratio function specified in Equation (6) for effective nullification of on granular materials with round shape particles, which is also used in this study. The outputs of various modes of measurement are normalized by the Equation (6).The normalized shear moduli are plotted against the normalized statically derived shear moduli in figures 14 – 16 (Figure 14: Results on Toyoura sand, Figure 15: Results on Hime gravel and Figure 16: Results on Silica sand). Both horizontal and vertical axes are expressed in MPa. The stiffness moduli derived by various modes of measurement are found showing approximate equivalency among those modes of wave measurement including static method. In those plots, the direct comparisons of the results amongst different densities as well as the results amongst the several modes of measurement are possible. The degree of scattering of the results in each stress levels reflecting the deficiencies on measurement systems including the reliability of void ratio functions for those materials.

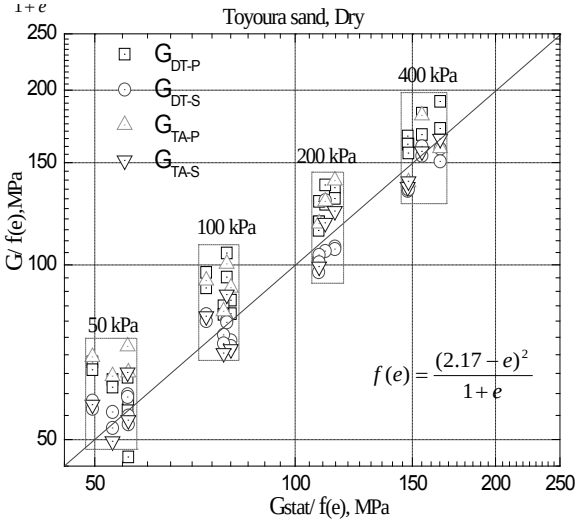

Figure 14 Results on Toyoura sand

These results showed the used void ratio function (equation 6) is effective to nullify the results and the results by both dynamic measurement techniques are equivalent to the static method. The results achieved measuring compression and shear waves are separately displayed in each plot for both Disk transducer and Trigger Accelerometer methods. The results obtained measuring compression waves are found to be higher than measuring shear waves in all stress levels (50kPa to 400kPa).

4.2 **POISSON RATIO**: Poisson's ratio evaluation of the geo-materials in laboratory needs great care and labors. Precise local deformation measuring transducer, LDT was employed to determine vertical and lateral deformations in static method. The success of measuring both compression and shear waves at each stress level in an identical specimen allows calculating the Poisson's ratio in terms of velocity as mentioned in Equation (5). The Poisson ratio is calculated on each test at loose and dense conditions. Figure 15 is the Poisson ratios obtained on Toyoura sand in loose and dense specimen conditions derived by various modes of measurements. The open symbols are representing the results of loose specimen condition and cross symbols are of dense specimen condition. The squares are results obtained by Disk Transducer method and circles are of Trigger Accelerometer method. Similar to Toyoura sand, the results obtained on Hime gravel and Silica Sand are plotted on Figure 16 and 17 respectively (the meaning of symbols also similar).

5. CONCLUSIONS:

The small strain stiffness measurement employing the wave measurement techniques were conducted on three granular geo-materials on loose and dense condition at normally and over consolidated stress conditions successfully and results were compared among them. Observing the results, the approximately equivalent stiffness moduli are found through both dynamic methods of measurement and to be comparable with the statically determined results. Poisson ratios are evaluated by both methods of elastic wave measurement at various stress levels which are found to be slightly higher than statically determined value on toyoura sand and Hime gravel. The statically determined results are referred from the previous works by Hoque et al., 1996 and De Silva et al. 2004) for Toyoura sand and Hime gravel respectively.

Abstract: Undrained cyclic torsional shear tests on loose Toyoura sand specimens subjected to single amplitude shear strain exceeding 50% were analyzed to study the effects of initial static shear on the strain localization properties of liquefied sand. Non-uniform specimen deformation was observed at strain levels higher than 20%. The limiting value of half of double amplitude ($\gamma_{DA}/2$) and single amplitude (γ_{SA}) shear strains, at which strain localization began during undrained cyclic loading, were evaluated by looking at the change in the deviator stress response as well as at the change in the strain accumulation properties. In the case of stress-reversal loading tests, it was found that the greater the static shear level the lower $\gamma_{DA}/2$; conversely, γ_{SA} was rather constant. These features suggested that, to define the limiting value of strain to initiate the strain localization of sand with initial static shear, γ_{SA} is a much more appropriate parameter than $\gamma_{DA}/2$. The limiting strain value of γ_{SA} was found to be of 23-28%. As long as the liquefied soil layer remains in uniform deformation, γ_{SA} values may be used in estimating the maximum amount of ground displacement due to liquefaction in natural and artificial slopes of sandy deposits.

1. INTRODUCTION

Following large-magnitude earthquakes (e.g., 1964 Great Alaskan, USA; 1964 Niigata, Japan; 1983 Nihonkai-Chubu, Japan; 1995 Kobe, Japan; etc.) extremely large horizontal ground deformation could be observed either in gentle sloped ground (Hamada et al., 1994; among others) or in level ground behind retaining walls (Ishihara et al., 1996; among others), resulting in severe damage to buildings, infrastructures and lifeline facilities (Hamada et al., 1988).

With the purpose of deeply investigate the large strain properties of liquefied sands, Kiyota et al. (2008) performed a series of undrained cyclic torsional shear tests on Toyoura sand specimens up to a double amplitude shear strain of about 100%. They found that there is a limiting value of double amplitude shear strain to initiate strain localization which increases with a decrease in relative density of the specimen.

Moreover, Kiyota et al. (2010) showed that the limiting value to initiate strain localization observed in torsional shear tests are consistent with the maximum amounts of liquefied-induced ground displacement observed in previous shaking table model tests (Yasuda et al., 1992; etc.) and most of the relevant case studies (Hamada et al., 1996; etc.). These features are reasonable considering the reduction in the mobilized cyclic shear stress in liquefied soils due to degradation of shear resistance.

By employing a torsional shear apparatus capable of achieving large torsional deformation, Chiaro et al. (2011) investigated the role which the static shear play on the large deformation behavior of Toyoura sand during undrained cyclic shear loading by performing a series of undrained cyclic torsional shear tests on loose specimens up to single amplitude shear strain of about 50%. In this paper, the test results presented by Chiaro et al. (2011) are analyzed in order to evaluate the correlation between the extent of initial static shear and the limiting value of both single and half of double amplitude shear strain required to initiate strain localization.

2. DEFORMATION OF SAND SPECIMEN WITH INITIAL STATIC SHEAR

Details of the employed hollow cylindrical torsional shear apparatus and the tested material have been already described by Chiaro et al. (2011). Thus, in this paper only the results from undrained cyclic torsional shear tests on loose saturated Toyoura sand specimens subjected to initial static shear will be briefly shown. It

should be noted that during the process of undrained cyclic torsional loading the vertical displacement of the top cap was prevented with the aim of simulating as much as possible the simple shear condition that ground undergoes during horizontal excitation. In these tests, three types of cyclic loading pattern were employed: stress-reversal, intermediate and non-reversal, as schematically shown in Fig. 1.

Typical test results are presented in Figs. 2 through 4, in terms of effective stress paths and stress-strain relationships. Specimen deformation at several states as numbered 1 through 4 in Fig. 2, Fig. 3 and Fig. 4 are shown in Photos 1, 2 and 3, respectively.

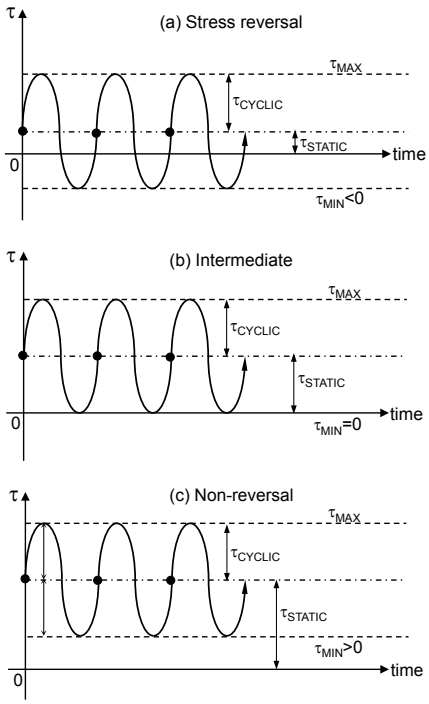

Figure 1. Schematic illustration of cyclic torsional shear loadings (after Chiaro et al., 2011).

2.1 Stress-reversal loading tests

As shown in Fig. 2, in the case of stress-reversal loading test (e.g., Test 3), cyclic mobility was observed in the effective stress path, where the effective stress recovered repeatedly after reaching the state of zero effective stress (i.e., full liquefaction); it was accompanied with a significant development of shear strain as indicated by the stress-strain relationship.

Photo 1 shows specimen deformation observed for this test. At state 1 (γ = 12 %), the deformation was almost uniform except for the regions close to the pedestal and the top cap that are affected by the end restraint; the outer membrane appeared slightly wrinkled. At state 2 (γ = 22 %), the outer membrane was visibly wrinkled; in the regions near the top cap the deformation of the specimen started to localize due probably to water film formation (Kokusho, 1999).

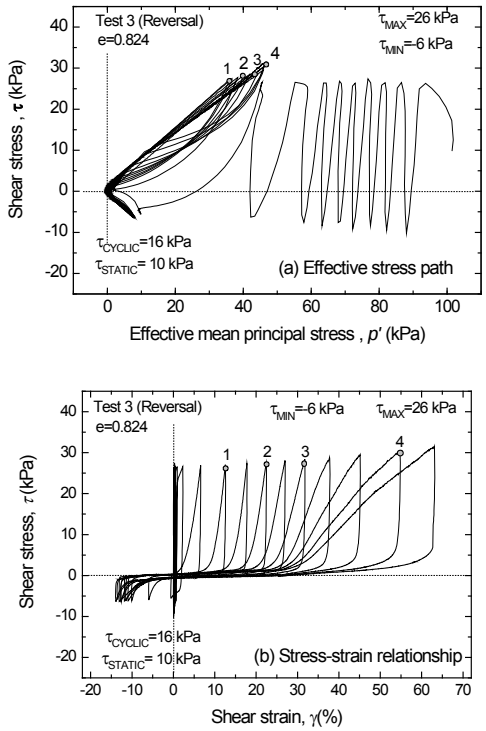

Figure 2. Typical stress-reversal loading test results.

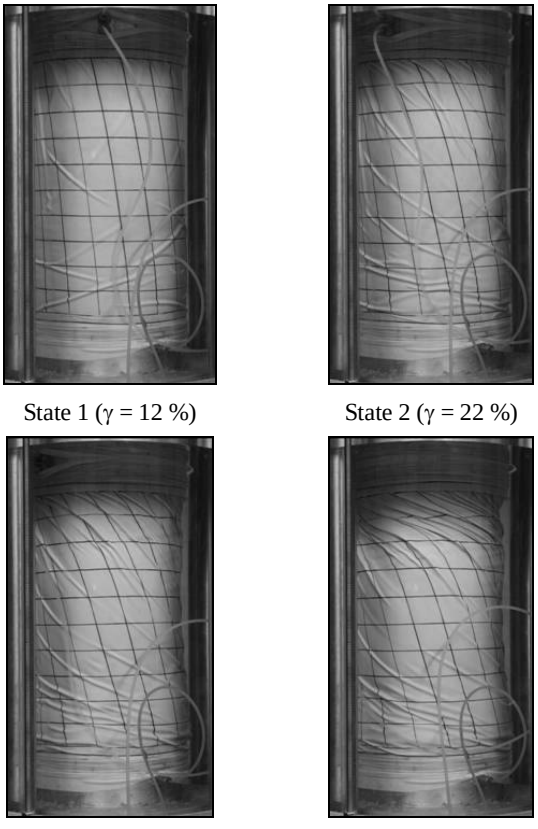

Photo 1. Specimen deformation at states 1 through 4 shown in Fig. 2.

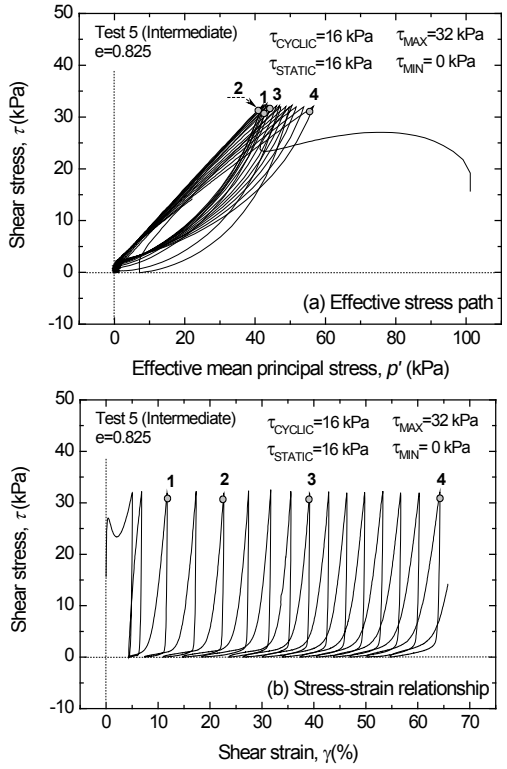

Figure 3. Typical intermediate loading test results.

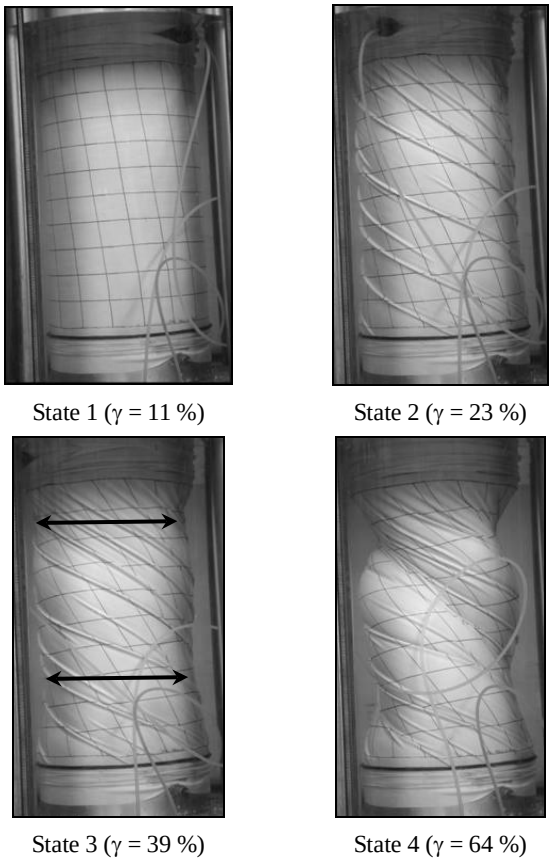

Photo 2. Specimen deformation at states 1 through 4 shown in Fig. 3.

At state 3 (γ = 31 %), the localization of the specimen deformation developed clearly in the upper part of the specimen. On the other hand, in the bottom part the uniformity of the specimen deformation was maintained even many wrinkles appeared. At state 4 (γ = 54 %), the specimen was almost twisted near the top cap.

2.2 Intermediate loading tests

Fig. 3 shows the case of intermediate loading test (e.g., Test 5). This type of test shows behavior that is similar to that of reversal case, in the sense that after reaching a fully liquefied state, progressive large deformation is developed while showing cyclic mobility.

However, it can be distinguished from the reversal one by looking at the specimen deformation as shown in Photo 2. At state 1 (γ = 11 %), the deformation was almost uniform except for the regions close to the pedestal and the top cap that are affected by the end restraint. At state 2 (γ = 23 %), the outer membrane was extensively wrinkled. Yet, it seems that the type of wrinkle observed in this test can have a different meaning with respect to the one observed in the reversal test described above; in fact, in this test, the extent of deformation before and after each wrinkle changed; this behavior suggests that several shear bands were formed in the specimen. At state 3 (γ = 39 %), the specimen reduced its diameter at several locations, as indicated by the arrows, due probably to the formation of shear bands. Finally, at state 4 (γ = 64 %), the specimen was completely twisted.

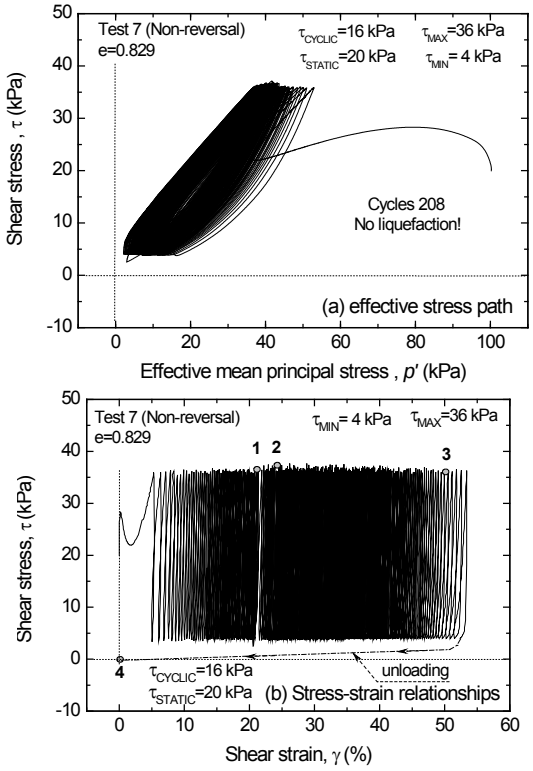
2.3 Non-reversal loading tests

Fig. 4 illustrates the case of non-reversal loading test (e.g., Test 7). The state of zero effective stress was not achieved even after applying 208 cycles of loading; however, large shear strain exceeding 50% was reached, and the formation of a single spiral shear band could be observed.

Specimen deformation observed for this test is shown in Photo 3. At state 1 (γ = 21 %), the deformation was rather uniform except for the regions close to the pedestal and the top cap that are affected by the end restraint. At state 2 (γ = 25 %), the outer membrane was wrinkled at several locations due to local drainage. At state 3 (γ = 50 %), the outer membrane was extensively wrinkled from the bottom to the top. At state 4 (γ = 0 %, after test), when the zero stress state was recovered while keeping undrained condition, formation of a single spiral shear band could be observed (dotted lines).

3. STRAIN LOCALIZATION DURING CYCLIC LOADING

Tatsuoka et al. (1986) performed drained monotonic torsional shear tests on hollow cylindrical specimens, while keeping the σ_v' and σ_h' constant. They reported that the vertical strain was accumulated on the extension side due to the mobilization of positive dilatancy, and it was



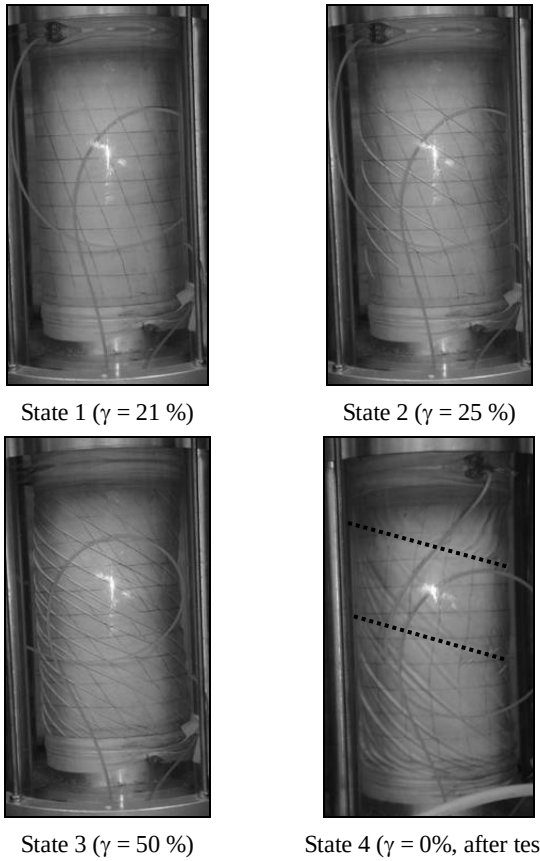


Figure 4. Typical non-reversal loading test results.

reduced suddenly when the shear band was formed in the specimen.

Kiyota et al. (2008) performed undrained cyclic torsional shear tests on saturated Toyoura sand, similar to those presented in this study, but without applying any initial static shear. In their tests the initiation of strain localization was defined by looking at the change in the response of the deviator stress q (= σ_v'- σ_h') which was measured during the undrained cyclic torsional shear loading while preventing any vertical displacement of the top cap.

The behavior that was observed during drained monotonic torsional shear tests by Tatsuoka et al. (1986) is consistent with the change in deviator stress observed in undrained torsional shear tests; therefore, Kiyota et al. (2008) considered the state at which the amplitude of q decreases as the limiting state to initiate formation of shear band and thus strain localization. Furthermore, it was accompanied with an increase in the shear increment of single amplitude shear strain ($\Delta\gamma_{SA}$). As a result, these features imply that the stress-strain characteristics of the specimen were changed by the formation of shear band and the initiation of strain localization in the specimen.

In the current study, non-uniform specimen deformations were observed at strain levels higher than 20%. Yet, similarly to Kiyota et al. (2008), the initiation of strain localization could not be clearly defined on the basis of visual observation; hence, to address this issue and evaluate the effects of initial static shear on the specimen deformation behavior, the attempt made by Kiyota et al. (2008) was employed. Consequently, from the analysis of deviator stress responses and stress-strain relationships, as typically shown in Figs. 5 and 6, respectively, the following two states were defined: i) State A: the state at which q suddenly decreases; and ii) State B: the state at which a change in the strain accumulation properties was observed.

The values of shear strain measured at state A and state B, respectively, are shown in Fig. 7 and Fig. 8. They were evaluated in terms of half of double amplitude shear strain ($\gamma_{DA}/2$), as employed by Kiyota et al. (2008), and single amplitude shear strain (γ_{SA}) which Chiaro et al., (2011) used to describe the effects of static shear on the deformation properties of sand.

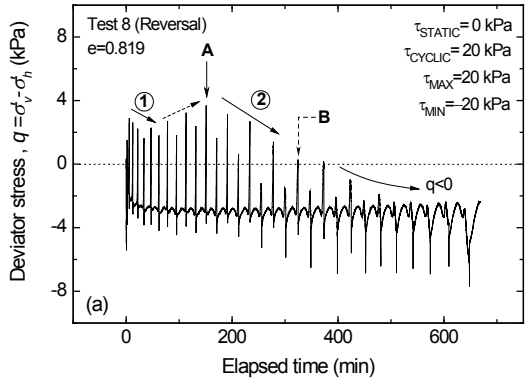

Figure 5. Change in deviator stress response based on the time history of deviator stress.

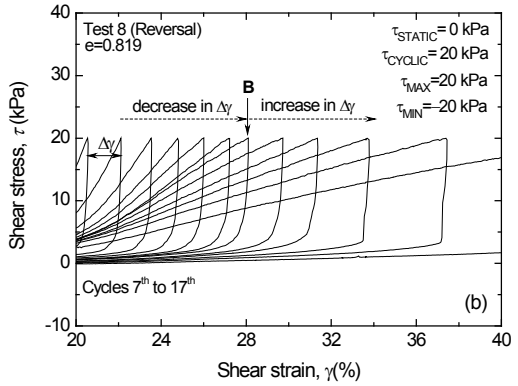

Figure 6. Change in shear strain accumulation during cyclic loading based on the stress-strain relationship.

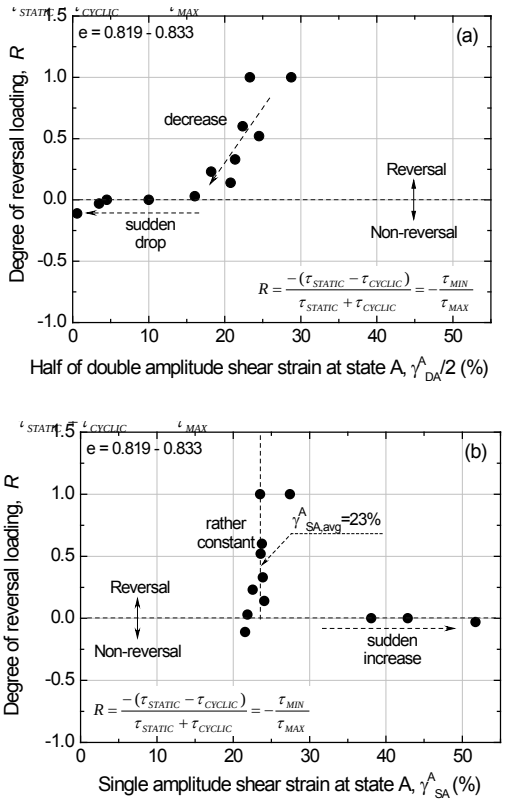

Figure 7. Change in deviator stress response at state A evaluated in terms of: (a) $\gamma_{DA}/2$; and (b) γ_{SA}.

In Fig. 7 and Fig. 8, to consider the combined effects of the initial static shear with the cyclic shear stress, the shear strain is plotted against the degree of reversal loading as defined by Yoshimi and Oh-oka (1975). One can see that in the case of stress-reversal loading tests, the greater the static shear stress (τ_{static}) is, the lower the $\gamma_{DA}/2$ value is; on the other hand, a sudden drop in the value of $\gamma_{DA}/2$ is observed in case of intermediate and non-reversal loading tests. In contrast, the γ_{SA} value is rather constant in the case of stress-reversal loading tests, which sudden increases in the case of intermediate and non-reversal loading tests.

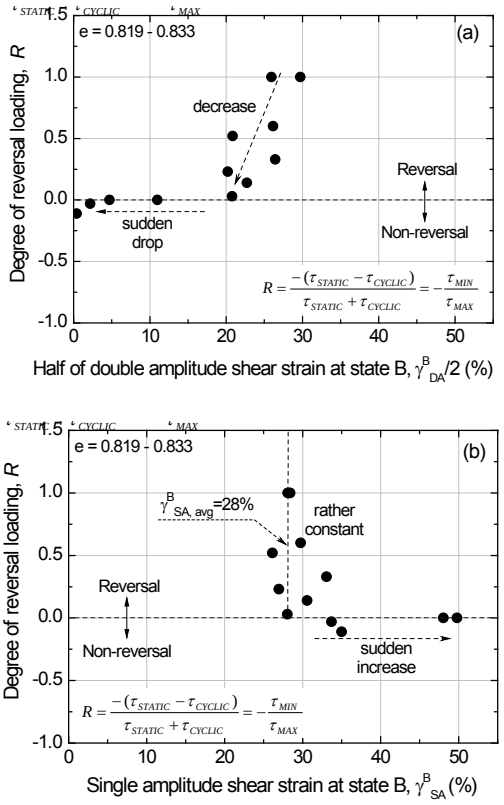

Figure 8. Change in shear strain behavior at state B evaluated in terms of: (a) $\gamma_{DA}/2$; and (b) γ_{SA}.

Based on these considerations, the shear strain required to cause the strain localization of sand specimens subjected to stress-reversal loadings was defined in terms of single amplitude shear strain γ_{SA}. Therefore, it was defined:

(i) $\gamma^A_{SA,avg} \cong 23$ %, which represents the state at which q suddenly decreases (state A);

(ii) $\gamma^B_{SA,avg} \cong 28$ %, which corresponds to the state at which a change in strain accumulation takes place (state B).

As mentioned above, the drop in q implies that the stress-strain characteristics of the specimen were changed by the formation of shear band(s) and the initiation of strain localization in the specimen. Yet, in this study, in several cases, state A was not easy to define (e.g., when the change in the deviator stress amplitude was not unique as shown in Fig. 5 by numbers ① and ②) and thus different evaluations may be given among different researchers. On the contrary, the change in stress accumulation at state B is the direct result of the specimen strain localization (i.e., formation of shear band), and it could be unequivocally evaluated in all the tests. The above observations suggest that, even if slightly over-estimated, the limiting state to initiate the strain localization in the specimen can be defined in terms of γ^B_{SA} which is the direct evidence of formation of shear band(s) and can be clearly determined.

As well, by analyzing the deviator stress responses, it was noted that after achieving state B, the deviator

stress becomes negative ($q < 0$) in the case of reversal loading tests, as typically shown in Fig. 5. This peculiar behavior would be associated with the full development of the shear band into the specimen. The latter behavior was not observed in case of intermediate and non-reversal loading tests.

4. DISCUSSION

As shown in Figs. 7(b) and 8(b), in the case of intermediate and non-reversal loading tests, the limiting values of single amplitude shear strain γ_{SA} evaluated on the basis of a change in deviator stress response or a change in strain accumulation properties, increases drastically up to about 50%, while the visual observation show that non-uniform deformation of specimens appears at shear strain level of about 20-30%. This suggests that the method may be inappropriate in evaluating the limiting value of shear strain to initiate strain localization, either in the case of intermediate or non-reversal stress loading tests. The authors are currently verifying the performance of other methodologies to set in a better and comprehensive understanding this issue.

5. CONCLUSIONS

The purpose of this paper is to investigate the effects of initial static shear stress on the limiting value of shear strain at which strain localization appears during undrained cyclic torsional shear tests. Therefore, a series of undrained cyclic torsional shear tests, carried out on saturated loose Toyoura sand specimens up to reaching a single amplitude shear strain exceeding 50%, was analyzed.

Non-uniform specimen deformation could be observed at higher strain levels; however, the initiation to strain localization could not be defined on the basis of visual observations. The limiting values of half of double amplitude ($\gamma_{DA}/2$) and single amplitude (γ_{SA}) shear strains were evaluated from the test results by looking at the change in the deviator stress response as well as at the change in the strain accumulation properties.

In the case of stress-reversal loading tests, it was found that the greater the static shear level is, the lower the $\gamma_{DA}/2$ value is; on the other hand, the γ_{SA} value is rather constant. These features suggested that to define the limiting value of strain to initiate the strain localization of sand specimens subjected to initial static shear, γ_{SA} is a much more appropriate parameter than $\gamma_{DA}/2$ which usually is employed in previous studies. Finally, the limiting strain value measured in terms of γ_{SA} was evaluated to be in the range of 23-28%. As long as the liquefied soil layer remains in uniform deformation, these limiting values may be used in estimating the maximum amount of ground displacement due to liquefaction in natural and artificial slopes of sandy deposits.

On the other hand, it was recognized that in the case of intermediate and non-reversal loading tests, the limiting value of shear strain to initiate the strain localization cannot be defined on the basis of a change in deviator stress response or a change in strain accumulation properties; therefore alternative methodologies should be explored for a comprehensive understanding on the effects of initial static shear on the shear strain localization characteristics of sands.

Abstract: We have obtained dynamic characteristics of the surface soils at eight places in Lima, Peru; specifically we estimated the shear-wave velocity profile. The method we used was the inversion of dispersion curves calculated from array measurements. Small and large arrays of microtremors were carried out, and a new type of sensor was introduced for the large array measurement. Important results are the relative shallow stiff soil layer in the area classified as alluvial gravel deposit, that covers most of the area of Lima city; and the apparently deep soft soil layer in places identified as VSV and CMA. In these last places, it is recommended to complete the analysis with large array measurements.

1. INTRODUCTION

This study is part of the project "Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru", in which Japanese Government represented by Chiba University and the Peruvian government represented by the National University of Engineering (UNI) are working together with the objective to estimate seismic risks, hazards and vulnerabilities in Lima, the capital of Peru, and two other cities of the country. In particular, the results of this study will focus on Lima city only.

Lima is situated in the central coast of Peru, bordered by the Pacific Ocean, in a zone of high seismic activity known as, the Ring of Fire.

Due to the high seismicity of this area and to the rapidly growing urbanization, a study of the soil conditions that characterize areas of low or high probability to be affected by earthquakes is of great importance, specially in places like Lima that have scarce information of deep soil structures.

In this context, this study aims to obtain a primary idea of the Lima's soil structure to the depth extending to the bedrock, which will make possible the analysis of the dynamic characteristics of the surface soils of Lima

To accomplish this objective, microtremor array measurement campaigns were carried out at 8 places of the city; new long-period sensors of microtremor were introduced as part of the technology enhancement politics.

2. AREA OF STUDY

The study was developed over the Lima metropolitan area; where 8 points of measurements were located. Table 1 shows a list of these points with details of their exact location.

Figure 1 shows a map of the Lima's surface soil distribution (estimated in 2005) and the distribution of the microtremor array measurement points.

3. SOIL CONDITION AND BORING DATA

As it can be seen from Figure 1, most of Lima area is covered by alluvial gravels that are found at few meter depth,; however, there are concentrated eolian, clays and

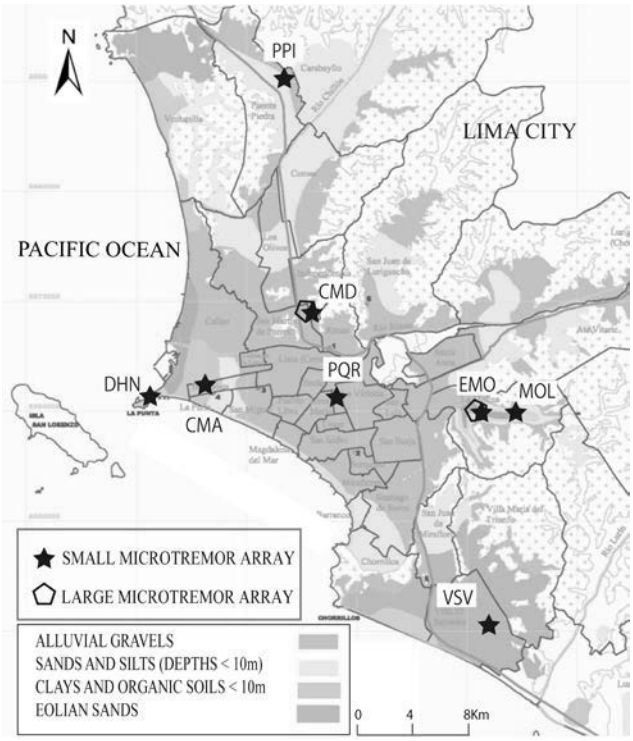

Figure 1. Soil distribution map (CISMID, 2005) and location of microtremor arrays.

silts deposits, of which depths to the base rock are in some cases unknown .

A typical soil profile of the alluvial gravel deposit is shown in Figure 2. The profile corresponds to a soil pit near the array set named CMD. In Lima, soil pits are more popular than SPT explorations because the stiffness of the soils in many areas does not allow the conduction of SPT explorations.

The majority of boring data available in Peru has a similar pattern of profile at CMD, it means the gravel is shallow and the depth of exploration is about 3m.

4. MICROTREMOR ARRAY MEASUREMENTS

One of the reasons to conduct array measurements was the limited depth in the available boring data and the practical way to perform it.

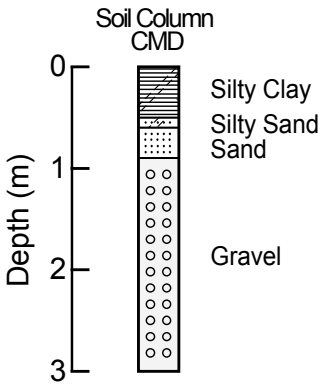

Figure 2. Soil Column CMD (collected data E13 of Rimac district in the study of CISMID, 2005) located at the National University of Engineering.

Two measurement campaigns were carried out, the first consists of 8 sets of small arrays (Figure 1); each set is made of linear arrays of 0.5 and 2m sensor distance, and circular arrays of 10, 20 and 45m radius.

The second campaign consists of 2 sets of large arrays, each set made of circular arrays of 100, 200, 400 and 800m radius.

4.1 Implementation of microtremor sensors

Two types of sensors of microtremors were introduced to Peru through this project. One was the well-known GEODAS sensor (with natural period of 1 second), and the other was a sensor produced by Tokyo Sokushin company with a natural period of 5 seconds.

5. ANALYSIS OF RESULTS

Array set CMD was chosen in this study to be the representative array set; in consequence we will show and comment the detailed procedure to come up with its shear wave velocity profile.

We used two methods to construct the dispersion curve; the high resolution F-k method proposed by Capon in 1979, and the Centerless Circular Array (CCA) proposed by Cho et al in 2006.

5.1 F-k spectrum

The F-k method uses the cross-spectrum between each pair of sensors as a factor to compute the F-k power spectrum. This can be seen with the formula of the F-k spectrum

$$P'(k_x, k_y, f) = \left[\sum_{n,m=1}^{K} q_{mn}(f) \cdot \exp\left\{-i2\pi\left[k_x(x_n - x_m) + k_y(y_n - y_m)\right]\right\} \right]^{-1}$$

where K is the number of channels, k_x is the wave-number in the x-direction, and k_y is the wave-number in the y-direction, and f is the frequency.

$q_{mn}(f)$ is the inverse of a Hermitian matrix whose elements are formed by the cross spectrum between channels m and n. (x_n, y_n) are the coordinates of the sensor n, and (x_m, y_m) are the coordinates of sensor m.

Since the cross spectrum is an important factor in the computation of the F-k spectrum, it is necessary to verify the cross-spectra to see if there is a good correlation between the signals. In general a well correlated cross-spectrum curve is a smooth descending or ascending curve from 0 to 360 degrees or vice verse. If the curve follows this trend the F-k spectrum is verified. Sometimes more than one smooth curve appears, in this case, in the period domain, the curve to verify should be the first at the right side. For example, in Figure 3(a) there are two curves but the one to verify is the curve from 0.025 to 0.07 s, and in Figure 3(b) the curve is from 0.2 to 0.4 s. We will expect that in the dispersion curve for the period ranges mentioned, the curve shows continuity for the array of 10 and 200m respectively.

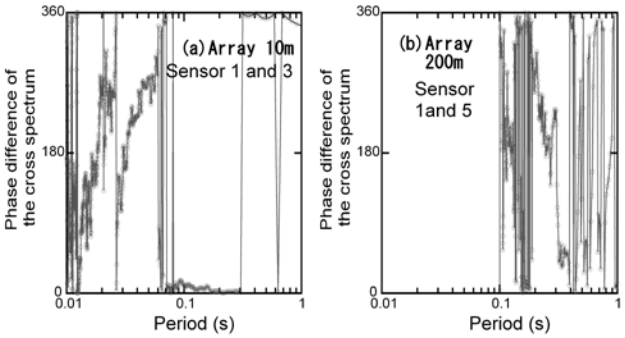

Figure 3. Cross spectra of CMD , (a) For the array of 10m, (b) for the array of 200m.

Figure 4 shows F-k spectra for different array sizes and different periods. It is well-known that a sharp peak develops for ideally noise-free data; from this statement we can conclude that the ratio of noise to signal is low for the periods shown in each F-k spectrum, because in almost all the cases the peak is sharp. This can be used as another way to verify the dispersion curve.

It is also known that the sharp of the peak vary with the coherence value, usually the coherence is high for sharp peak spectra. Another factor that affects the coherence is the number of peaks in the F-k spectrum, when more than one peak appears the coherence decreases. The presence of more than one peak may be due to external noise, in our case we can see that more than one peak occurs specially for the large arrays, which can tend to receive more noise.

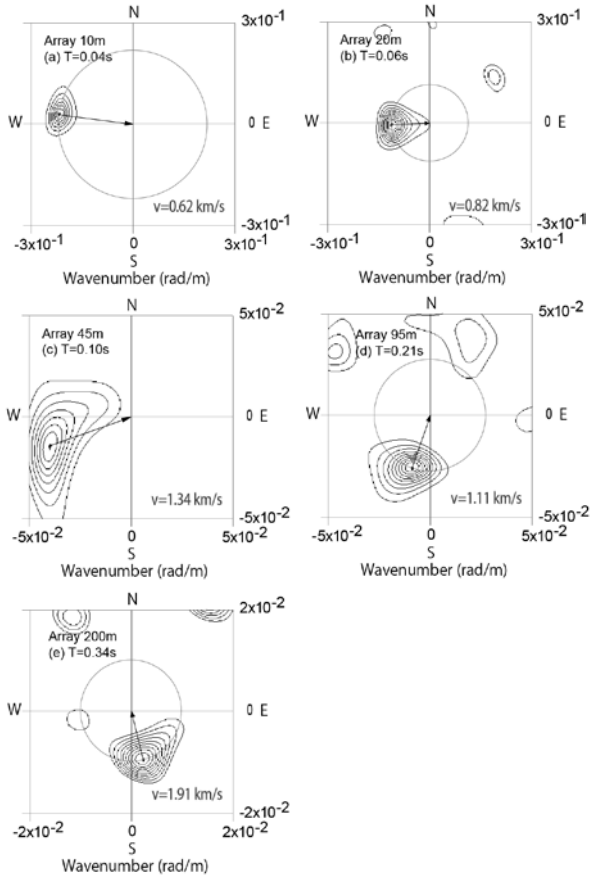

Figure 4. F-k Spectra for CMD arrays

5.2 Dispersion curve

Tokimatsu (1995) mentioned that to obtain reliable results of phase velocities, the effective wavelength range is related with the sensor distance as follows

$$Dmax > \lambda max/3$$
$$Dmin < \lambda min/2$$

which can be written as:

$$2Dmin < \lambda < 3\,Dmax$$

where *Dmax* and *Dmin* is the maximum and the minimum sensor distance respectively, and λ is the wavelength.

This criterion, together with the cross spectrum and the F-k spectrum verification were used to select the points of the dispersion curve when using the F-k method (Figure 5).

However, in the case of the CCA method; Cho et al (2004) found phase velocities at very long wavelength ranges, up to 30 meters the array radius. They stated that it is possible to calculate phase velocities at very long wavelengths when the signal to noise ratio is high, which occurs normally in few meter radius arrays.

In Figure 5 we can observed the continuity between the dispersion curves from array L0.5 (linear array of 0.5m sensor distance) to array C45 (circular array of 45m radius). Nevertheless, arrays C95, C200 and C400 follow another curve. The cause of this difference could be the fact that these large arrays were measured at a place separated about 800m from the place where the small arrays were measured, that is, the surface soil may be different in both places. Small array measurements in the second place are necessary to verify the dispersion curve of the large arrays.

5.3 Inversion of dispersion curves

Several methods of inversion are available, from the conventional least square methods to the genetic algorithm method. The genetic algorithm approach developed by Goldberg (1989) is recently very popular; this method in comparison with the typical least square method has the advantage in which a search can be done for an optimal solution in the local and global space.

In this study we applied the genetic algorithm (GA). To apply this method we input an observed dispersion curve, such as the one in dots in Figure 6(a). Previously we had determined this curve base on the dispersion curve of Figure 5.

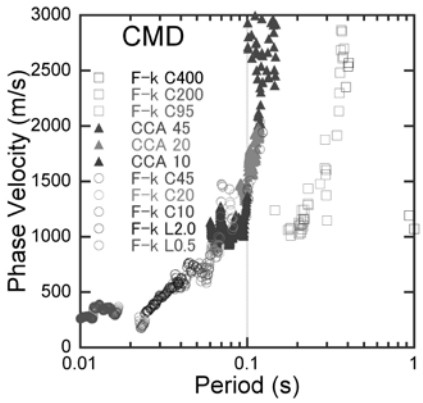

Figure 5. Dispersion curve

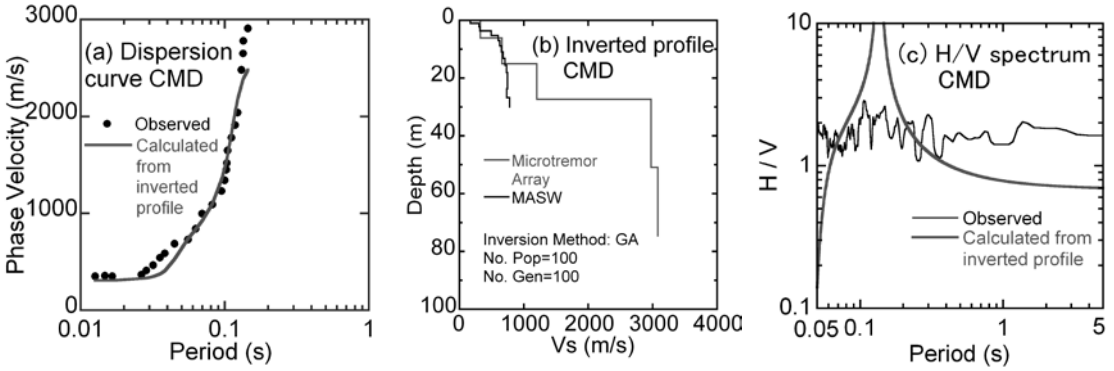

Figure 6. (a) Comparison between the observed and calculated dispersion curve, (b) Comparison between the profiles estimated by inversion of dispersion curves calculated by microtremor arrays and by MASW, (c) Comparison of H/V spectra

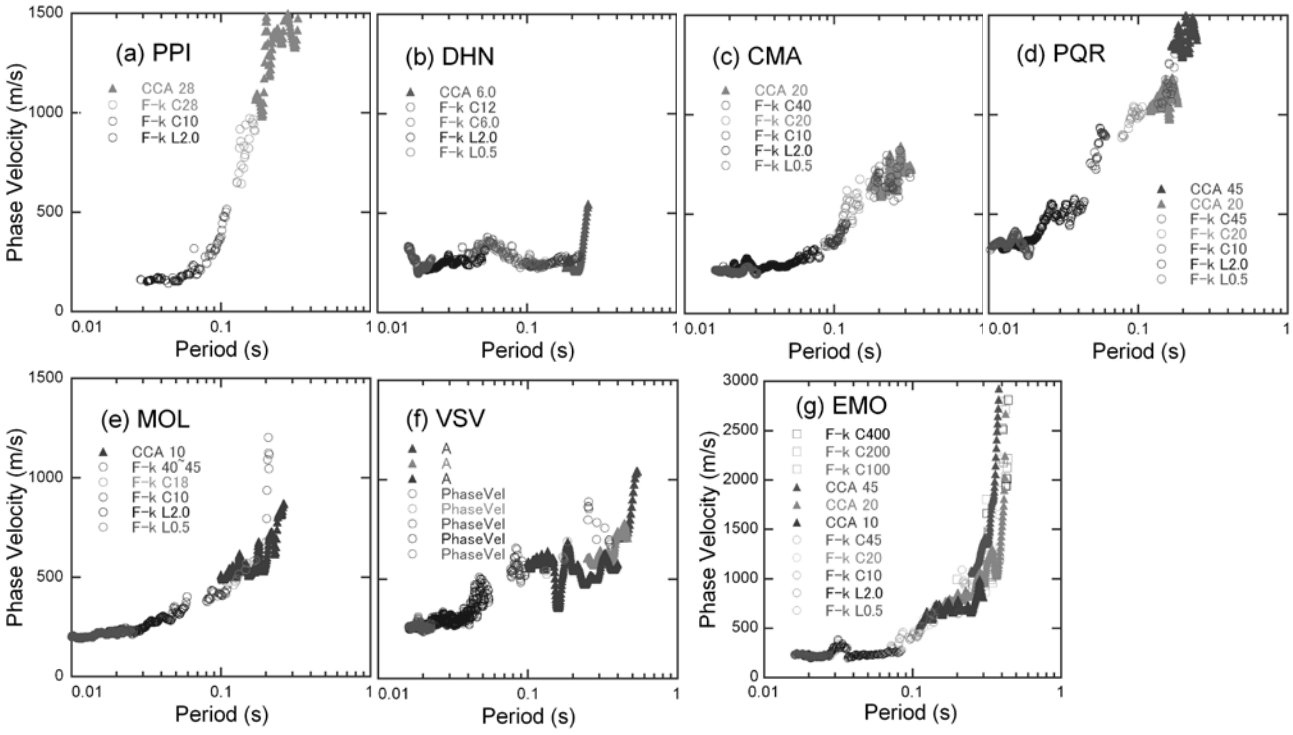

Figure 7. Dispersion curves

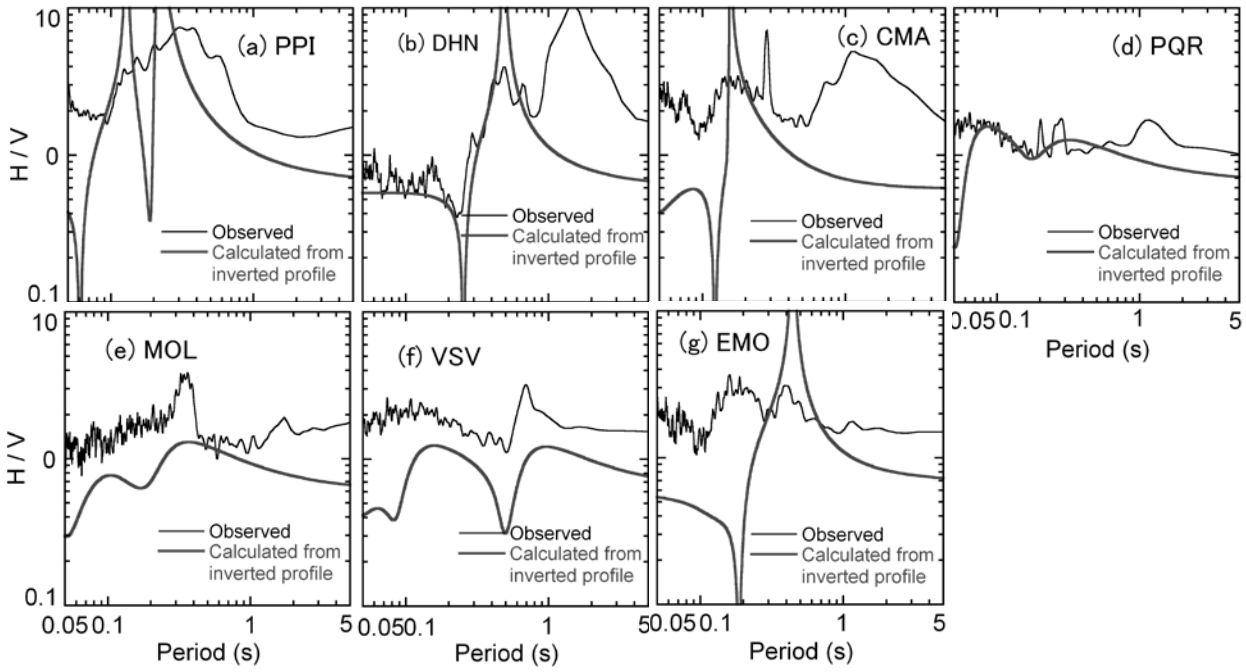

Figure 8. H/V Spectra

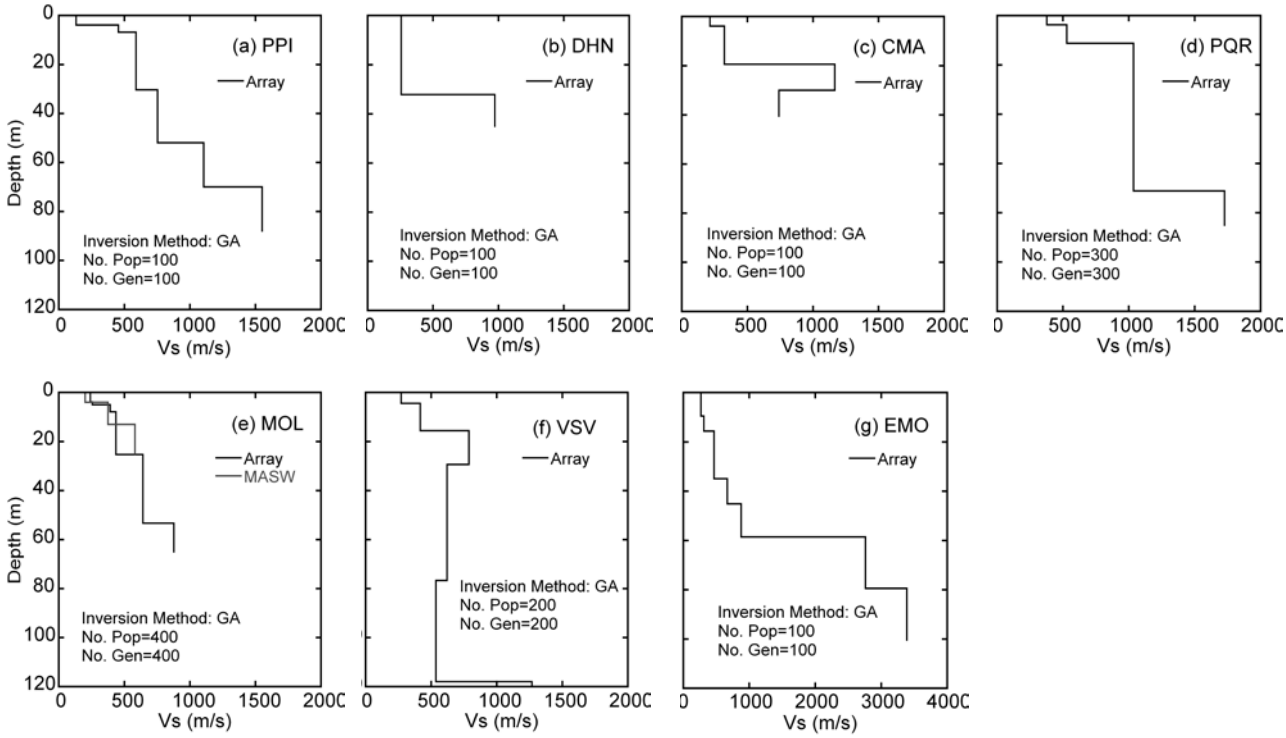

Figure 9. Comparison of Observed and Calculated H/V spectra

This observed curve or target curve, is used to compare all calculation curves obtained in the process of the inversion. The final calculated curve is the one that satisfy the ending criterion, which can be either a limit number of iteration (number of generation) or a minimum fitness value. In this study the first criterion was used, and the value of this limit was up to 100.

Figure 6(b) shows two profiles, one corresponds to the inversion of the dispersion curve calculated from microtremor arrays and the other corresponds to the inversion of the dispersion curve calculated with the MASW method. It is observable that both profiles are in good agreement until the depth of 15m more or less.

Finally to verify the profile obtained with the microtremor array, the H/V spectrum of this profile is calculated and compared with an observed spectrum. Figure 6(c) shows that there is an agreement between both spectra.

5.4 Additional Results

The same procedure taken for the calculation of dispersion curves and estimation of shear-wave velocity profile of study point CMD was used at the other study points.

Figure 7 shows the dispersion curves for the rest of the points of study, Figure 8 shows the the H/V spectra, and Figure 9 shows the shear-wave velocity profiles;

6. DISCUSSION

Looking at the dispersion curves we can see that the CMD place has the most rigid shallow surface soil, it can be explained from the rock formation proximity.

The places with apparent soft deep deposits are DHN, CMA, and VSV.

In the case of CMA, the dispersion curve at long period (array of 45m) does not show a clear curve, and it seems that there is a dip in this part of the curve; it could mean that there is a layer of high velocity overlying one of lower velocity, which is what we found in the inverted profile (Figure 9(c)). Indeed, the H/V spectrum of this place has three clear peaks (Figure 8(c)), one with a period of about 1s, this peak could belong to soft layer mentioned before. To verify this peak we need phase velocities at long period, which can be obtained with large array measurements.

For VSV, the inverted profile (Figure 9 (f)) apparently points out that there is an important contrast down to 100m. The H/V spectrum of the calculated and observed data shows an agreement. However to verify this statement, a large array measurement is necessary.

7. CONCLUSIONS

The results of this study brought the following conclusions:

1. Places located in the area of alluvial gravel of Lima, showed high shear-wave velocities at shallow depths.
2. In the majority of the places studied, the implementation of large array measurements is necessary to estimate the depth to the base-rock.
3. In order to verify the results of array inversion, additional studies, preferably direct exploration test, such as PS logging is of great importance.

Abstract: The strong ground motions recorded at Kyoshin Network Kashiwazaki (K-NET) and Gas Water Department (GWD) in Kashiwazaki city had strong spiky acceleration time history, while JR Kashiwazaki station (JR) had not such spiky waves. Our previous study showed that the computed ground motion at the K-NET using the bedrock motion deconvoluted from the observed recording at JR site, agreed reasonably well with the observed one. However, the strong motion at GWD site has not been well estimated probably because it contains more and stronger spiky waves than the recorded motion at the K-NET. In this paper, an attempt is further made to examine whether such spiky waves were recorded at both K-NET and GWD stations, using nonlinear dynamic response analysis together with the dynamic soil properties based on borehole investigation and laboratory tests made for the three sites after the earthquake.

1. INTRODUCTION

Niigata-ken Chuetsu-oki Earthquake (Mj=6.8) occurred on July 16, 2007, with an epicenter off the Niigata prefecture. The quake affected the coastal areas of the southwestern Niigata prefecture, including Kashiwazaki city and Kariwa village as well as the Kashiwazaki-Kariwa nuclear power plant of Tokyo Electric Power Company (Tokimatsu, 2008). The earthquake claimed a death toll of fifteen people, with more than 2,340 people injured, as of December 28, 2007. More than forty-one thousand houses were either totally collapsed or were damaged.

The strong ground motions recorded at the Kyoshin Network Kashiwazaki (K-NET) station and those at the Gas and Water Department (GWD) station in Kashiwazaki city had strong spiky acceleration time histories, whereas those at the JR Kashiwazaki station nearby did not show such spiky waves (Yoshida et al, 2007; Tokimatsu, 2008).

Our previous study showed that the computed ground motion at the K-NET using the bedrock motion deconvoluted from the observed recording at JR site, agreed reasonably well with the observed one. However, the strong motion at GWD site has not been well estimated probably because it contains more and stronger spiky waves than the recorded motion at the K-NET.

The objective of this paper is to propose and employ a method for searching reasonable bedrock motion that could simulate the ground surface motions recorded at the three sites during the earthquake, based on numerical analyses using dynamic soil properties obtained from field investigations that were made after the earthquake.

2. GEOLOGICAL SETTINGS

Figure 1 shows a geomorphological map of the central part of Kashiwazaki city (Kashiwazaki city, 1983). The city has been developed in the Kashiwazaki plain that faces the Sea of Japan on the northwest. The Kashiwazaki plain consists mainly of the Holocene alluvial deposit formed by the U and Sabaishi rivers and their tributaries. Running in parallel with and between the coastline of the Sea of Japan and the alluvial deposit is the Arahama sand dune that is trisected by the U and Sabaishi rivers where they flow into the Sea of Japan. It extends from the southwest of the city towards the northeast, with its plateau altitude of about 10 m in the central city of Kashiwazaki.

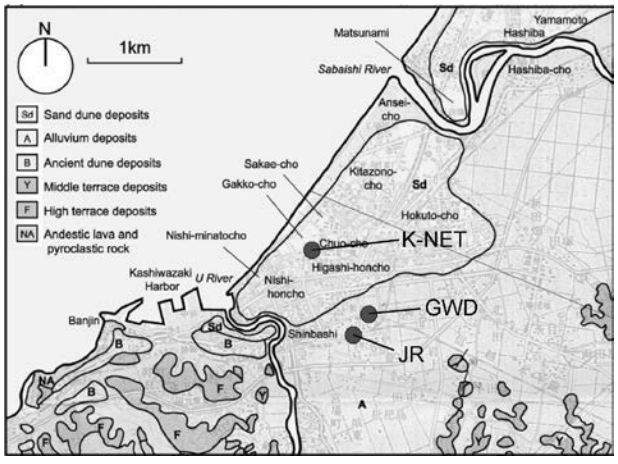

Figure 1 Geomorphological Map of Kashiwazaki City (Kashiwazaki City 1983)

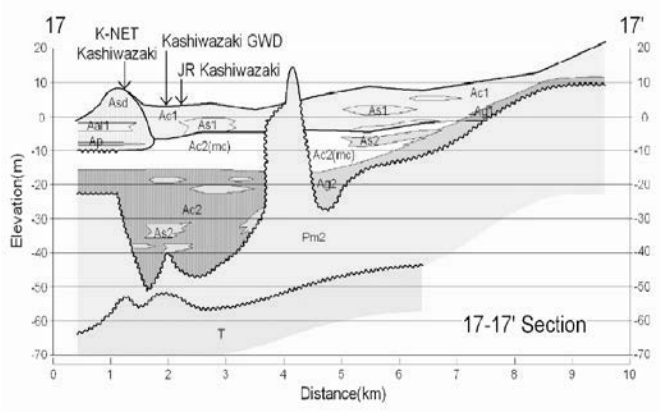

Figure 2 Geological Sections of Kashiwazaki City (ASENP, 2002)

Figure 2 shows a NS geologic section across the city. The Holocene deposit in the lowland consists of the Top, Upper and Lower Kashiwazaki Formations (Ac1/As1, Ac2/As2, and Ac3/As3), with thicknesses varying from 40-70 m along the lower courses of the two rivers, that overlie the Pleistocene and Tertiary Formations (Pm2 and T). The Arahama sand dune about 2 km in width consists of the New Holocene sand dune (Asd) and Pleistocene sand dune called Banjin Formation (Psd) that is underlain by the Kashiwazaki Formations on the south of the Sabaishi River. Typical shear wave velocities of the New Sand Dune, Banjin Formation, Kashiwazaki Formation, Yasuda Formation, and Nishiyama Formation are 100-200 m/s, 200-350 m/s, 100-200 m/s, 350 m/s, and 500-600 m/s, respectively.

The K-NET station is located on the Arahama sand dune, while the GWD and JR stations are on the Holocene deposit about 0.8km and 1.2 km southeast of the K-NET. Geological and geophysical field investigation was made at three stations after the earthquake including laboratory tests to determine dynamic soil properties of the sites.

Figure 3 shows shear wave velocity logs and the geological boring logs for the three sites. The groundwater table was located at a depth of about 5.0 m (K-NET), 1.6m (GWD) and 0.8 m (JR), respectively. The surface soil at the K-NET station to a depth of 13 m is dense sand with SPT N-values ranging from 10 to 40 and Vs from 110-250 m/s, which is underlain by a thick clayey soil with Vs 200-290 m/s. Mudstone with Vs over 500 m/s occurs at a depth of about 65 m. The surface soil at the GWD site to a depth of 0.7 m is sand, which is underlain by a silty clay layer with N-values smaller than 10 to a depth of 3.7 m. Underlain by this layer are alternate layers of sand and clay with N-values less than 10 and Vs of about 100 m/s to a depth of 12.2 m. This is further underlain by clay and silty soils with N-values ranging from 10 to 30 and Vs greater than 200 m/s at a depth of 49 m where an engineering bedrock with Vs larger than 500 m/s occurs. The surface soil at JR station to a depth of 18 m consists of soft silty clay and sandy silt with N-Values of 0-1 and Vs of 70-100 m/s, which overlays alternate sand and clayey silt with N-values of 3-20 and Vs of 190-450 m/s. Mudstone with Vs over 500 m/s occurs at a depth of about 66 m. It seems that the sandy soils at depths between 5-10 m at K-NET and GWD sites might have undergone cyclic mobility and/or liquefaction, although no evidence of soil liquefaction was identified nearby.

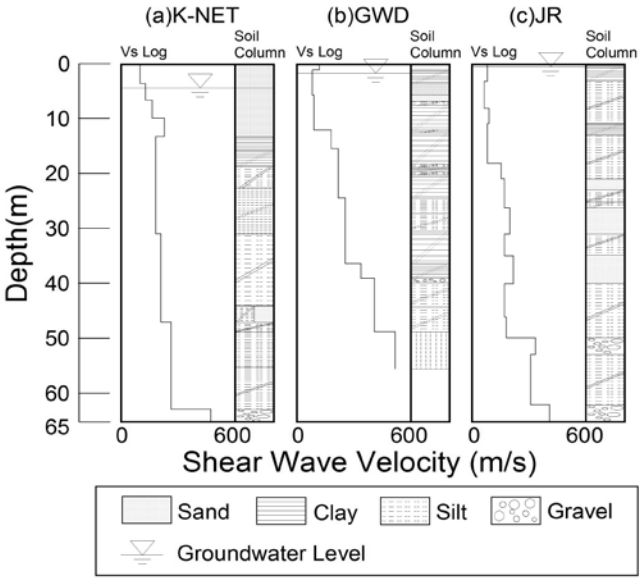

Figure 3 Geological and Geophysical Logs of Three Stations

3. STRONG GROUND MOTION RECORDS

Figure 4 shows acceleration time histories at K-NET, GWD and JR stations during the main shock. The acceleration time histories at all stations have long period components, probably reflecting the thick alluvial deposit underlying the sites. It is interesting to note that the strong motion recording at the K-NET shows strong spiky waves, associated with liquefaction or cyclic mobility of sand, but rapidly decreasing its amplitude with time due probably to cyclic degradation of the sand. The strong motion recording at the GWD shows similar but stronger spiky waves that do not decrease its amplitude with time. Similar spiky waves are not however observed in the acceleration time histories at the JR station.

Some of the strong ground motions recorded at the K-NET and JR stations during other earthquakes are also available, whereas such records are unavailable at the GWD station. Figure 4 shows such acceleration time histories during the aftershock of the Niigata-ken Chuetsu Earthquake that occurred at 18:12 hrs on October 23, 2004. Neither spiky waves nor long period component can be seen in any of the records, contrasting with the strong nonlinear soil behaviour including soil liquefaction and/or cyclic mobility at the K-NET and GWD stations during the main event as shown in Figure 4.

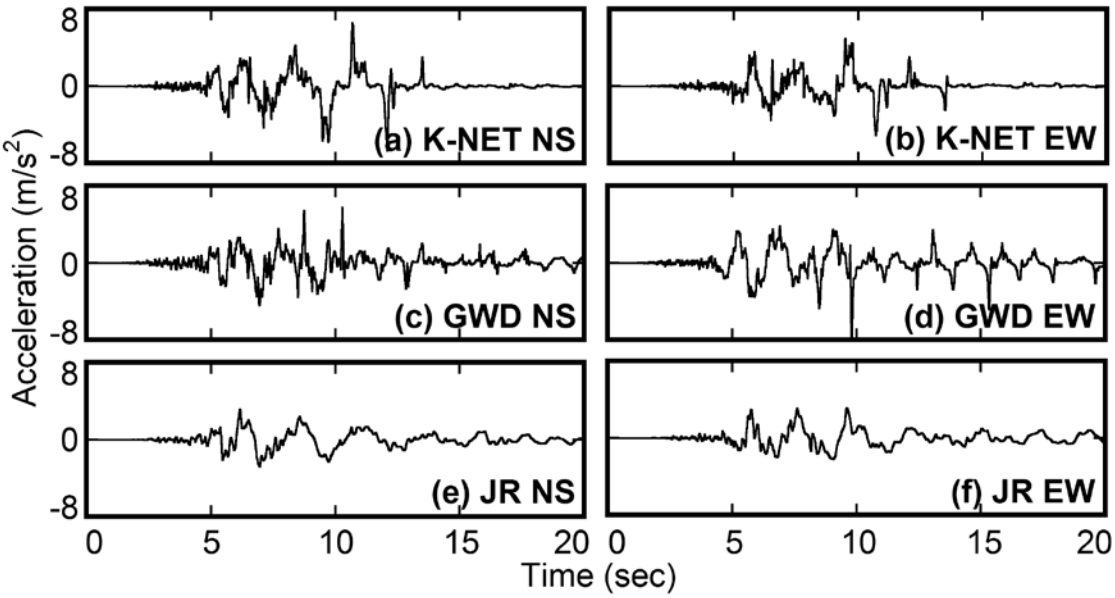

Figure 4 Acceleration Time Histories of K-NET, GWD and JR during the Main Shock

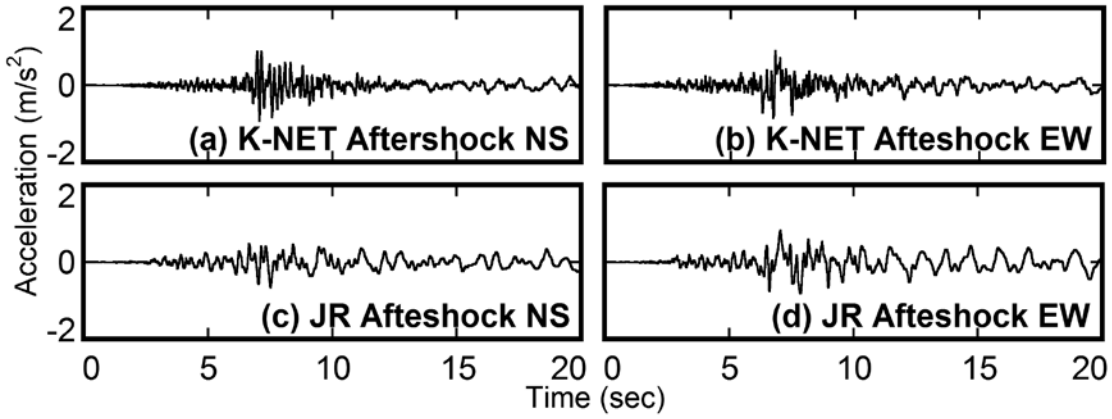

Figure 5 Acceleration Time Histories of K-NET and JR during the Aftershock

4. ANALITYCAL SIMULATION

4.1 Ground Motions during a Moderate-Intensity Earthquake

Figure 6 shows a flowchart to estimate the ground motion recorded at the K-NET and GWD sites from one at JR station. It was assumed that the rock occurring at a depth of 49-66 m of which shear wave velocity is over about 500 m/s is the equivalent rock for the three sites. First, the bedrock motion was estimated, based on the deconvolution analysis using the observed ground motions and soil profile at the JR site. Second, the ground surface motions at the K-NET and GWD stations were estimated, with the back-calculated bedrock motion as input to the bedrock. The programs used for this deconvolution and convolution analyses include the following:

(1) A one-dimensional equivalent-linear response analysis of a deposit subjected to a vertically incident SH waves in which damping ratios of soil depend only on shear strain developed in the soil (hereby called SHAKE 1). The program is exactly the same in concept as the original SHAKE (Schnabel et al, 1972).

(2) An extended version of the equivalent linear response analysis described above in which the damping ratios of the deposit are assumed to be dependent on the Fourier amplitude of shear strain in the frequency domain (e.g., Sugito et al, 1993), which has been developed to improve over-damping nature of the original SHAKE in the short period range during strong shaking (hereby called SHAKE 2)

(3) A nonlinear effective response analysis (Shamoto et al, 1992, hereby called ESA).

The same program was used for both deconvolution and convolution analyses, except for the convolution analysis of ESA for which SHAKE 2 was used for deconvolution analysis.

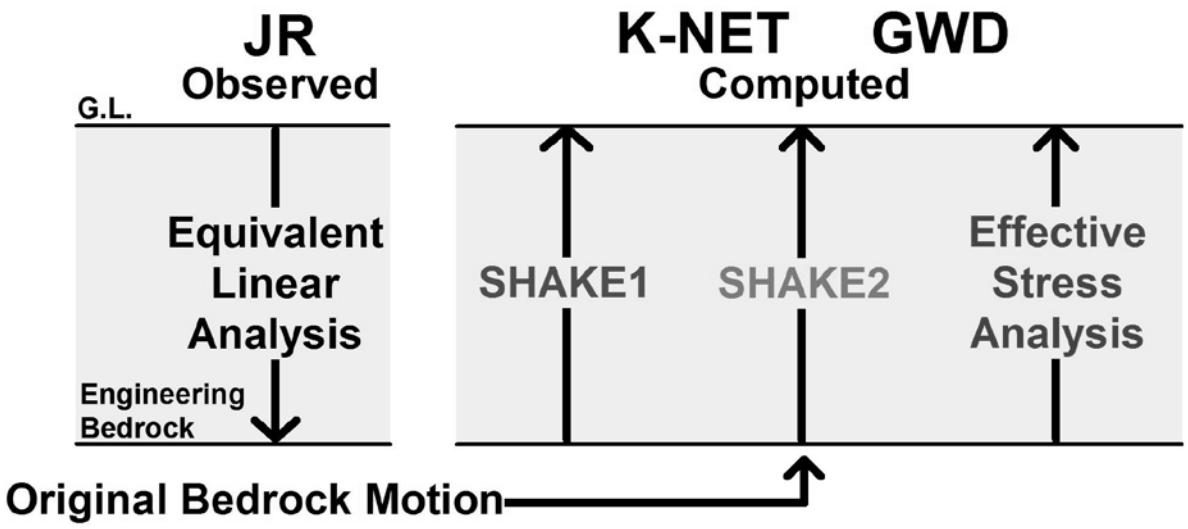

Figure 6 Flowchart to Estimate Ground Motion at K-NET and GWD from Recorded Motion at JR

To confirm the applicability of the deconvolution and convolution analyses shown in Figure 6 for a moderate-intensity earthquake, strong motions recorded at the K-NET and JR stations during the aftershock of the Niigata-ken Chuetsu Earthquake that occurred at 18:12 hrs on October 23, 2004 were used. Similar analysis and confirmation were unable to be performed for the GWD station because of the absence of the strong ground motion at the station during the same earthquake.

Figure 7 shows the time histories computed by the three methods, compared with the recorded ones. There is a good agreement between the observed and computed values, confirming the applicability of any of the deconvolution and convolution analyses for this particular pair of stations subjected to a moderate-intensity earthquake.

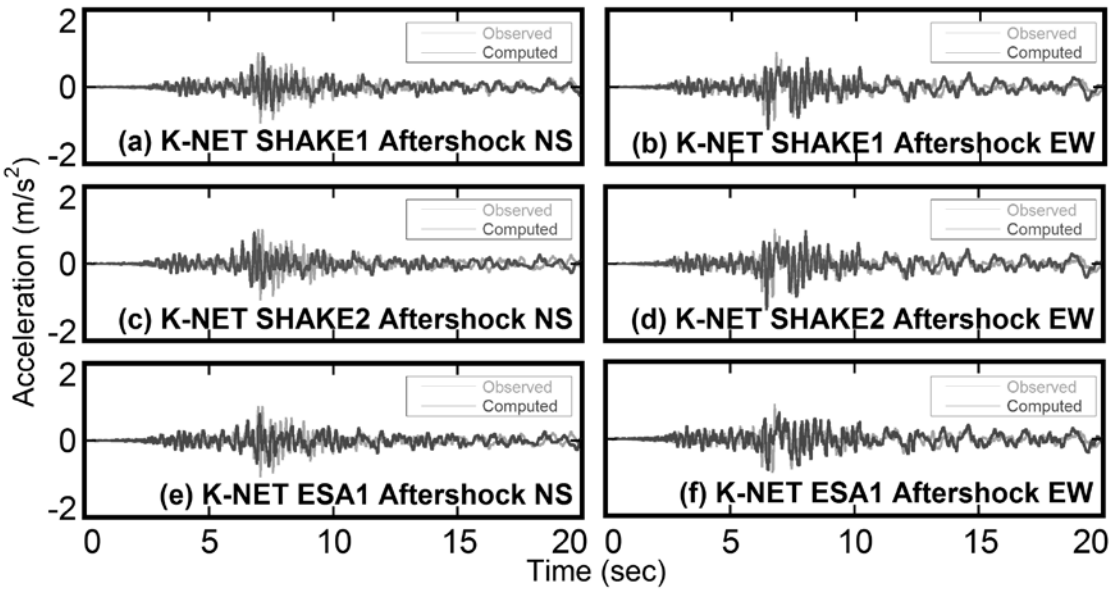

Figure 7 Acceleration Time Histories of Computed Ground Surface Motions, Compared with Those Recorded at K-NET during a Moderate-Intensity Earthquake

4.2 Ground Motions during a Strong-Intensity Earthquake

To study further the applicability and limitation of the three deconvolution and convolution methods for estimating site response during strong-intensity shaking and to examine the cause of the spiky waves observed at the K-NET and GWD stations, the analysis described in Section 4.1 was also performed using the strong ground motions recorded during the 2007 Niigata-ken Chuetsu-oki Earthquake.

Figure 8 shows the acceleration time histories of the deconvoluted bedrock motions using SHAKE2 and the ground surface motions computed from the three methods, compared with those of the recorded motions at the K-NET station. Figure 9 also shows the acceleration time histories computed with the same bedrock motions (Figs. 8(g) and (h)), compared with the observed ground motion at the GWD station. It seems that the computed results from any of the three methods are inconsistent with the recorded motions and are unable to reproduce spiky waves observed in the recorded motions.

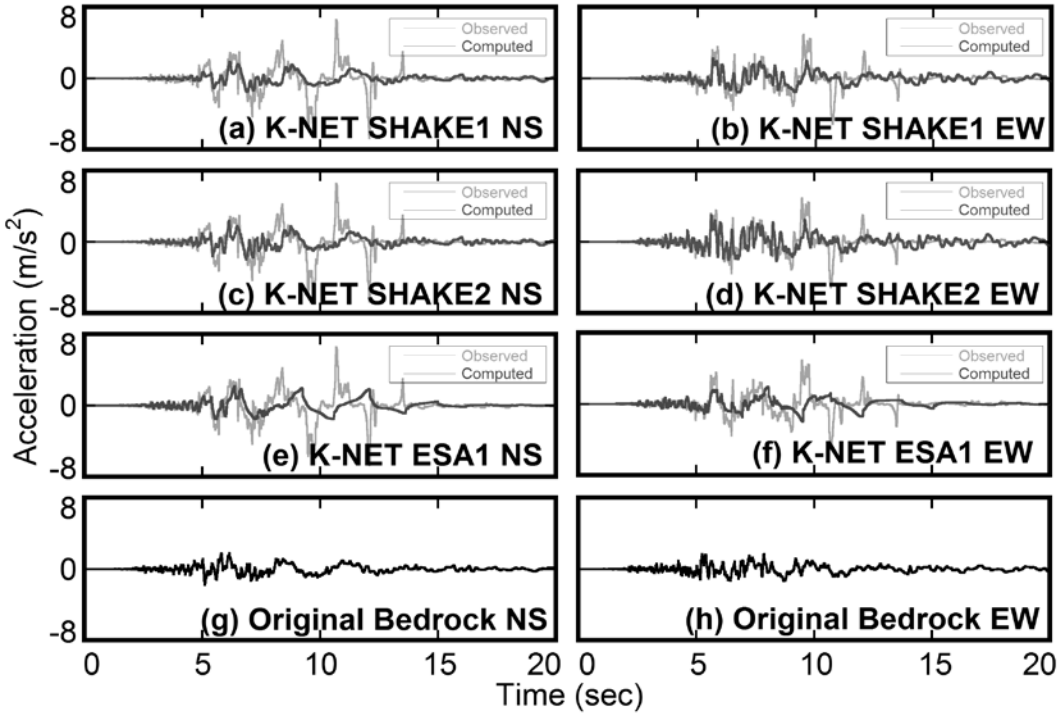

Figure 8 Acceleration Time Histories of Computed Bedrock and Ground Surface Motions, Compared with Those Recorded at K-NET during the 2007 Niigata-ken Chuetsu-oki Earthquake

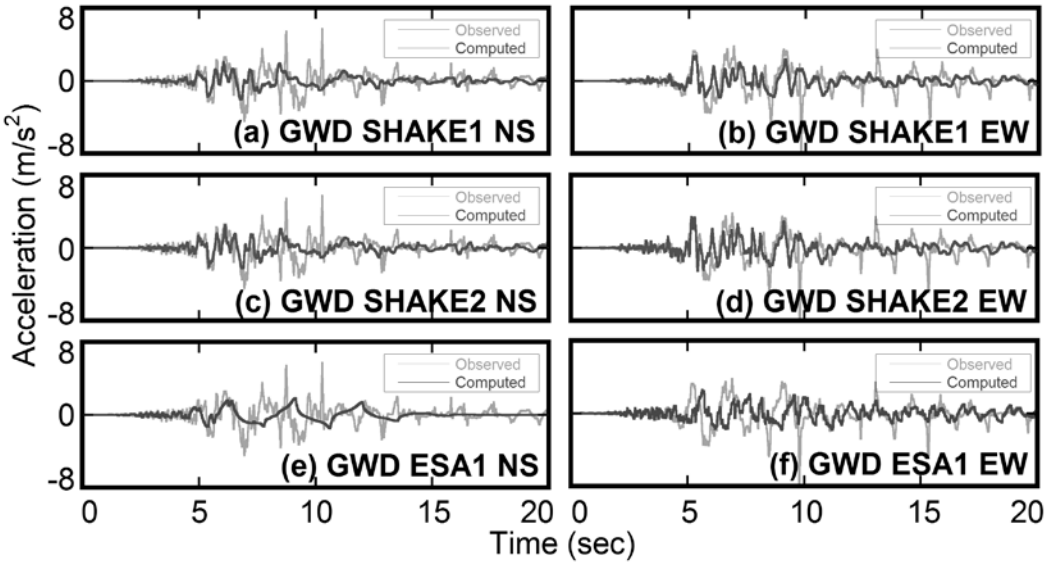

Figure 9 Acceleration Time Histories of Ground Surface Motions, Compared with Those Recorded at GWD during the 2007 Niigata-ken Chuetsu-oki Earthquake

4.3 Searching a Reasonable Bedrock Motion

A close examination of the simulation results further suggests that the computed ground motions shown in Figs. 7 and 8 are smaller in amplitude and more delayed particularly in the later phase than the observed one. This suggests that the actual bedrock motions in the later phase might have been larger and more behind than those deconvoluted by the equivalent linear method.

Based on the above discussions, a preliminary attempt was made to search for more reasonable bedrock motions that could simulate ground motions recorded at the three sites during the main shock. This was made by a trial-and-error method as shown in the flowchart of Figure 10 in which the bedrock motion is updated so that the difference in Fourier spectra between observed and computed ground surface motions can be minimized.

The bedrock motions initially assumed ($2E_{N,1}$) are those determined with the deconvolution analysis of SHAKE2 using the observed ground surface motions ($2E_{1,O}$) at the JR station. The effective stress analysis was then employed to estimate the ground surface motions ($2E_{1,i}$) at the three sites using the deconvoluted bedrock motions.

The bedrock motions ($2E_{N,i+1}$) were updated based on the following equation in such a way that the difference in Fourier spectra between the computed and observed ground surface motions at the three sites becomes small.

$$2E_{N,i+1} = 2E_{N,i} + \alpha \cdot \frac{2E_{N,i}}{2E_{1,o}} \cdot (2E_{1,o} - 2E_{1,i}) \qquad (1)$$

in which E is displacement Fourier spectra; first subscripts *1* and *N* are the ground surface and the bedrock; second subscripts o and I correspond to the observed values and the iteration number of the computed ones and α is a coefficient that is assigned a value greater than zero. This convolution analysis and modification of bedrock motion was repeated until the observed and computed ground surface motions become compatible with each other.

Figure 11 shows the acceleration time histories of the ground surface motions computed with the most updated bedrock motion, compared with the recorded ones. Good agreement exists between the observed and computed values at the K-NET and JR stations, whereas the computed results could not simulate well the observed acceleration time histories including the strong spiky waves.

Figures 12 and 13 show the velocity and displacement time histories of the computed ground surface motions, compared with those of the recorded motions. Again, good agreement exists between the observed and computed values at the K-NET and JR stations. In addition, those of the stronger NS components at the GWD station begin to show a fairly good agreement with those of the observed values, while those of the weaker EW components are still inconsistent with the observed ones.

The good agreement between the computed and observed time histories at the K-NET suggested that the cyclic mobility of the dense sand that occurs at depths of 5-12 m would be the primary cause of the strong spiky waves observed in the acceleration time histories at the site (Tokimatsu et al, 2010). Although similar cyclic mobility of dense sand and/or other unidentified phenomena that induced the stronger spiky waves could have taken place at the GWD station, the present analysis using the dynamic soil properties determined for the site has not identified the possible cause of the spiky waves at this site.

A comparison of the back-calculated bedrock motions between the initial and final trials shown in Figure 11 confirms that the actual bedrock motion in the later phase might have been larger and more behind than the one deconvoluted by the conventional equivalent linear method.

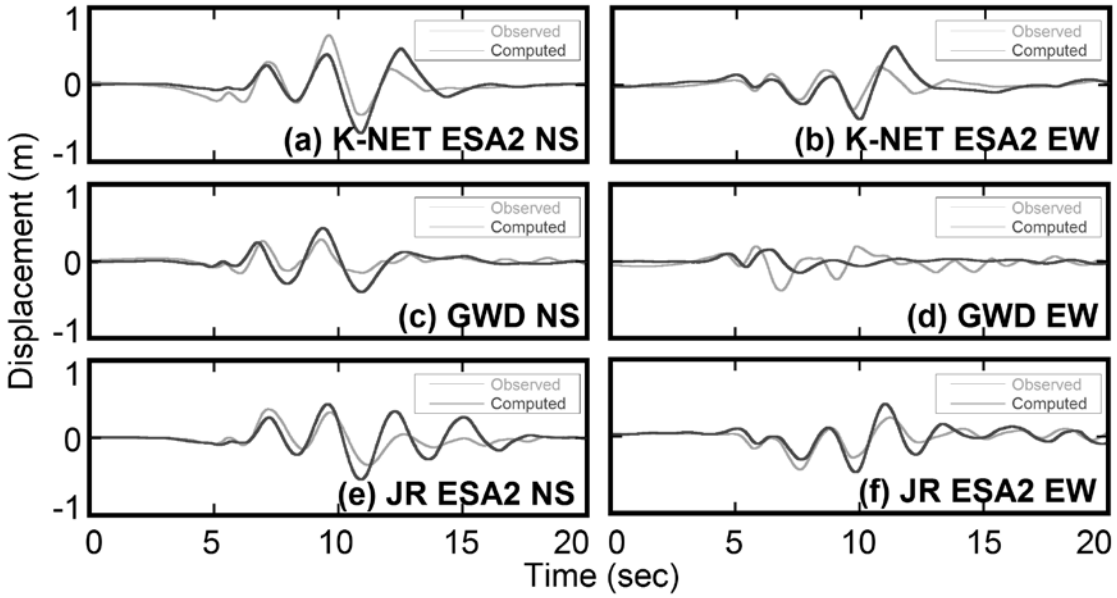

Figure 13 Results of Displacement Compared with Observed Records of the Three Sites

5. CONCLUSION

The strong ground motions recorded at the K-NET and GWD stations in Kashiwazaki city had spiky acceleration time histories, suggesting liquefaction or cyclic mobility of the ground, while those at nearby JR Kashiwazaki did not show such spiky waves. A preliminary attempt has been made to examine why such spiky waves were induced during the main shock and, for this purpose, to propose and employ the method for searching reasonable bedrock motions that could simulate the ground surface motions recorded at the three sites during the main shock. On the basis of the analysis and discussions, the following conclusions have been made:

(1) Conventional deconvolution and convolution analysis using strong motions recording at one site as reference for estimating those at nearby station has been proven effective for a moderate-intensity earthquake, whereas it was ineffective for a strong-intensity shaking which would induce liquefaction of soil deposits under consideration.

(2) The proposed method can reproduce reasonably well the recorded motions including the spiky waves at the K-NET Kashiwazaki and thus could show promise in estimating reasonable bedrock motion from strong ground motions recorded during strong-intensity shaking which would induce liquefaction of soil deposits under consideration.

(3) The proposed method can also reproduce reasonably well the velocity and displacement time hitories of the stronger NS records at the GWD station during the main shock, but cannot simulate the spiky acceleration time histories.

Abstract: Although the buried pipelines systems have responded quite satisfying during past earthquakes, in the case of poor ground conditions catastrophic damages have been observed, because of soil instabilities and large deformations. Liquefaction is one of the most destructive side effects of earthquake in loose sandy soils, which induces large permanent ground displacements that could harm underground lifelines. In this paper, system reliability of Tehran gas distribution is challenged by liquefaction. First the probable liquefaction potential pattern is selected based on previous analyzes. After analyzing high and medium pressure buried pipelines as the link portions of the system, by means of simplified equivalent static and also finite element method using beam elements, the global reliability of the distribution system is examined by consideration of lateral spreading and settlement distribution maps in the area. The results show that effect of lateral spreading is negligible for Tehran gas network, but the settlement due to liquefaction in the southeast of Tehran has some major effects on local medium-pressure buried pipelines, that could disrupt the functionality of the system in some parts.

1. INTRODUCTION

Generally, the occurrence of liquefaction due to earthquake in high potential areas can have destructive effects on the buried pipelines. For reduction of the risk of this phenomenon, in the large urban areas, the only way is mitigation of the losses, however, in some isolated locations, the elimination of the hazard could be considered by means of soil rehabilitations or compaction. In order to mitigate the damage of lifelines, real-time monitoring, retrofit and field reconnaissance is needed in addition to seismic analysis and design. Nowadays, major progresses in liquefaction potential assessment and prediction of the complex behavior of buried pipelines are made, that would help to design these structures to resist severe hazards.

Liquefaction could affect the buried pipelines in different ways, reduction in bearing forces of the soil, buoyancy forces due to the submergence of the pipeline in the liquefied soil, ground settlement and lateral spreading as the most hazardous effect. Each of these effects takes place in a specific case, based on the soil characteristics and the location of the buried pipe. In this paper, the potential of liquefaction in Tehran is first reviewed and different effects of liquefaction as discussed above are evaluated. Then the response of Tehran gas pipelines in the high potential area is evaluated by means of simplified methods and also finite element method, and based on the analyses, general quantitative countermeasure plans are suggested.

2. LIQUEFACTION POTENTIAL IN TEHRAN

The evaluation of liquefaction potential is the first step for the risk assessment of the pipelines network. Here, recent researches that evaluated the possibility and potential of liquefaction in different parts of Tehran is reviewed. All of these researches are based on common equations in soil dynamics. A summary of these methods is presented herein.

2.1 Basic Method of Evaluation

Generally, the evaluation is carried out by F_L method in each soil layer, while the liquefaction potential is evaluated by P_L method in the selected point, based on F_L values.

Based on most seismic design guidelines, the FL values are evaluated for sandy soils to the depth of 20 meters in each borehole, where the ground water level is lower than 10 meters from the surface (JRA 2002). The F_L is obtained by the Eq. 1.

$$F_L = R_r / L \quad (1)$$

where, R_r is the cyclic shear resistance, and L is the shear stress ratio, both derived from the specifications of the selected seismic hazard and soil specifications. If the F_L ratio is not less than 1, the soil layer is judged as liquefied.

If for a selected borehole, the F_L values of the layers are greater than 1, liquefaction index (P_L) is derived as below (Iwasaki et al. 1982):

$$P_L = \int_0^{20} F_L W(x) dx \qquad (2)$$

where, W(x) is a prescribed function of x the depth of layer below ground surface in meters. After evaluation of P_L values in a point, the liquefaction potential is assessed based on the Table 1.

Table 1 Liquefaction Potential Judgement Criteria

Liquefaction potential	Criterion
Very high	$P_L > 15$
Relatively high	$5 < P_L < 15$
Relatively low	$0 < P_L < 5$
Very low	$P_L = 0$

2.2. JICA Studies for the Greater Tehran

These studies were carried out in 1999 and 2000 by Japan International Cooperation Agency for Iran as a part of the microzonation studies for the greater Tehran. In this research, the basic evaluation methods summarized above are used, thus the boreholes in the territory in southeast of Tehran, that have a ground water level less than 10 meters are selected for the study. Moreover, the selected earthquake scenario is Ray Fault model which has the largest PGA distribution in the studied area.

This research showed that, in the almost whole area, the liquefaction potential is evaluated as "very low" and "relatively low". A hard cohesive clay soil covers almost the entire area and only in one borehole, the potential is evaluated as "relatively high", while the distribution of the liquefied soil is very limited in the region. The result of this study is presented in the Figure 1 (JICA 2000).

Based on these calculations and results, a distribution map for the horizontal flow of the liquefied soil, known as lateral spreading, is provided as shown in Figure 1 (a), using the flow estimation formula on the slope areas presented in Eq. 3 (JGA 2001).

$$\delta_h = 36c\left\{\sum_{i=1}^{n} \frac{0.5\gamma_i H_i^2 + \sigma_{vi} H_i}{\left(0.5\gamma_i H_i^2 + \sigma_{vi}\right)^{3/2} N_{bi}}\right\}\theta_g \qquad (3)$$

where, δ_h is the amount of lateral flow (m), c is the location correction parameter here equal to 0.5, H_i , γ_i , N_{bi} and σ_{vi} are the properties of the soil layer i, and θ_g is the slope of the area.

Another effect of the liquefaction is the ground settlement, which is assumed to be 5% of the thickness of the liquefied soil, so the values of settlement due to liquefaction were evaluated as shown in Figure 1 (b). As it is understood from Figure 1, lateral spreading effects could be neglected in the analysis of the structures, but the settlement values should be considered as a seismic input on the structures.

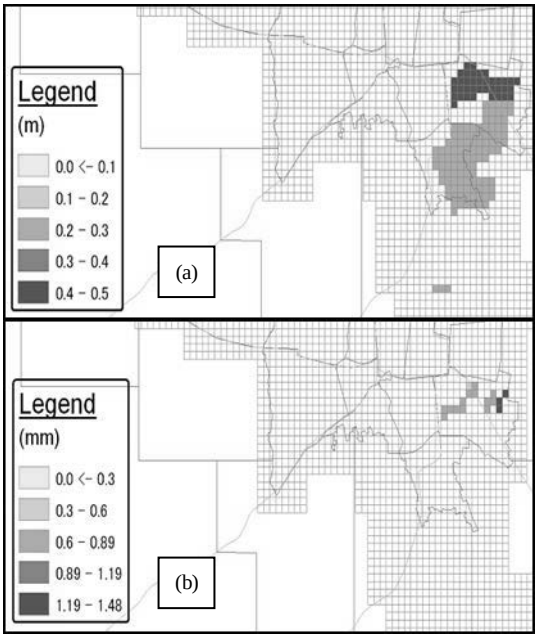

Figure 1 (a) Lateral Spreading, (b) Settlement distribution for Tehran (after JICA 2000)

2.3. IIEES Studies

Different research groups from International Institute of Earthquake Engineering and Seismology (IIEES) have analysed liquefaction potential in Tehran. First in 1993, the occurrence of liquefaction in the southern parts of Tehran was tested in a medium scaled evaluation (Hosseini and Kari 1993). Later, on 1998, the potential of southwest of Tehran was examined using PGA of 0.35g, that showed very low liquefaction potential for liquefaction (Hosseini et al. 1998). One year later in 1999, a joint study by IIEES and the laboratory of Ministry of Roads and Transportation was taken out on 41 boreholes in southeast of Tehran, PGA distribution ranging from 0.2g to 0.4g, locating areas with relatively high liquefaction potentials for 0.3g to 0.4g PGAs (Hosseini 2002). Finally, in 2002, a large scaled study was carried out on the southeast area of Tehran using site specifications and seismic hazard analysis which is discussed in the following (Askari and Kasaei 2002).

In this study, the selected area in the southeast of Tehran as shown in Figure 2 (a), was divided into the 1km by 1km blocks, and in each block PGA according to the calculated Maximum Credible Earthquake (MCE) was assumed, and based on the F_L and P_L method described above, the liquefaction potential of he selected area was evaluated. The P_L values for every block are shown in the Figure 2 (b).

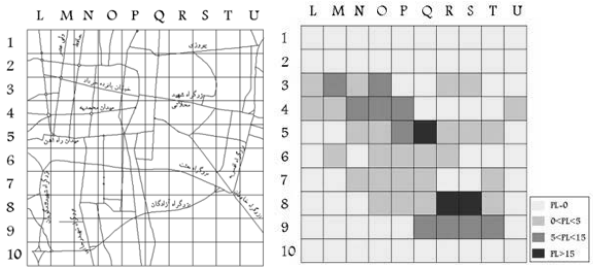

Figure 2 (a) Location and discretization of the analyzed area, (b) F_L values distributions in the blocks (after Askari and Kasaei 2002).

3. SELECTED AREA FOR THE STUDY

According to the previous studies discussed above, the area for analysis of liquefaction effects on the gas pipelines is the southeast of Tehran. For the purpose of analysis, a region which includes all the risky areas in the previous analyses was selected as shown in Figure 3 (a). The buried pipelines of 250 psi and 60 psi gas distribution networks in this region are shown in Figure 3 (b) and (c) respectively.

Figure 3 (a) Location and discretization of the analyzed area, (b) High pressure gas pipelines, (c) Medium pressure pipelines in the area.

4. ANALYTICAL MODELS FOR BURIED PIPELINES

In this section, the numerical analysis of buried gas pipelines which were located in the selected are in the southeast of Tehran is discussed. For determination of the response of these lifelines under the probable liquefaction hazard, first the two different pipelines network was analysed using equivalent static method based on major seismic design codes for lifelines (JGA 2001, ALA 2001, and JGA 2003), and then a more detailed finite element analysis was conducted. The pipelines are considered as continuous welded pipelines. Moreover, as it was discussed earlier, the effect of lateral spreading and buoyancy is negligible and the only considerable effect of liquefaction is the settlement, which two levels of settlement hazards based on JICA studies are selected as the major loading and are included in the cases. In the table below, Ks is the soil stiffness coefficient obtained from the seismic design references.

4.1. Equivalent Static Model

The approach for design and analysis of high pressure and low or medium pressure pipelines differ in the codes because of different functions and post-earthquake performance demands. So for the analysis of response of Tehran gas pipelines, these two types were separated.

4.1.1. High pressure pipelines

In the seismic design codes (JGA 2003), there are formulas for determination of the distortion angle of high pressure pipelines buried in the liquefiable areas. These formulas are different for straight, curved and T-portions of pipes. Hence, since there is no bending or curves in the pipeline length in the planes of the settlement loading (vertical), all the pipelines in the area could be assumed to deform like straight pipes, and the effect of curves and elbows could be neglected in the studies. Thus the bending angle of the straight pipes due to the liquefaction deformations of the ground could be obtained from Eq. 4 (JGA 2001).

$$\omega_s = \frac{180}{\pi} \cdot 127 \cdot D_i \cdot \sqrt{\frac{P_1 \cdot \gamma_\delta \cdot \delta_h}{EI}} \quad \text{for} \quad P_1 = D_i \cdot \gamma_k \cdot \sigma_c \qquad (4)$$

where ω_s is the bending angle in degrees, D_i is the pipe diameter in meters, γ_δ and γ_k are the partial safety coefficients taken 1.0 and 1.1 respectively, δ_h is the soil displacement in centimeters, EI is the bending stiffness of the pipe in N.cm^2, and σ_c is the yielding stress of the soil in the direction of the loading.

Also the bending capacity of the straight pipelines in the liquefaction could be obtained from the formulation below (JGA 2001).

$$\varpi_{sc} = \left\{ 0.44 \frac{t_s}{D_i} \left(8k - \frac{2k^2}{3} \right) + \frac{3.44}{\sqrt{\frac{2D_i}{t_s}}} \left(1 + \frac{\varepsilon_f}{2} \right) \right\} \cdot \frac{180}{\pi} \qquad (5)$$

where t_s is the wall thickness of the pipe, k is assumed to be 3.2, and ε_f is the ultimate strain of the pipelines suggested to be taken 0.35.

These two demand and capacity values are calculated and shown in the Table 2. As it is carried out by this method, the capacity of Tehran gas distribution pipelines in the selected region in southeast is more than the probable liquefaction hazard by a large safe margin.

Table 2 Results of ESM Analysis of High Pressure Pipelines

16	30"	500	Steel- X42	1.08	24.18

4.1.2. Medium pressure pipelines

For analysis and design of medium and low pressure pipelines, the codes suggest evaluating the response displacement of the pipeline and checking it with the demands, which are mostly assumed as amplitude of 5cm displacement in each direction for design purposes (JGA 2003). However, in the case of risk analysis, the displacement capacity is compared with the selected hazard level. Thus, in this study the relations to calculate the vertical displacement capacity of the straight medium pressure pipelines such as shown in the Eq. 6 and 7 are used and the results are compared with 30cm and 50cm values of settlement induced by liquefaction.

$$\Delta v = \frac{2\sqrt{2}e^{\frac{\pi}{4}}}{D_i} \sqrt{\frac{4EI}{k_s D_i}} \varepsilon_0 \quad \text{(cm) for free ended pipes} \qquad (6)$$

$$\Delta v = \frac{1}{D_i} \sqrt{\frac{4EI}{k_s D_i}} \varepsilon_0 \quad \text{(cm) for clamped pipes} \qquad (7)$$

where Δv is the vertical capacity of pipelines, and ε_0 is the critical strain of the pipe material, assumed 0.03 for steel pipes and PE pipes.

As it could be obtained from the Table 3, the capacities of some pipes that are highlighted are not sufficient for this level of liquefaction settlements, and a more detailed study should be done.

Table 3 Results of ESM analysis of medium pressure pipelines

Case	D_i	Material	δ (cm)	ΔV (cm)	ΔV (cm) (clamped)
1	4"	Steel-GrB	30	73.05	11.78

29	90 mm	PE101	50	7.94	1.28
30	125 mm	PE102	50	10.58	1.71

4.2. Finite Element Model

Although the previous analyses suggested no damages in high pressure pipelines, here multiple cases for both high and medium pressure pipelines were selected to be analysed by FEM. In this analysis, PIPE type elements (BEAM elements enabling the internal pressure effects) were used in

the FE code ABAQUS v.6.9, and also surrounding soil was modelled as nonlinear Winkler vertical and axial springs (JGA 2001, ALA 2001). Moreover, the loadings included internal pressure and also soil pressure on the pipes, and the liquefaction settlement was inserted to the end of the soil springs, and quasi-static analysis was carried out. The outline of this FE modelling is shown in the Figure 4.

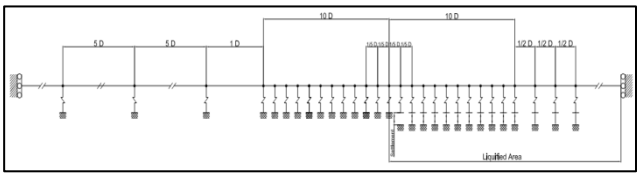

Figure 4 Schematic model of FE analysis and meshes

Different lengths for the liquefied area was tested ranging from 100m to 2km, and also the effect of curves along the pipelines were tested by using elbow elements, but as it was predicted it was negligible. Also the material nonlinearities were modelled as the basic nonlinear curves (Pezeshki, et al 2004). The results of this analysis are shown in Table 4. In this table, every value for the strains represents the maximum of numerous test results including 45 and 90 degree bended pipes, different assumed dimensions for liquefied area, and different boundary conditions for pipelines. As it is understood from the table, small diameters of PE pipes could have troubles to resist the amount of liquefaction settlements, as it is highlighted.

5. CONCLUSION AND COUNTERMEASURES

1. As it is shown in the results of the analyses, high pressure pipelines of Tehran would not encounter any major risks during the possible liquefaction occurrence in the southeast of Tehran. Although these types of gas pipelines could maintain their integrity and functionality, they may experience some plastic which implies the need for inspections after the earthquake occurrence.
2. This problem for 60psi pipeline network is more sever. These pipelines could experience large deformations in the southeast of Tehran, and also Polyethylene pipelines with diameters smaller than 125mm, could lose their functionality after the liquefaction.
3. The places in the region which was selected in this study should be marked for urgent post-earthquake measures to check the safety of the pipelines and using shut-off valves for medium pressure pipelines especially PE pipes could be a good retrofit plan.
4. As far as there is no real-time monitoring for Tehran gas network, the urgent post-earthquake planning is necessary to shut the flow and diagnose the disruptions. However, the necessity of establishing a monitoring system such as SCADA, for all types of lifeline systems in Tehran is felt. The SCADA should be synchronized with a dense array of seismographs for real-time monitoring and immediate measures in the cases of earthquake occurrence.

Abstract: The aim of this research is to develop a generic procedure for the assessment of the serviceability of a system (single system or system of systems) if one or more interacting components of the system are damaged by an earthquake. The system serviceability (functionality) is evaluated starting from the expected degree of damage of the single components (direct physical damage estimated using appropriate fragility functions) and accounting for their functional interaction (functional system architecture and single or by-directional interactions among components). Through the evaluation of the components' non-functionality, the overall serviceability of the system is assessed, possibly in the form of a "system serviceability curve", for different levels of seismic input intensity. Aleatory and epistemic uncertainties are treated using a Bayesian inference. The applicability of the proposed approach is established through an illustrative example. It is shown that the methodology is quite general and applicable to real systems with diverse degrees of complexity and knowledge of system and components details.

1. INTRODUCTION

In the framework of a comprehensive risk analysis and management of interacting lifeline and infrastructure systems, their seismic performance should be considered in a rigorous and unified way. This could only be achieved through the assessment of the systems' functionality, considering the complexity of structures and the interdependencies among systems and their components.

Several approaches are available to help describe the relations existing between system's components. Some of these are: Graph theory, Fault-tree analysis (FTA), Event-tree analysis (ETA), Series system in parallel (SSP), Agent-based models and Complex Adaptive Systems (Amin 2001, Little 2002, Brown et al. 2004, Bernhardt and McNeil 2004, Tolone et al. 2004). The probabilistic evaluation of the performance of the system (PNET) can be carried out employing the methods of System Reliability Analysis. These include expansion methods, such as FORM/SORM or the response surface technique (Ditlevsen and Madsen 1996), as well as the Monte Carlo simulation methods (Rubinstein 1981). Depending on the nature of uncertainty and the aptitude to determine them, the probabilistic approach may be replaced or enhanced by possibilistic approaches based on Fuzzy Logics, so-called Fuzzy Networks. Also, non-simulation methods have recently seen interesting advances, e.g. in the form of Matrix System Reliability Analysis (Song and Der Kiureghian 2003, Der Kiureghian and Song 2008).

Moving to a higher level, several researchers have proposed different types of interdependency (interactions between different critical infrastructures) simulation models (Kameda 2000, Giannini and Vanzi 2000, Rinaldi et al. 2001, Peerendoom et al. 2001, Amin 2001, Haimes and Jiang 2001, Little 2002, Li and He 2002, Tang et al. 2004, Yao et al. 2004, Brown et al. 2004, Bernhardt and McNeil 2004, Santos and Haimes 2004). Only few methodologies have incorporated interdependencies in the seismic risk analysis of lifelines (Nojima and Kameda 1991, Scawthorn 1992, Eidinger 1993, Shinozuka et al. 1993, Shinozuka and Tanaka 1996, Menoni 2001, Duenas-Osorio et al. 2007, Tang and Wen 2008).

Furthermore, very few studies can be found in the literature dealing with the highest level problem of multiple systems interaction in the case of seismic vulnerability and loss estimates (Duenas-Osorio et al. 2007, Kim et al. 2007). They have still an exploratory character and are based on rather extreme simplifications, being limited to the analysis of at most two systems. Network analysis and graph theory are usually adopted. The Bayesian approach is often used for network analysis. The systems' serviceability is also analyzed using flow or connectivity analysis. Some recent studies have been focused on the proposal of a methodology to evaluate the associated losses of interacting lifeline elements for various strong motion intensities and the estimation of complex fragility curves of interdependent components (Kakderi et al. 2007, Kakderi et al. 2008, Alexoudi et al. 2008a, b).

There is a need for the development of a rigorous methodology for the assessment of systems functionality, considering the complexity of structures and the interdependencies among systems and their components. The ultimate goal is the formulation of a system function that allows the evaluation of the state of the system as a function of the states of its components. The availability of such a function is a prerequisite for the evaluation of the system performance.

Herein, a generic procedure is developed for the assessment of the serviceability of a system, if one or more interacting components of the system are damaged by an earthquake. With the word system, we consider either a single system composed by many interacting components (e.g., one lifeline) or a system of systems (e.g., a set of lifelines and infrastructures), where interaction among components and systems are accounted for. The various types of uncertainties (aleatory and epistemic) are treated with the use a Bayesian inference.

The method introduces a formal and schematic way to account for several innovations in the systemic vulnerability field, such as, different levels of damages, their uncertain link to different levels of functionality, the uncertain configuration of each sub-system, the epistemic uncertainties related to each probability value, the summarization of single functionalities through a normalized performance index of the whole system. All these issues are developed in a generic and coherent framework. However, given the modularity of the methodology, each one of such innovations may be adapted to be applied as single module in the previously presented methodology. In any case, the proposed methodology is quite general and it is applicable, eventually with several further assumptions and/or simplifications, to real systems with diverse degrees of complexity and knowledge of system and components details.

2. SERVICEABILITY MODEL – UNCERTAINTIES AND INTERDEPENDENCIES

The modular procedure to assess the system serviceability proposed by Selva et al. (2011) is adopted. The procedure starts from the Physical Damages (PD) of each component of the system, as assessed through its specific fragility curves. Then, the PDs of all components are translated into their Physical Non-Functionality (PNF), that is, the impossibility of the component to provide its service (supply) to the other components of the system due to the experienced damages. Interactions among the functionality of the components, i.e., their interdependencies, are accounted for assessing the Actual Non-Functionality (ANF) of components and/or sub-systems, i.e., the impossibility to provide services not only because of physical damages (PNF), but also because of the lack of external supplies that are necessary to it. Note that the ANF can be referred to either single "physical" components or "sub-systems", for which a global ANF is modeled starting from the PNF of the "representative" components. Finally, the overall Serviceability of the System (Ss) is assessed, by analyzing the ANF of the "real components" and/or of the "representative sub-systems" that provide the system's final service(s).

The procedure is schematically reported in Figure 1, and it can be summarized as following:

- STEP 0: FC (Fragility curve of a component) → PD (Physical Damages of the component).
- STEP 1: PD → PNF (Physical Non-Functionality of the component due to physical damages).
- STEP 2: PNFs → ANF (Actual Non-Functionality of a component or a sub-system, given the interaction among components).
- STEP 3: ANFs → Ss (overall Serviceability of a System).

The method aims at accounting for all the uncertainties involved in the serviceability assessment. In particular, it explicitly deals with (i) the epistemic uncertainties related to all probability assessments (e.g. Woo 1999), (ii) the uncertainties related to loss estimation and quantitative risk probability assessment [uncertainty related to seismic hazard, response and vulnerability of structures, probability of damage or collapse and the damage/ collapse to loss relationships (e.g. Spence 2007)], and (iii) the problems related to the partial knowledge of systems, in particular regarding missing components and/or links (e.g. Pitilakis et al. 2005). This goal is achieved by combining several strategies.

First, the process is schematized in several consequent events, making the model more readable (and testable) and allowing the use of conditional probabilities (Marzocchi et al. 2010, Grezio et al. 2009). Second, all parameters and values of the model (including probability estimations) are evaluated in a Bayesian perspective, that is, through probability density functions (pdf) (e.g. Gelman et al. 1995). All the probability density functions are then combined together by the extensive use of Monte Carlo simulations. Third, since several "sub-systems" (e.g., networks) cannot be completely known and/or change quickly through time, they are modeled starting from their general characteristics, without assuming specific configurations. In this case, groups of "representative" components are modeled jointly, so that the range of applicability of the method is by far increased, but also the sensibility of the results to missing or not known elements/ links is minimized.

Other important aspects of this model are the fact that it allows (i) to account for the interdependency among different components of the same system (e.g. Kakderi et al. 2007, Duenas-Osorio et al. 2007, Alexoudi et al. 2008 a or b) (ii) to assess and merge the different levels of both "physical damage" and "non-functionality" that each component may experience (Kim et al. 2007, Menoni et al. 2002), (iii) to circularly apply the procedure from single systems to higher level system of systems.

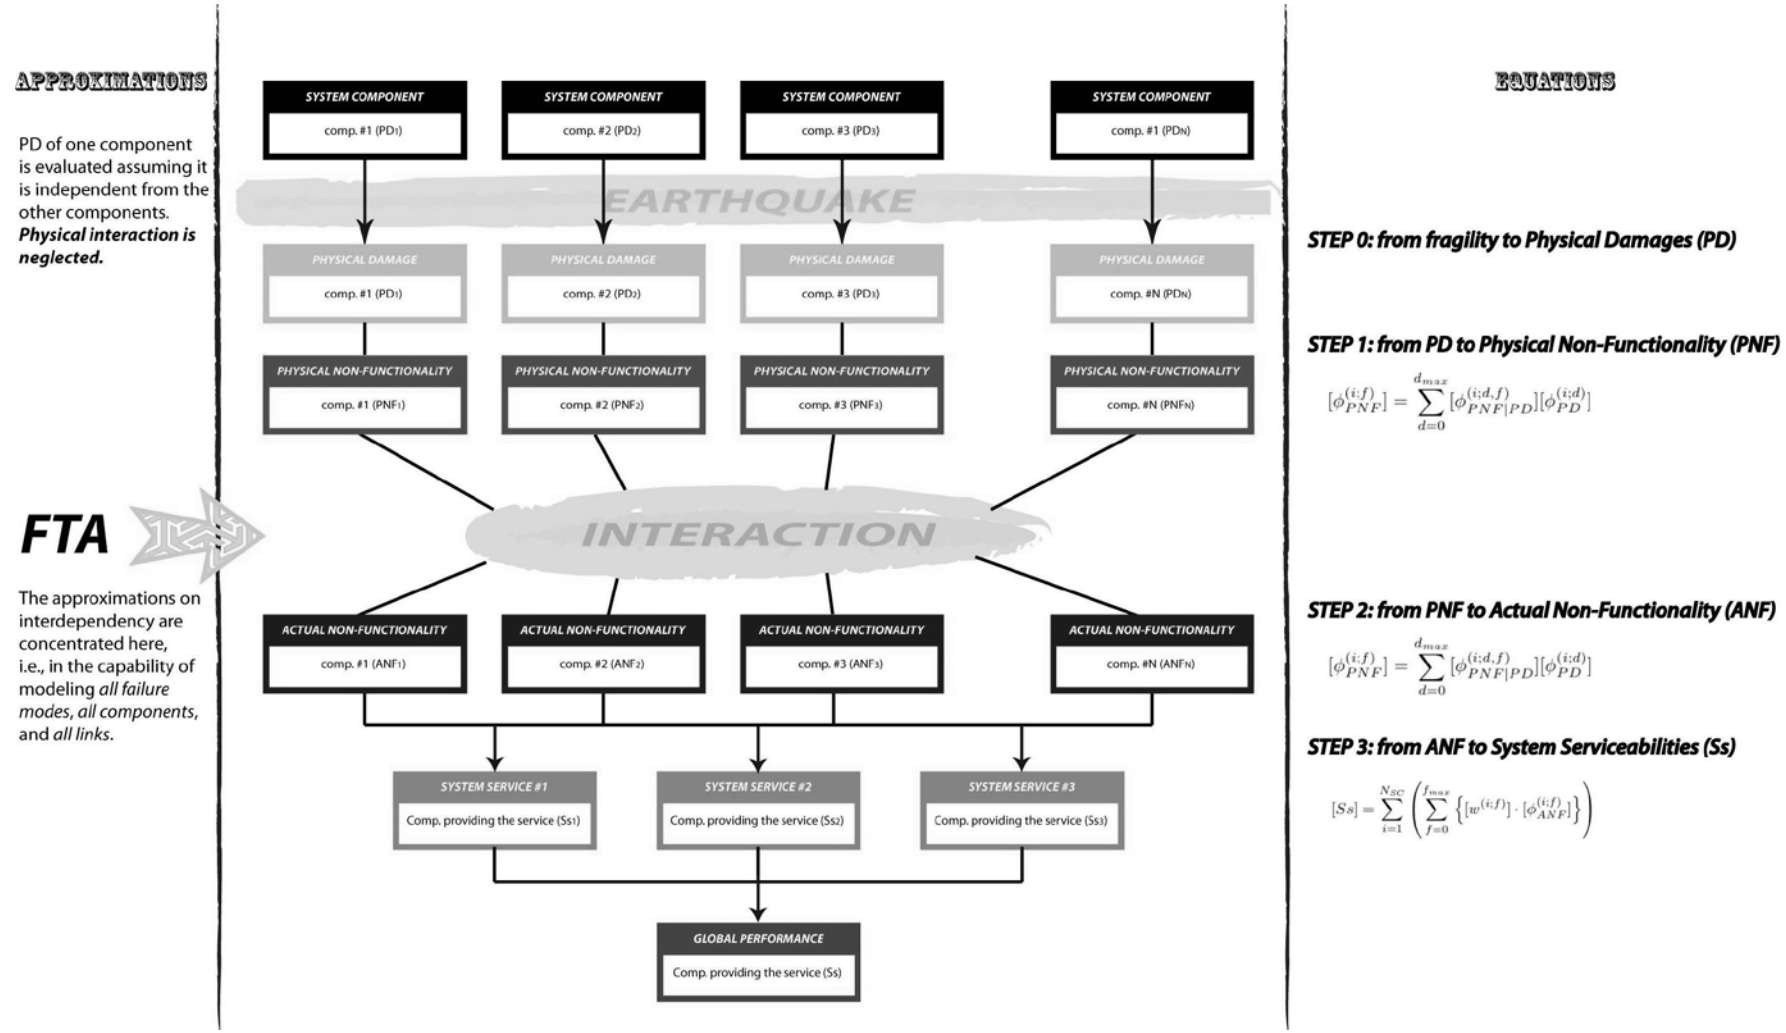

Figure 1. Framework of the proposed methodology (Selva et al. 2011).

3. ILLUSTRATIVE EXAMPLE

The goal of this application is to show a possible implementation of the model described above at various levels of seismic intensity, by considering the elements that contribute to provide service, accounting also for interaction with other infrastructure systems. Herein, two lifelines are examined, the water and electric power supply systems, with the final demand being the supply of potable water to the end users. The final serviceability is evaluated at two levels a) for all end users and b) for emergency use. The system is essentially divisible into three inter-dependent sub-systems: the electric power supply, the pumping and the pipe network sub-systems.

The whole system is assumed only partially known, and it is simulated through its main characteristics. The various sources of uncertainties are modeled following the Bayesian approach, so that all the uncertain parameters (including probabilities) are modeled through appropriate statistical distributions.

The seismic input is expressed in terms of PGA and it is made vary from 0 to 1 g. At each PGA level, the actual input for all elements is randomly sampled from a uniform distribution centered on the level and with a width 0.1 g. The analysis is then performed with 50 different sampled inputs, which simulate the variability of the seismic intensity at a local scale.

Three levels of application are performed, in order to capture all possible modes of inter and intra-dependencies and assess the altering mode of systems serviceability with an increasing level of induced interactions among components and systems. The three cases examined are the following:

Case 1: Water supply system comprised only of pipeline elements (study of interactions between the same components of one system). The Actual Non-Functionality (ANF) of the Pipeline Network (PN) depends only on its Physical Non-Functionality (PNF) (Figure 2A), as assessed through global properties of network (see below).

Case 2: Water supply system comprised of pipeline elements and one pumping station (study of interactions between different components in the same system). The Actual Non-Functionality (ANF) of the Pipeline Network (PN) depends on its PNF and the Actual Non-Functionality (ANF) of the Pumping Station (PST). In a row, the ANF of PST depends only on its PNF (Figure 2B).

Case 3: Water supply (pipelines and pumping station) and electric power system (electric substation) (study of interactions between systems). The Physical Non-Functionality (PNF) of the Pipeline Network (PN) depends on its PNF and the Actual Non-Functionality (ANF) of the Pumping Station (PST), as in Case 2. However, in this case the ANF of the PST depends on its PNF and the ANF of the Distribution Network (DS). Finally, the ANF of the DS depends on its PNF that depends on the PNF of the ETMS and a probability of transition that models the not perfect knowledge of the network (Figure 2C).

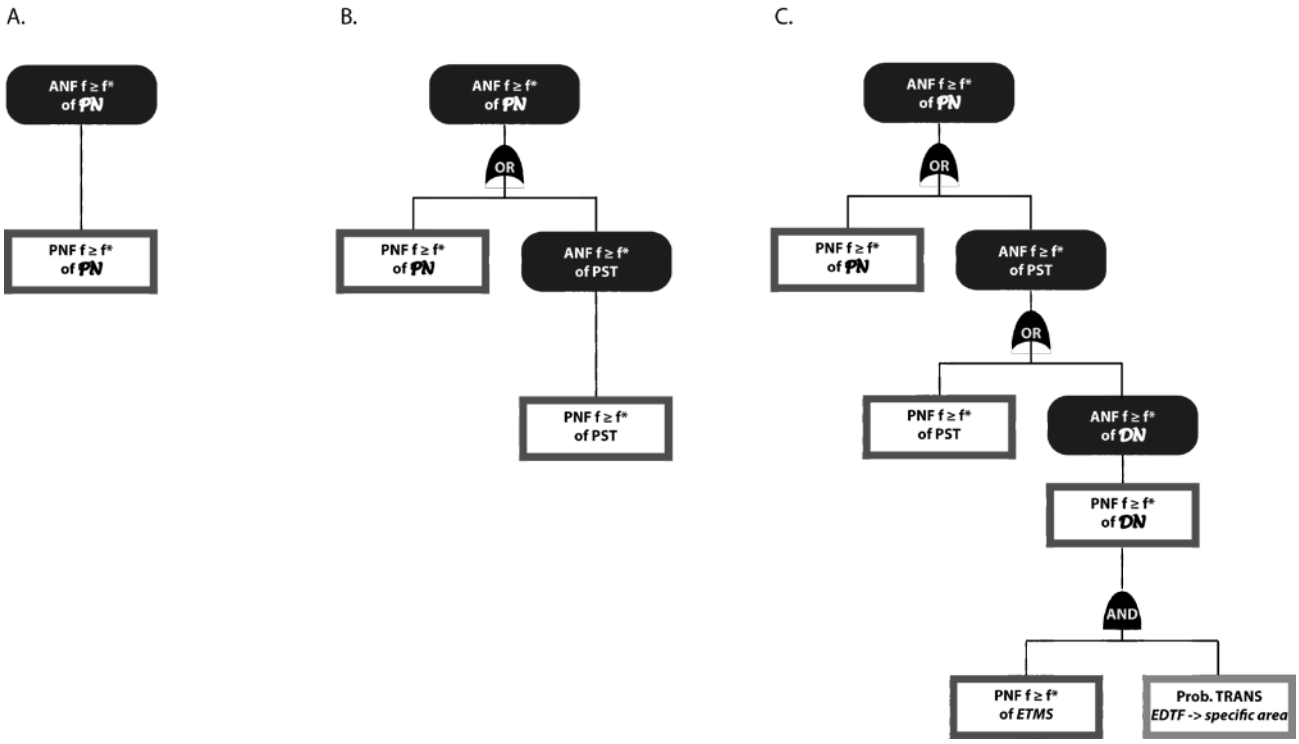

Figure 2. (A) FTA for Case 1 (water supply system- pipeline elements), (B) FTA for Case 2 (water supply system- pipeline elements and pumping station), and (C) FTA for Case 3 (water supply and electric power systems).

The Physical Non-Functionality of the Electric Substation (ETMS) and the Pumping Station (PST) is defined based on the 5 damage states fragility functions proposed in HAZUS (NIBS 2004) for medium voltage substations with anchored subcomponents and for medium /large pumping stations with anchored subcomponents respectively. A 5-d Dirichlet distribution is used to model the uncertainty with a quite high level of confidence (equivalent number of data Λ is set in both cases to 50). The best guess values at all degrees of functionality (f) for the Electric Substation and the Pumping Station are reported in Table 1. Since the Electric Substation (ETMS) is a representative element of the electric supply system (its non-functionality does not necessarily leads to the non-functionality the entire system) a "probability of transition" equal to 0.3 is considered in order to simulate the possibility that the failure of the ETMS is compensated by the rest of the network.

Table 1. Best guess values at all degrees of functionality (f) for the Electric Substation (ETMS) and the Pumping Station (PST).

	0 – complete functionality	1 - partial non-functionality	2 - complete non-functionality
0 (no damages)	1	0	0
1 (minor damages)	0.9	0.1	0
2 (moderate damages)	0	0.65	0.35
3 (extensive damages)	0	0	1
4 (complete damages)	0	0	1

The Pipeline Network sub-system (PN) is a complicated network of different types of pipe, subject to spatially varying seismic input. Their functionality is evaluated at the network level, instead of at the level of single elements based on the statistics of the Repair Rate per pipeline length (RR/km) of each one of the element. For the estimation of the RR/km, O'Rourke and Ayala fragility function is used as proposed in HAZUS (NIBS 2004) for wave propagation. A network composed by 1000 pipeline elements, nominally with a length of 30 m, with a total length of 30 km is considered herein. Each one of them is characterized by its RR/km and the population mean for the entire network (μ_r) is computed. The mean μ_r, normally distributed for central limit theorem, is then compared with appropriate values of the thresholds of μ_r (t_1 and t_2) separating the (non)-functionality states. In practice, the probability of complete functionality is the probability of $\mu_r<t_1$, the one of partial non-functionality the probability of $t_1<\mu_r<t_2$, and the one of complete non-functionality the probability of $\mu_r>t_2$. The thresholds are chosen according to the age and the connectivity degree of the system, the physical and the actual non-functionality of the network are estimated. The uncertainty is modeled using a 3-d Dirichlet distribution. For this application, a new and moderately connected network is considered. The uncertainty on thresholds t_1 and t_2 is modeled through uniform distribution, that is $t_1 \sim$ Unif (0.28, 0.33) and $t_2 \sim$ Unif (0.50, 0.55). By applying the method above, the means of the Dirichlet distribution of the Physical Non-Functionality (PNF) for the Pipeline Network are set, while Λ is subjectively set to 10 (quite low confidence).

Note that for the case of pipelines the seismic intensity to be considered is Peak Ground Velocity (PGV) which presents a better correlation with damages. Also, only ground shaking and not ground failure is examined. For simplicity, we assume uniform stiff soil conditions in the area and hence, PGV may be assessed starting from PGA using simplified empirical relationships (Seed and Idriss 1982). Each sampled PGA_i is translated in terms of PGV_i through an empirical linear relationship. The constant of proportionality is chosen for stiff soils, and it is sampled from a uniform distribution between 90 and 190 cm/sec (due to the variability on source magnitude M_w from 6.5 to 8.5 and source-site distance from 0 to 100 km) to simulate the uncertainties. Also, for reasons of simplicity, PGA values (and thus PGV) are treated as completely spatially uncorrelated. In real applications however, some level of correlation should be taken into consideration, as well as the dependence of the spatial variability of PGV on the specific site effects, which in turn, will be also influenced by the seismic magnitude, source and azimuth effects. However, the correlation given by spatial proximity cannot affect the results since we do not assume any specific spatial configuration for the sub-system.

4. RESULTS

The Physical Non-Functionality (PNF) and the Actual Non-Functionality (ANF) of the three sub-systems, Electric Substation (ETMS), Pumping Station (PST) and Pipeline Network (PN) are presented in Figure 3 for Case 1 (PN independent), Case 2 (PN dependent on PST) and Case 3 (PN dependent on both PST and ETMS). The results of all the elements are given at all PGA levels (0-1.0 g). For Case 1 and for the Pipeline Network the Physical and Actual Non-Functionality are plotted in respect to PGV values, to facilitate the critical consideration of the results also in respect to available fragility relations and real earthquake damage records. By comparing out the Physical Non-Functionality (PNF, dots) and the Actual Non-Functionality (ANF, continuous lines) curves the effect of interaction on each component of the system becomes evident. If, for one component, the PNF and ANF are not significantly different, the component is substantially independent from the other ones, since its functionality depends essentially only on its physical state. On the contrary, great differences in PNF and ANF indicate strong levels of interdependency.

The model seems to capture well the anticipated behavior of the system for all three cases. In case of the independent Pipeline Network (Case 1) the probability of Physical Non-Functionality for both the Electric Substation

(ETMS) and the Pumping Station (PST) seems to increase with PGA, but the probability of Actual Non-Functionality to the supply of water (final system service) is zero since the two systems are not connected with the Pipeline Network considered as the final supply point to the end users. The same is true for the ETMS in Case 2. Another observation is that both the Pumping Station (PST) in Case 2 and the Electric Substation (ETMS) in Case 3 are completely independent from the other elements, i.e., their PNF and ANF are equal.

The effect of interaction is obvious in the alteration of the Actual Non-Functionality of the dependent sub-systems in Cases 2 and 3. The complete non- functionality state seems to be more affected compared to partial non-functionality. The effect of the interaction between the Pumping Station (PST) and the Pipeline Network (PN) is more predominant compared to the interaction with the Electric Substation (ETMS) and always in respect to the level of final supply of water. This could be attributed to the quite "soft" connection assumed between the ETMS and PST with the "probability of transition" equal to 0.3.

Finally, the effect of interaction is obvious in the functionality curves of the final supply point, i.e. the Pipeline Network (PN). Moving from Case 1 to 3 with increasing level of interaction, the functionality curves become more spread (less steep) and move towards greater values of seismic intensity. Even for the case of independent network (Case 1) the probability of both states of non-functionality (partial and complete) seem to be in line with existing fragility functions and experience from past earthquakes. For example given a PGV equal to 80-90 cm/sec, the probability of complete non-functionality is almost 100%, while for PGV values around 60 cm/sec, the partial non- functionality of the network is almost certain. The quite steep shape of the functionality curves of the Pipeline Network (PN) could be attributed to the very stable average RR/km with very small errors. This sudden change in functionality for the PN can be understood when plotting the average RR/km, as a function of both PGA and PGV (Figure 4 for Case 1).

In Figure 5, the results regarding the serviceability of the system are reported. In particular, the probability of serviceability of the system for end-users and emergency operators are reported along with the respective realizations of serviceability. The determinant role of the Pumping Station (PST) is thus identified; a fact of major importance in possible future risk management and mitigation studies.

5. CONCLUSIONS

A generic, modular procedure for the assessment of the serviceability of a system (a single system or a system of systems), if one or more interacting components of the system are damaged by an earthquake is developed. The serviceability (functionality) of each single system, as well as of the entire system of systems, is evaluated, starting from the expected degree of damage (physical damage) of the single components and accounting for their functional interaction. The serviceability is then expressed as the expected (normalized) performance of the system(s) in terms of the service provided to final user(s).

The proposed methodology is quite general and it is developed in a way in order to be applicable to real systems with diverse degrees of complexity and knowledge of system and components details (engineering sound simplifications and assumptions are always necessary). This is established through an illustrative example given for 3 different cases: a single system comprised of the same components (Pipeline Network; Case 1); a simple system (water system) composed by two main interacting components (Pipeline Network and Pumping Station; Case 2) and a system of systems which includes two main water system components (Pipeline Network, Pumping Station) that interact with a main component (Electric Substation) of another lifeline (electric power system). The method presented briefly herein, through the three representative illustrative examples, gives the basis to account for the interdependency among different components of the same system, to assess and merge the different levels of both "physical damage" and "non-functionality" that each component may experience and to circularly apply the procedure from single systems to higher-level system of systems, accounting for the significant uncertainties at each of these steps. The analysis of (aleatory and epistemic) uncertainties plays a central role in the developed methodology, allowing a full treatment of the different sources of uncertainty.

The proposed approach can straightforwardly be applicable to any set of interacting systems, as for example modern urban regions, where the existence of strong dependence between lifeline systems and infrastructures makes the assessment of their functionality a very challenging issue. The quite high level of complexity inherent in such cases can be encountered for, providing not exactly "precise" but, what is most important, "reliable" and "accurate" estimates of the system(s) serviceability after the occurrence of earthquakes with variable levels of seismic intensity. On the other hand, the identification of the more uncertain steps allows concentrating future research efforts on these specific topics.

Incorporating infrastructure dependences in the analysis of post-seismic serviceability of complex systems can lead to a more rigorous assessment of lifeline seismic vulnerability and system reliability. Finally the identification of possible weak points and/or components/ systems with larger influence on the whole performance of the integrated "urban lifeline network", also allows the definition and implementation of effective risk mitigation actions.

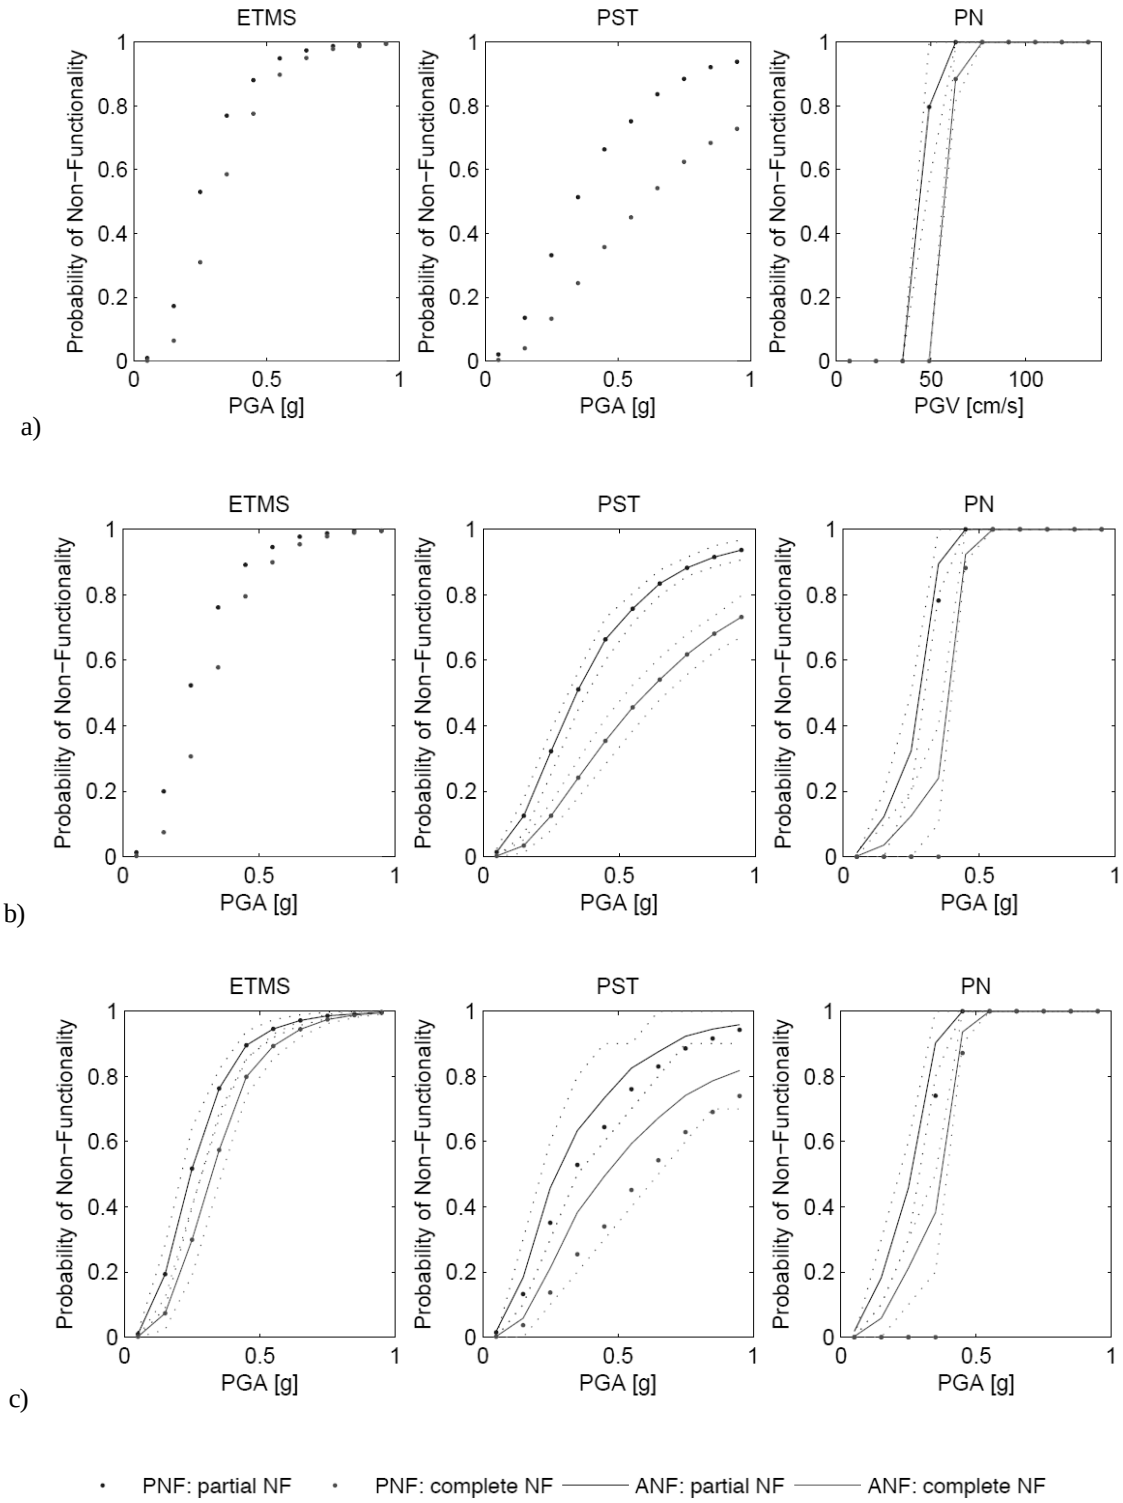

Figure 3. Physical Non-Functionality (PNF), illustrated with dots, and Actual Non-Functionality (ANF), illustrated with lines, for the Electric Substation (ETMS), Pumping Station (PST) and Pipeline Network (PN) and for the three Cases; a) Case 1/ PN independent, b) Case 2/ PN dependent on PST and c) Case 3/ PN dependent on both PST and ETMS. In blue is reported the partial functionality degree (f = 1)) and in red the complete non-functionality degree (f = 2).

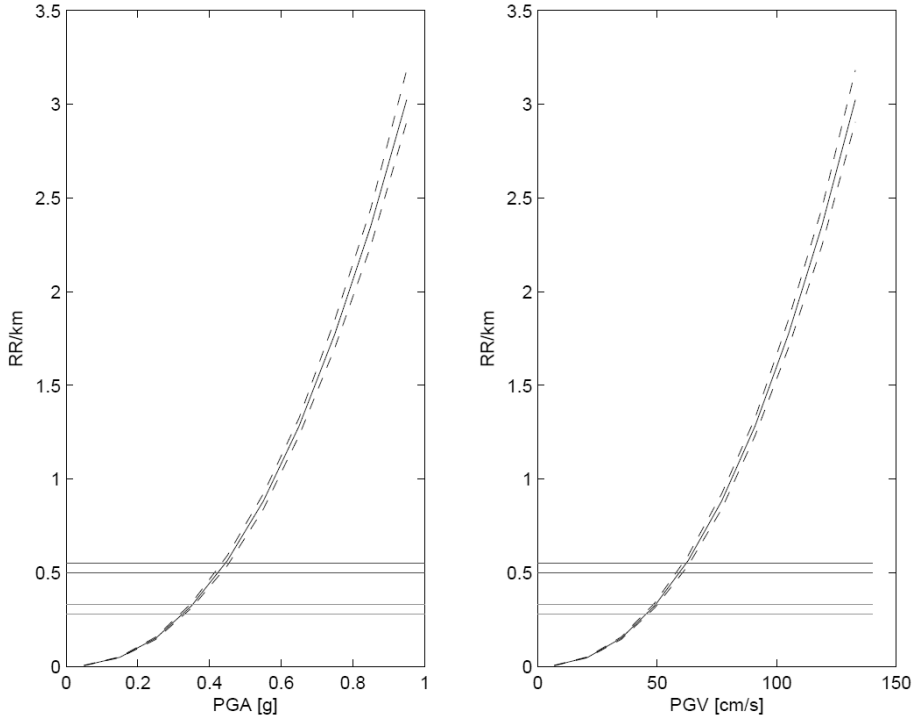

Figure 4. Average Repair Rate/km (RR/km) as a function of both PGA and PGV for Case 1(Pipeline Network independent).

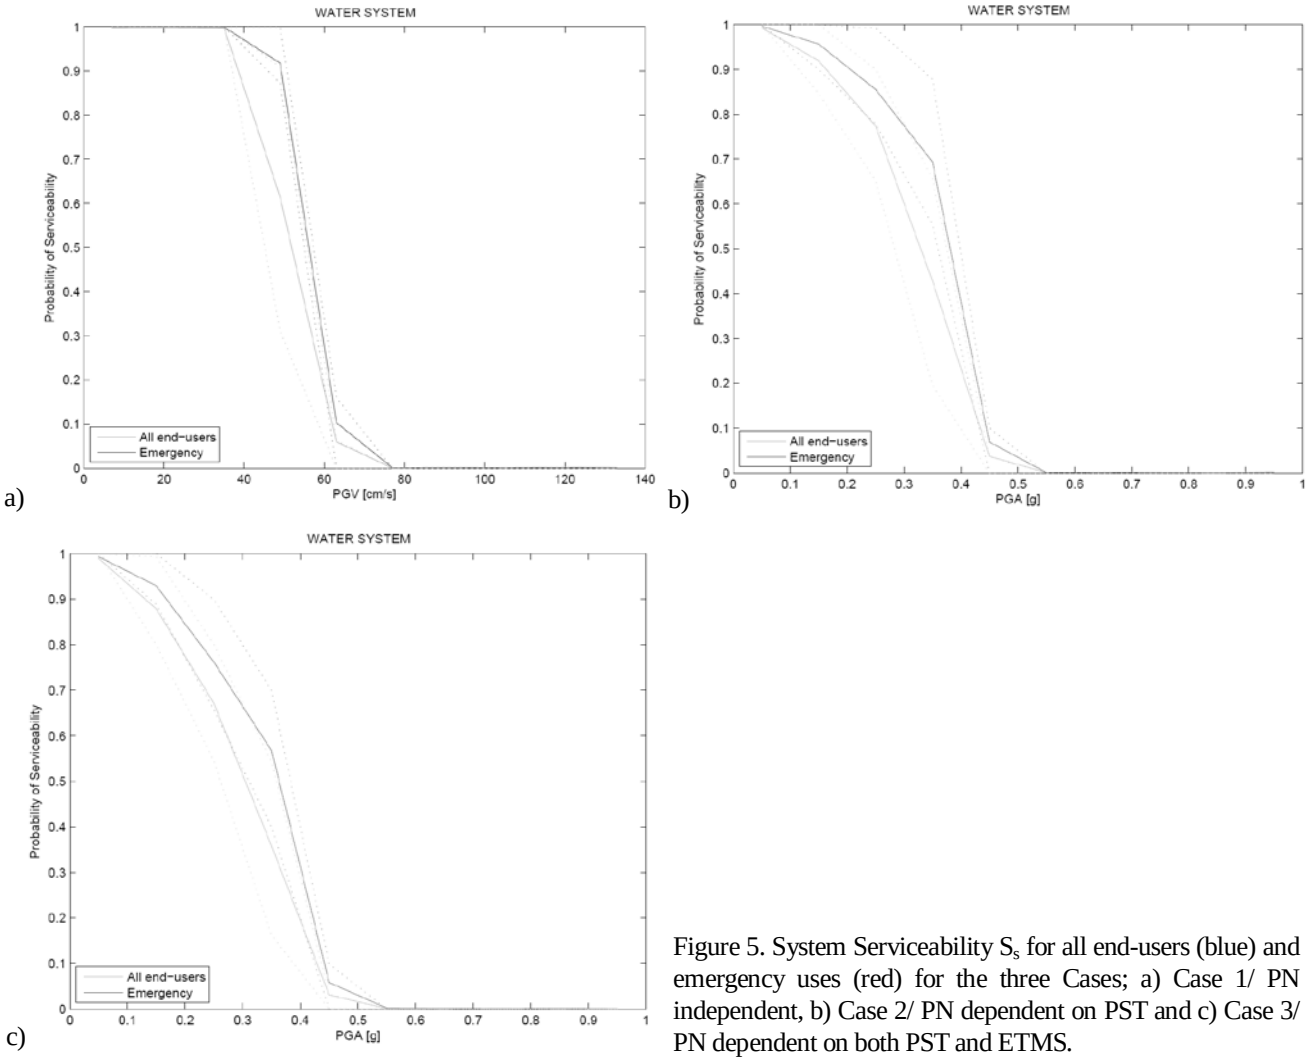

Figure 5. System Serviceability S_s for all end-users (blue) and emergency uses (red) for the three Cases; a) Case 1/ PN independent, b) Case 2/ PN dependent on PST and c) Case 3/ PN dependent on both PST and ETMS.

Abstract: In this paper an attempt was made to evaluate the site specific ground response of overburden soil using microtremor observations of three major cities - Kathmandu, Lalitpur and Bhaktapur of Kathmandu Valley Nepal. Kathmandu Valley cities are built on the former bed of a drained lake over soft soil deposition of lacustrine origin. The thickness and properties of these sediments vary from one place to other and hence the behavior of the seismic waves might be different from one place to others. It is therefore imperative to conduct a detailed site specific hazard assessment, which can assist in systematic earthquake mitigation program. The predominant time periods of the ground were determined from the horizontal to vertical spectral ratio technique. A map showing the distribution of site predominant periods was developed and the related results in relation with the building vulnerability were done. The time periods showed good agreement with period obtained from the borehole data analysis and distribution of the soil in three cites of Kathmandu Valley. The study shows that there is a longer period ground vibration in an area towards the center of Kathmandu city in compared to other two cities.

1. INTRODUCTION

It has been known for many years that buildings supported on different types of soils suffer different levels of damage from earthquake shaking. It is also well known that the major damage arise at resonance, when the natural period of structure is equal or very close to the dominant period of the site. Therefore, the ground response analysis of an area is an important component in the correct evaluation of site dominant period which is widely used by the geotechnical experts, engineers and/or city planners for the design of buildings and infrastructures.

Numerous ground response studies in earthquakes during the last few decades showed large concentration on damage in specific area overlain by soft sediments. The 1934 Great Bihar Nepal earthquake (Pandey and Molnar, 1988) and the 1985 Michochan Earthquake, Mexico (Estrellav and Gonzalez, 2002) have demonstrated the significant contribution of local geology which controls the intensity of ground shaking. The 1985 Michochan Earthquake is well known for heavy damages in buildings in the Mexico city. Although this city was located at 390 km from the fault area, the capital city suffered an unexpectedly significant damage. The devastation caused in Mexico city was due to the strong amplification of the ground motion by the soft deposit of soil in the city. From this earthquake and damage condition, it can be understood that the natural period of ground depends not only on the stiffness of soil but also on the thickness of soil. The response of earthquake is thereby site specific.

Kathmandu Valley, the capital of Nepal, consists of three major cities – Kathmandu, Lalitpur and Bhaktapur. Historically and archeologically these cities are famous for ancient cities of fine arts and crafts and cities of devotees. These cities are seismically most vulnerable because of their seismicity, population density, building condition and geological setting. They are laying on thick unconsolidated lacustrine soil deposits which vary from one area to other (max upto 550 m). Many observers have likened the soil condition of Kathmandu to those of Mexico city which is notorious for its susceptibility to damage during the earthquake.

Nepal has experienced several devastating earthquakes in the past resulting in huge amount of property damage and large number of human deaths. In each and every earthquake, Kathmandu Valley's cities have been heavily devastated. In 1934, an earthquake of M 8.4, epicenter located about 240 km towards east of

Kathmandu Valley, produced strong shaking in Kathmandu Valley and destroyed 19% and damaged 38% of valley`s building stock (Pandey and Molnar 1988). In Kathmandu itself, one quarter of all homes were destroyed. The destruction was most complete at Bhaktapur and neighboring villages in the eastern part of the valley.

Devastation of these three cities of Kathmandu Valley from historical earthquakes, the M8.4 Bihar-Nepal Great Earthquake of 1934 in particular, suggest that spectral ground amplification due to unconsolidated quaternary sediments is playing the major role in the intensification of ground motion. The intensity distribution in the valley by this earthquake varies from VIII to X MMI within different sedimentary facial domains of unconsolidated sediments. From the evidence of Kathmandu basin, it can be understood that the unconsolidated sediments in the three cities of Kathmandu basin shows far most complex picture with considerable local variation over short distances and this composition of subsurface structure makes its susceptible to intensification of incoming seismic waves and hence damage to the structures. The actual behavior of soil to the incoming seismic waves could be different from one area to others within the city as sediment properties and thickness change. No in depth studies have been carried out for ground response study of these cites to date. So it is urgent and necessary to analyze the ground response in various areas of these cities so that the site dominant period of the ground can be evaluated correctly in different areas of these three major cities of Nepal.

Study of subsoil condition has great importance in civil engineering and is usually performed by drill holes. However, this method has different limitations when applied in urbanized and densely populated area mainly because of its cost, time and environmental impact (use of drilling). Methods based on the analysis of strong motion records are straight forward for determining the site response. However, availability of ground motion record is limited to very few countries and possibility of data recording in required station is almost impossible in developing countries like Nepal because of urbanization and economic feasibility. So, this method is not suitable for the site response analysis of urban areas. In this context, the method based on ambient noise recording became more and more popular over the last decades and it offers a convenient practical and low cost tool to be used in urbanized area and has become the most appealing approach for site response studies.

A technique horizontal-to-vertical spectral ratio (H/V) of microtremors was first proposed by Nogoshi and Igarashi (1971) where they relate the H/V ratio of microtremors with a measure of ellipticity of Rayleigh waves, as an indicator of the fundamental resonance frequency of structure. Nakamura (1989) modified microtremor analysis by proposing a new understanding, generally referred to as the Nakamura or H/V method. He indicated that the horizontal-to-vertical (H/V) spectral ratio at a site roughly equals to the S-wave transfer function between the ground surface and basement layer at the site. This means that the H/V predominant period and the peak value at the period themselves correspond to the natural period and peak amplification factor of the site, respectively. He proposed this new technique, based on his understanding of microtremors and demonstration of consistency between actually observed damage distributions by the earthquakes and microtremor measurement results by this technique. This method does not require any borehole and is, hence, more convenient and inexpensive compared to the traditional borehole method. As a result, this technique for microtremor studies has gained much popularity over the past years due to its inherent advantages of the ease of microtremor recording with a single station and ability to provide reliable information related to site response (Nakamura, 1989, 1997, 2000, 2008; Bard and Chavez-Garcia, 1993; Field and Jacob, 1993; Lermo and Chavez-Garcia, 1993, 1994; Theodulidis and Bard 1995; Theodulidis et al., 1996, 2005; Field et al., 1995; Bour et al., 1998; Teves-Costa et al., 1996, 2001; Hung and Teng, 1999; Delgado et al., 2000; Zaslavsky et al., 2000; Fäh et al., 2000; Diagourtas et al., 2001; Estrella and Gonzalez, 2002; Huang, 2002; Parolai et al., 2004; Carniel et al. 2005; Hung et al., 2005; Bonnefoy-Claudet et al., 2006; Hasancebi and Ulnsay, 2006; Gosar, 2007; Gueguen et al., 2007; Herak, 2007; Birgören et al., 2008). Although his theoretical explanation remains questionable to many scientists, this method is now widely used for microtremor observations. Different experimental data analysis supported that the H/V ratios are stable and on soft soils they exhibit a clear peak which is well correlated with the fundamental resonant frequency of the sites. Among several proposed microtremor methods, the H/V method has proven to be one of the most convenient techniques to estimate the fundamental frequency of soft deposits (Fäh et al., 2008). Nowadays this method has extremely been used for evaluation of seismic characteristics of many areas of the world situated within the thick soil deposit, where devastation is expected due to future earthquakes.

In this study, microtremor measurements were performed in the core area of three cities in Kathmandu Valley of Nepal and subsequent analysis and interpretation of result will be done to assess the geotechnical condition of subsurface structure of these three cities. The objectives of field investigation in the cities were to measure the microtremors in many locations especially in the core area of cities and to analyze and interpret them by the H/V method in order to find out the dominant period of the different locations.

2. GEOLOGY AND SEISMICITY OF THE STUDY AREA

2.1. Study area and geotechnical setting.

The Kathmandu Valley lies in central part of Nepal. The valley's maximum width is approximately 25 km

from east to west and 20 km from north to south and it has average elevation of around 1340 m. Its three districts- Kathmandu, Lalitpur and Bhaktapur- cover an area of 899 square kilometers, out of which the valley covers 665 square kilometers. The cities of Kathmandu and Lalitpur are separated by the Bagmati River and, due to the expansion of the urban areas in both the cities, the boundary between the two now has only historical, political and administrative importance. Likewise, the spatial separation between Bhaktapur and the other two cities is rapidly becoming less and less conspicuous. The location map of three cities and microtremor observation area are shown in Figure 1.

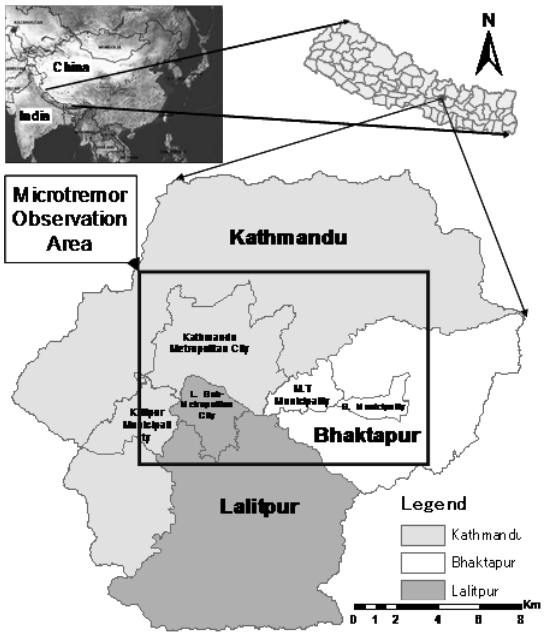

Figure 1 Location map of study area

surrounded by the Mahabharat Mountains in the south and the Shivapuri Mountain in the north. The evolution of the basin started in neogene - quarternary time as a consequence of higher rate of uplift in the south in relation to north as a response to evolving Himalaya thrust tectonics. The southward flowing valley drainage stopped because of this uplift and formed a lake and the subsequent deposition of layers of rivers and lake sediments (Sakai, H. et al., 2001).

The basin is filled with thick sediments composed of unconsolidated clay, silt, sand and gravel ranging in the age from the late Pliocene to the present and all are derived from the Shivapuri and Mahabharat mountains around the valley (Dongol, 1985; Sakai, H. et al., 2001). The unconsolidated clay of the valley varies widely in composition and is divided into three groups (Sakai, H., 2001). The northern part of the valley consists of marginal fluvio-deltaic facies (typical riverbed layered deposits of clays, silts, sand and gravels) while those in the southern part mainly alluvial fan facies (lake deposits of clays and silts, usually sandwiched between thin layers of coarse sediments) and the central part of the basin consists of open lacustrine facies (a thick organic mud, the black (kalimati) clay). Based on the gravity measurement in the Kathmandu Valley, Moribayashi and Maruo (1980) estimated the maximum thickness of the basin-fill sediments to be 650 m. A number of drill well data prove that more than 300 m thick mud and sands are extensively distributed under the Kathmandu Basin (Moribayashi and Maruo, 1980; Katel et al., 1996; Sakai, H. et al., 2001). Figure 3 shows the fence diagram of subsurface structure of the Kathmandu basin prepared by Katel et al., 1996 which indicates extensive distribution of black clay sediments of lacustrine origin, rich in organic matter. From the above discussion, it is clear that the sediment in Kathmandu basin shows far more

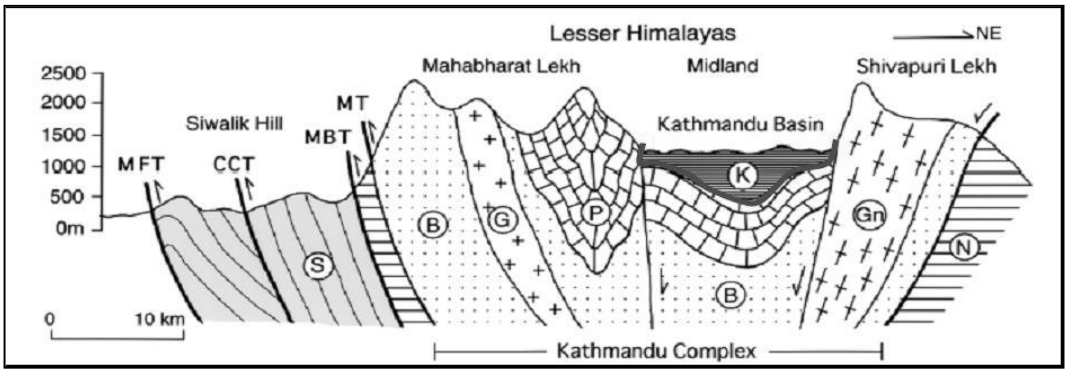

Figure 2 A schematic cross section in the Central Nepal Himalayas based on Sakai, H. et al. (2002) (modified after Stocklin and Bhattari, 1981). S: Shivalik group, P: Phulchauki group, N: Nuwakot complexes, G: Granite, Gn: Gneiss complex, K: Kathmandu complex, MFT: Main Frontal Thrust, CCT: Central Churia Thrust, MBT: Main Boundary Thrust (Main Central Thrust: MCT)

Kathmandu basin has been evolving as a tectonic intramontaine, bowl shape, basin in Lesser Himalaya of Central Nepal since the neogene - quaternary period (Yoshida and Igarashi, 1984; Katel et al., 1996; Sakai H. et al., 2002) as shown in Figure 2. The basin is complex picture with considerable local variation over short distances. Such a composition of the valley subsurface makes it susceptible to promoting damage during an earthquake.

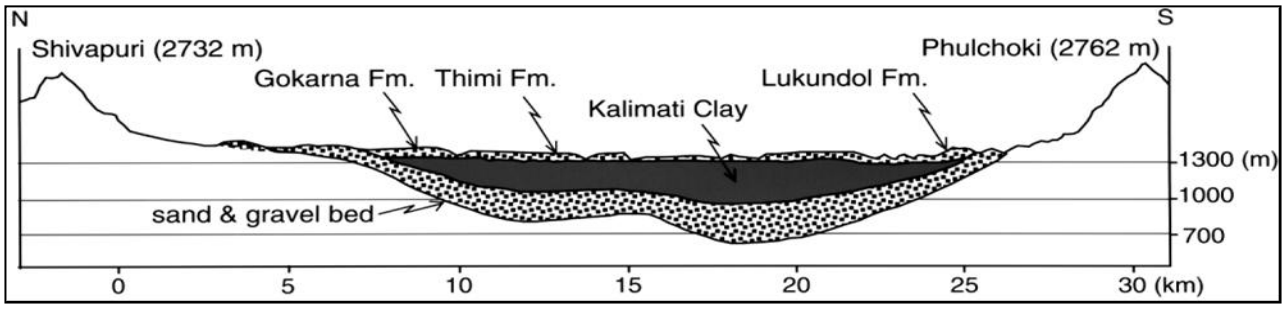

Figure 3 A schematic geological cross-section of the Kathmandu basin, showing sediment distribution in north-south direction through center of the Kathmandu Valley (Katel et al., 1996)

2.2. Seismicity

Geologically, Nepal and the Himalayan range that forms its northern border with China were formed as a result of the collision of the Indian Plate with the Eurasian Plate about 55 million years ago (Molnar, 1986). The collision was followed by subduction of the Indian plate underneath Tibet, which continues today at an estimated rate of about 2 cm per year (Bilham et al., 1995). This makes Nepal and the entire Himalayan range one of the seismically active spots on the earth.

The major fault systems are parallel to the Himalayan arc formed by the collision and subduction of these two plates. The fault systems in the Himalayan arc are divided into four major systems:

- Main Frontal Thrust (MFT)
- Main Boundary Thrust (MBT)
- Main Central Thrust (MCT)
- South Tibetan Detachment system (STDS)

The subduction results in tectonic stresses along these fault systems and the movement of these major fault systems and their branches creates the earthquakes in the region. Numerous earthquakes have occurred in this region, including four major ones of magnitude greater than M8 within the last 100 years and resulted in huge amount of economic loss and large number of casualties (Molnar, 1984; Bilham et al., 1995).

During the development of Nepal National Building Code in 1994, five active faults have been identified (UNDP 1994) within KV. Most of the faults are dip-slip and some of them are strike-sip also and lie within 5 to 8 km from the center of KV. These faults are believed to be capable of generating a maximum of 6.6 Richter magnitude events. However there has not been any detailed study carried out to quantify these faults and their activity. There are other faults which are within the distance of 20 to 50 km from KV. These faults are believed to be capable of generating a maximum of 6.9 to 7.1 Richter magnitude events and hence any major earthquakes along these faults definitely affect the Kathmandu Valley.

Moreover, during the study of earthquake risk management in KV in 2002, Japan International Cooperation Agency (JICA) has developed a four scenario earthquake for KV based on the historical earthquake catalogue, recent seismicity, and tectonic aspects in and around Nepal and the KV and prepared earthquake intensity map of each scenario for KV. Out of them, Mid Nepal earthquake scenario is considered to be the most severe scenario for KV in which earthquake with a magnitude of 8 has been included considering the seismic gap in the middle of Nepal. Several researchers have pointed out that a huge earthquake may occur in near future in this gap. The Kathmandu Valley would experience peak ground acceleration of about 200 to 300 gal (JICA, 2002).

From the review of the past study and historical seismicity in Nepal, it is found that there is a high possibility of occurrence of huge earthquake in mid Nepal and the condition of Kathmandu Valley in terms of geology, building, building code enforcement, urban planning is so poor that it would suffer very heavily if this earthquake strikes at any time in this region.

3. MATERIALS AND METHOD

Microtremors are continuous small amplitude vibrations of ground originating from unknown sources, which have amplitude varying between 0.01 – 0.001 mm and period of 0.01 – 20 seconds. Sources of microtremors can be natural, like ocean waves or wind, and/or artificial due to human activity such as traffic, industrial noise, etc.

The most common procedure of microtremors analysis is to divide the Fourier amplitude spectrum of ground motions observed on soft soil site by that observed at nearby reference site on bedrock. The ratio thus obtained can be considered as transfer function between the bedrock and the free surface of the site for estimating the site response, provided that the two recordings are of the same source, the same path effects, and that the reference site has a negligible site effect. Nakamura (1989) introduced a new method to estimate the dynamic characteristics of surface layers by measuring solely the microtremors at the surface of the ground. He assumed that components of ground motion are equal in all directions at the bed rock and there is no amplification in vertical ground motion components. According to him only horizontal microtremors are influenced by soil and that source spectral characteristics

are maintained in vertical as well as in horizontal microtremors. It was confirmed by many observational results that the transfer function can be obtained solely from the motion of microtremors at surface which obviously makes it easier to estimate the characteristics of ground motion.

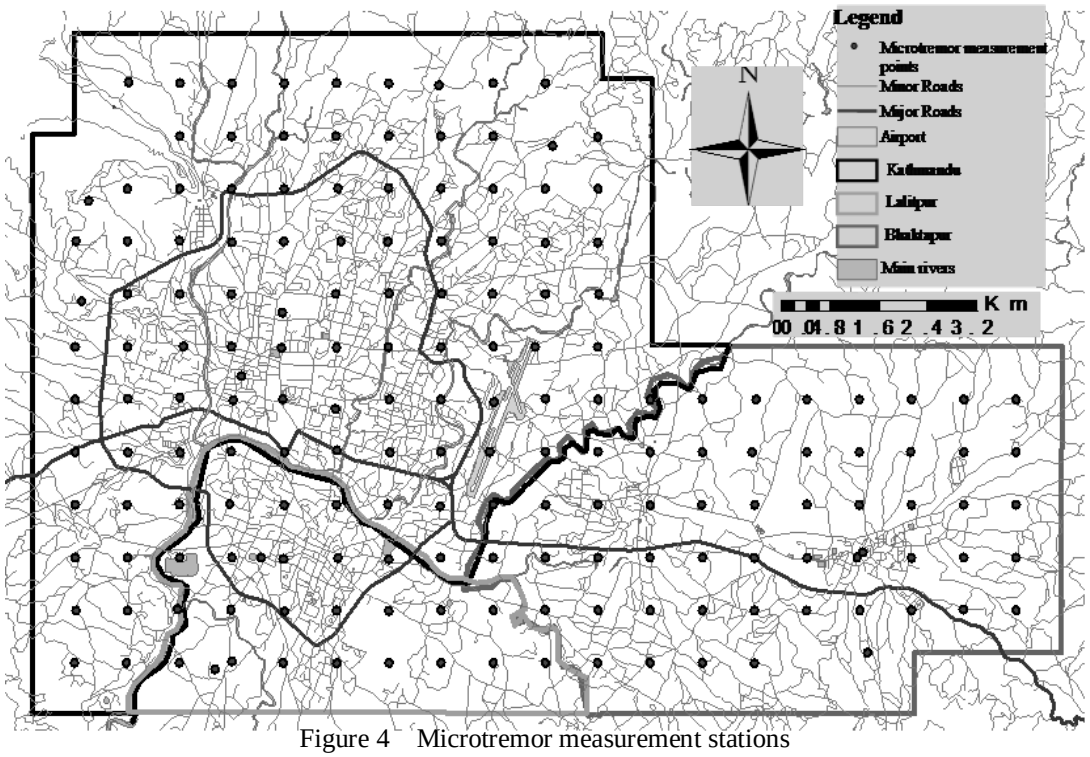

Figure 4 Microtremor measurement stations

The microtremor observation was carried out in January and February 2010 covering the densely populated urban area of Kathmandu, Lalitpur and Bhaktapur City of Kathmandu Valley of Nepal. The main rationale of this study is to evaluate the characteristic site period of ground of these cities. For this purpose, city core areas were divided into different zone by 1 km grid along east-west and north-south direction respectively as shown in Figure 4. Latitude and longitude of the sites were taken from Geographic Information System (GIS). To accurately identify the sites for microtremor survey, site maps were prepared. Then, site map and GIS coordinates were used to accurately set up microtremor measurement instrument set in a site. Microtremor observations were performed using portable microtremor equipment. Sensor for New PIC made by System and Data Research (SDR) Co. Ltd. Japan was used for the data acquisition. The sampling frequency for all measurements was set at 100 Hz. The velocity sensor used can measure three components of vibration: two horizontal along east-west and north-south and one along vertical direction. A global positioning system (GPS) was used for recording the coordinate of observation sites.

The microtremor instrument was set up in each grid points and measurements were carried out at each point along the grid as shown in Figure 4 at a distance interval of 1 km. Microtremor recordings were carried out in regular grid as far as possible. A single recording was enough if there was not any influence on recorded data by traffic and human activity, but more than one time of recording were conducted when the recorded data was unsatisfactory. The microtremors sensor are very sensitive one, even a small disturbance or vibration caused by human foot steps nearby or vibration caused by heavy vehicles far away from the measurement station is recorded during measurement. These unwanted recorded vibrations may affect the results of the analysis and output might not represent the actual condition of the sites. So, these unwanted recorded vibrations data such as the vibration from the heavy traffic especially large vehicles and nearby pedestrians must be removed before the data analysis.

Microtremor data measurements were done at more than 100, 30 and 57 sites in Kathmandu, Lalitpur and Bhaktapur city areas, respectively. At each site, data was recorded for 300 seconds (i.e. 30,000 data points at the sampling rate of 100 Hz). The recorded data was extracted from the data acquisition system. The time history graph of all recorded data was drawn. The recorded time series data were divided into 15 segments each of 20.48 s duration. For each site, as many as possible (generally 8 – 12) segments of the data were chosen from 15 segments, omitting the segments that are influenced by nearby heavy noise sources, for the calculations. The Fourier analysis of the selected segments was carried out using the Fast Fourier Transform (FFT) computer program and the Fourier spectrum and H/V ratio of all segments were obtained and then smoothened using a Parzen window of bandwidth 0.5 Hz. The average spectral ratio of the

horizontal-to-vertical components was calculated according to:

$$H/V = \sqrt{[(F_{NS}^2 + F_{EW}^2) \Big/ (2F_{UD}^2)]}$$

Where, F_{NS}, F_{EW} and F_{UD} are the Fourier amplitude spectra in the north-south (NS), east-west (EW) and up-down (UD) direction, respectively.

This procedure was repeated with the remaining segments. After obtaining the H/V spectra for all the segments, the average of the spectra was obtained as the H/V spectrum for a particular site. The frequency corresponding to the maximum amplitude of H/V spectrum plot shows the predominant frequency of the site. So, measuring the three components of background noise at a site, site specific resonance frequency will be calculated.

4. RESULTS AND DISCUSSION

Data analysis of all measurement sites of three cities were performed by H/V method and the predominant time period of all sites were obtained. The predominate time period in the case of Kathmandu city were found in the range from 0.11 to 2.05 sec while Lalitpur and Bhaktapur city predominant time period were found in the range from 0.166 to 1.428 sec and 0.263 to 1.28 sec respectively. The results showed that the range of time period in the case of Kathmandu city is longer than that of other two cities and also the maximum time period of Kathamndu city is higher than that of other two cities. In the case of Kathmandu city the maximum time period was found 2.05 sec while 1.42 sec and 1.28 sec were found for Lalitpur and Bhaktapur city respectively. The variations of time periods in three cities are shown in Figure 8, Figure 9 and Figure 10.

From the result of microtremor observation in three cites of Nepal, it can be observed that the predominant time period of ground increases towards the center of Kathmandu city whereas such increasing pattern is not seen in the case of other two cities. In the case of Kathmandu city, especially in the center part, variation of time periods were found from 1.2 to 2.05 s as shown in Figure 8 but in the case of Lalitpur and Bhaktapur city such large variations were not seen. Most of the densely populated core area of Kathmandu city have time period in the range from 0.8 to 2.05 sec while area outer side of the core city area have time period in the range of 0.11 to 0.8 s as shown in Figure. 8. Similarly most of the area of Lalitpur city have time period in the range of 0.7 to 1.2 sec while most of the area of Bhaktapur city have time period in the range from 0.5 to 1.0 sec as shown in Figure 9 and Figure 10. Moreover, the average time period in the case of Bhaktapur city is found lower than that of the other two cities. Figure 5 shows the H/V spectral ratio of microtremor for sites within the densely populated core city area the Kathmandu city. Similarly Figure 6 and Figure 7 show the H/V spectral ratio of microtremor for Lalitpur and Bhaktapur city area in which most of the sites were with in the range of time period as mentioned in Figure 6 and Figure 7.

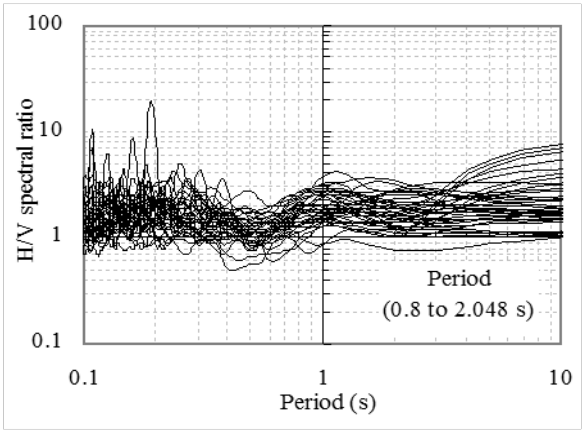

Figure 5 H/V spectral ratio of microtremor for Kathmandu city having time period 0.8 to 2.05 s (core city area)

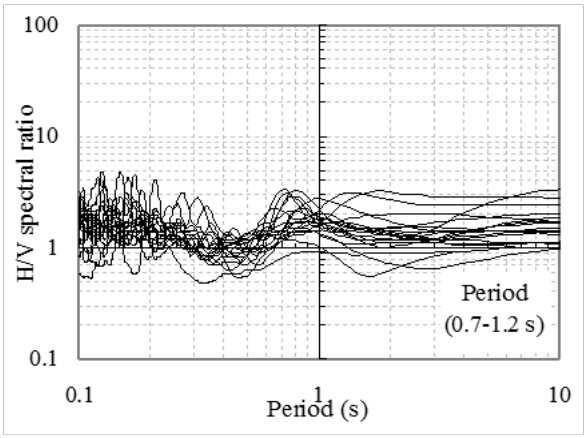

Figure 6 H/V spectral ratio of microtremor for Lalitpur city having timet period 0.7 to 1.2 s (covering most of the city area)

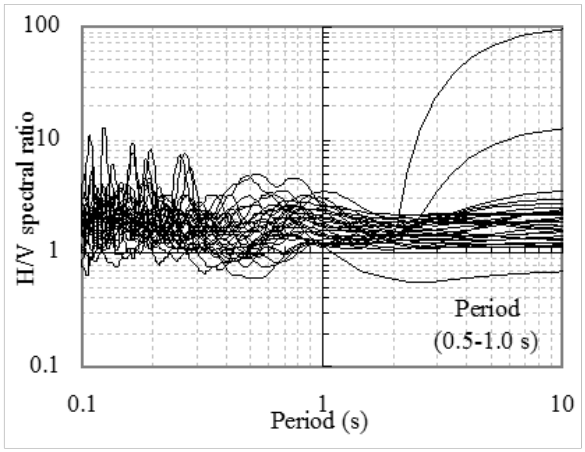

Figure 7 H/V spectral ratio of microtremor for Bhaktapur city having time period 0.5 to 1.0 s (covering most of the area of city)

The profile as shown in Figure 11 drawn along the center of Kathmandu Valley along north to south direction based on predominant time period obtained by the H/V method shows good correlation with the variation of the sediment thickness of the Kathmandu basin proposed by Katel et al. (1996) as shown in Figure 3.

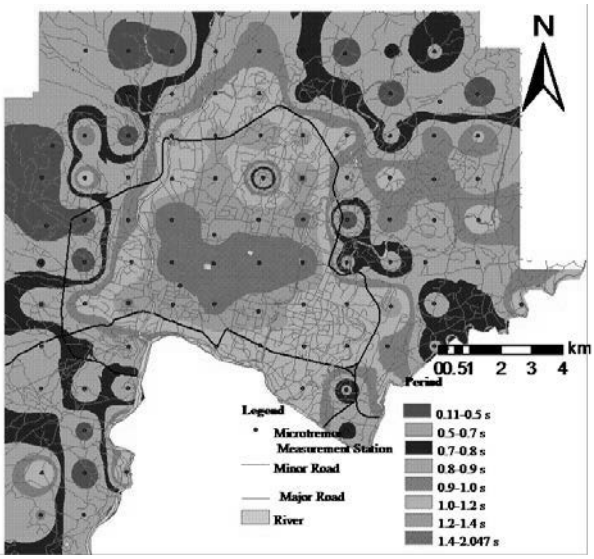

Figure 8 Microzonation of Kathmandu city based on the predominant time period

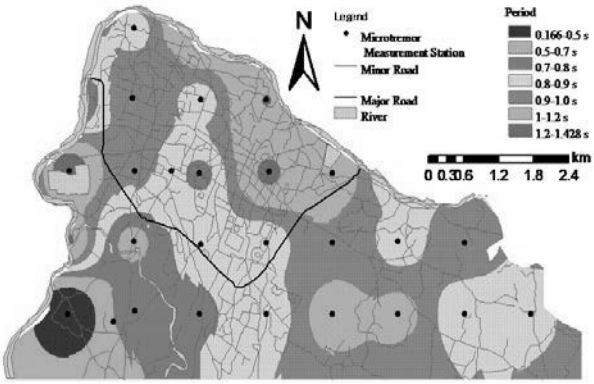

Figure 9 Microzonation of Lalitpur city based on the predominate time period

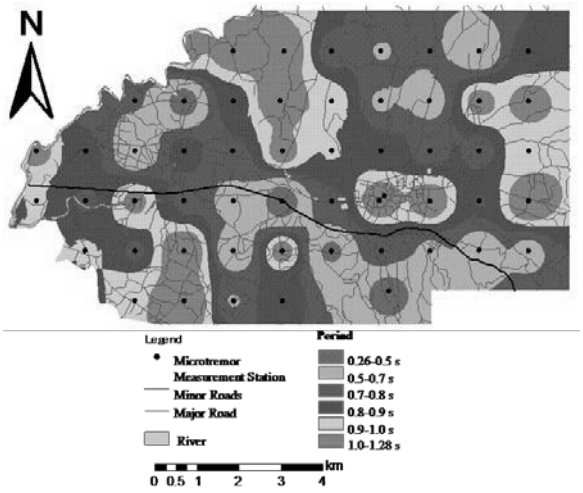

Figure 10 Microzonation of Bhaktapur city based on the predominant time period

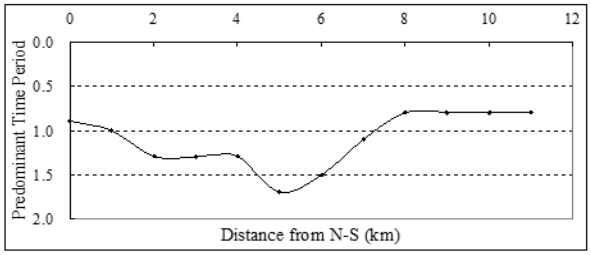

Figure 11 Profile of time period along north to south direction through center of Kathmandu Valley

5. CONCLUSIONS

In this study, microtremor measurements were carried out at more than 100 sites in Kathmandu city, 30 sites in Lalitpur city and 57 sites in Bhaktapur city, especially in densely populated urban areas. Predominant time periods of the ground were obtained using the horizontal and vertical spectral ratio (H/V) technique. Based on the H/V ratios of the microtremors, the predominant periods in the core city areas of Kathmandu were found higher than the Lalitpur and Bhaktapur city area as the sediment thickness is higher in center of Kathmandu city.

The classification into areas of different hazard level was done based on the dominant time period of the ground in different areas of three cities. Since the predominate time period of ground, which depends on the soil thickness, plays a very important role in the resonance effect with seismic waves and structures, it will be useful from hazard estimation point of view.

The time period obtained with H/V method shows good correlation with the variation of the sediment thickness of the Kathmandu basin carried out by Katel et al. (1996). With in the center part of Kathmandu city, the predominant time period were found maximum where the basin attains the maximum thickness and gradually decreases in the predominant time period towards the periphery of the basin, as the sediment thickness decreases, confirming the structure of the basin.

This study shows that the predominant time period of ground is different in different area of cities, which may affect structures having period according to the period of ground. Hence special attention should be given towards seismically design and construction of such structures.

Abstract: Local scour induced by tsunami floods or rover floods is the major problem that causes the failure of a structure. However, due to the difficulty on describing the sediment transport mechanism, engineers deeply rely on empirical or semi-empirical formulae which are mostly derived from steady and equilibrium conditions. Unfortunately, the structure failure usually occurred in the event of extreme flood which deviates tremendously from the assumption mentioned above. In this paper, we propose a 3D numerical scouring model based on the Bingham rheological theory. The bed load, suspended load, and laminated load in the conventional sediment transport theory are converted into a clear water area, mixed area, and plug area in the Bingham model. The model is validated by the analytical solution of a Bingham flow in a channel with excellent agreement. This model is further used to simulate the submerged jet-scour problem. The multi-fluid flow, including air-water and water-sediment, is described by the Volume-of-Fluid (VOF) method. The profile of the scouring bed is compared with the laboratory experiment. Both the maximum scouring depth and location can be well predicted. At the end, this model is used to simulate the failure of Shuan-Yuan Bridge in the event of 2009 Typhoon Morakot. The computed scouring depth is compared with the field measurement with good agreement. The profile of the riverbed around the bridge piers after scouring is presented.

1. INTRODUCTION

Local scour is the removal of the streambed material from bridge foundations due to the flooding water, and is the most common cause of bridge failures during the typhoon events in Taiwan. To minimize the future bridge damage, an accurate estimation or simulation on the scouring depth is the key. However, very few studies have been developed for evaluating bridge scour under extreme weather. In the past few decays, the estimation of scour depth relayed on the empirical formula. One example is the Lacey's formula (1930). In Lacey's formula, the scour depth was related to the discharge, sediment particle size, as well as some local empirical parameters. Followed by Lacey's formula, many efforts have been made to evaluate the local scour depth around bridge piers. A number of prediction methods are available (Melville 1997; Rahman and Haque, 2002, and many others). Most of the formulae are empirical or semi-empirical which can be applied at a limited range of hydraulic condition. In other words, the variability of natural rivers often exceeds the limitations of these formulae, not to say under the extreme weather condition.

In order to predict the local scour around the bridge piles more accurately, efforts are made to couple the sediment transport theory with the flow solver. Mao (1986) applied a modified potential flow theory and sediment continuity equation to simulate scour below a long cylinder on a sandy bottom subject to a mean current. An empirical sediment transport formula is adopted. Li and Cheng (2000) solved the Navier-Stokes (NS) equations with Smagorinsky sub-grid scale (SGS) closure. They calculated the equilibrium scour pit size by assuming that the shear stress on the seabed is close to the far-field shear stress when an equilibrium state is reached. Their model was able to predict the upstream portion of the scour hole with reasonable accuracy. Brørs (1999) utilized a finite element method to solve the RANS equation with k−ε closure. In his study, the sediment transport model is solved simultaneously which included both the bed-load and suspended-load transports. Liang et al. (2005) utilized the similar approach to simulate the scouring around pipelines. In order to avoid the appearance of unrealistically sharp irregular scour profiles and numerical instabilities, a special smoothing technique was employed. Later on, many models were developed based on the sediment transport theory in the frame work of Navier-Stokes equations. In order to avoid using the purely empirical sediment transport formulae, two-phase formulations are developed based on more fundamental concepts. Zhao and Frenando (2007) developed an Eulerian two-phase model embedded in FLUENT software to simulate scour around pipelines. The flow-particle interaction and particle-particle interactions are considered in the model formulation. Good agreement with the laboratory measurement can be seen in terms of the

development of the scouring profiles.

However, the free-surface effect was neglected in most of the studies mentioned above. This is valid only if the free-surface does not change too much along the channel. For rapidly changing water surface, this assumption will introduce nonphysical errors. In the scour problem, the bed deformation needs to be coupled with the flow field. Liu and García (2008) developed a 3D VOF model with k−ε closure. The behavior of the water-sediment interface is captured with a moving-mesh method, which is a Lagrangian approach. The bed-load and suspended load were considered in the bed morphology model. They demonstrated the model performance on the 2D turbulent wall jet flow and the scour hold. Very good agreement can be seen. A 3D wave scour around large vertical circular cylinder was simulated with reasonably good results. However, their model adopted the moving-mesh method which increased difficulty on simulating complex geometry, and only one sediment material can be simulated. In the practical scouring problem, the field measurement always shows complex combination with stratified layers. Also, using the conventional sediment transport theory requires calibration and validation on many model parameters. Such as Shields number, critical Shields numbers, bed-load transport coefficient, suspended-load coefficient, and more. These coefficients have to be determined prior, and the simulation results are sensitive to some of the empirical coefficient. The validation on the empirical coefficients impedes the application on solving the real case with nature riverbed.

In this study, we intend to avoid using the conventional transport model. Instead, adopting the Bingham model coupled with the VOF-NS model to simulate the local scour problem under the situation of violent flood. The Bingham model has been widely used to study the nature phenomena, such as the mudflows, landslides, lava flows in formation of depth-integrated method. The characteristic stress-strain relationship of a Bingham fluid is that the applied shear stress must exceed a threshold value, referred as yield stress, to liquefy the fluid from a solid material. Once the yield stress reaches, the liquefied material behaviors just like the Newton fluid. This Bingham characteristic is very close to the sediment transport on the river bed. However, implementation of Bingham model with 3D NS equation is rare. One of the reasons is that NS equation cannot be used to describe the solid motion. To overcome this problem, the solid part of the Bingham is simulated as the high viscous fluid. An extreme high viscous is set to the plug area and the Bingham model is transformed to the "bi-viscous" model. Assier-Rzadkiewicz et al. (1997) proposed this method on simulating 2D landslide generated waves. However, due to the stability constrain, large value of viscosity will significantly reduce the time marching step if the explicit scheme is adopted. The small time step impedes the implementations to the physical cases. To overcome this problem, the implicit viscous solved is adopted in this study.

2. ALGORITHM

2.1 Rheological Model of Dense Part

Many materials such as river mud, river sediment, snow, volcanic lava, and even the toothpaste behave like a non-Newtonian fluid. Some of them are called viscoplastic materials with a critical value of shear stress. The critical shear stress represents the plasticity of the material. This critical value is called the yield stress, or the Bingham yield. Below this yield stress, the material behaves like a rigid body, and the cohesion is important. Above this critical value, the material behaves like a Newtonian fluid. There are many rheological models to simulate this viscoplastic behavior. However, the Bingham plastic model is the simplest and best-known one. As described in the Bingham model, there is no deformation takes place until a specified shear stress is applied. By combining the yield stress τ_0 and the plastic dynamic viscosity μ_B (Liu and Mei, 1989), this model is able to describe the rheological behavior of these fluids. The nonlinear stress-strain relation between the shear stress and the strain rate can be expressed by $\tau = 2\mu\bar{D}$, in which τ is the deviatoric part of the stress tensor. $\bar{D}$ is the strain rate. $\mu = \mu(\bar{D})$ can be expressed as

$$\begin{aligned} &\mu\left(\bar{D}\right) = \mu_B + {\tau_0}\Big/{2\sqrt{\tfrac{1}{2}\bar{D}:\bar{D}}}, \text{ if } \frac{1}{2}\tau:\tau > \tau_0^2; \\ &\mu\left(\bar{D}\right) = \mu_\infty \text{ and } \bar{D} = 0, \text{ if } \frac{1}{2}\tau:\tau \le \tau_0^2 \end{aligned} \tag{1}$$

where μ_∞ is a large number indicating the solid behavior. This nonlinear relation leads to two distinct zones in the flow, a shear zone and a plug zone. In this study, μ_∞ is set to $10^5 \sim 10^{12}$ Pa·s which is much greater than water viscosity at 10^{-3} Pa·s.

2.2 Fluid Solver: 3D VOF model

The complete scouring model is a coupling between sediments and free-surface flow. The open-source code, "Truchas", developed by Los Alamos National Lab (LANL) is utilized and modified. The Eulerian code, Truchas, solves the 3D complete incompressible NS equations for multi-fluid flow based on the VOF method. The details of the algorithm can be found in Liu et al. (2005).

In this study, the Bingham material is treated as one of the multiple fluids. A fixed Cartesian grid is adopted for simulating each fluid. No grid deformation technique is required. The mixture concept is adopted for calculating the effective viscosity in a numerical cell: $\mu_{eff} = \sum f_m \mu_m$, in which f_m is the volume fraction of the m^{th} fluid. μ_m is the viscosity of the m^{th} material.

Based on the mixture concept, the conventional sediment transport theory can be transferred into the Bingham model. The Shields number is close to the Bingham yield. The fixed water bed is represented as the plug area. The bed load, laminated load, and suspended load

are the mixture of water, air, and Bingham fluids with different concentrations.

3. MODEL VALIDATION

3.1 Comparison with Analytical Solution

To validate the scouring model, the numerical simulations and analytical solutions are compared for a Bingham flow between two fixed parallel plates. The analytical solutions were derived by Bird et al. (1983). A Bingham fluid between two parallel plates of length L and width 2B is being driven in the x direction by a pressure gradient. The problem is stationary and the velocity profile can be derived with no-slip boundary conditions applied along the plates. Two zones are distinguished inside the fluid. In the simulation, the length L is 10 m. The half width is 1m. $P_0 = 10$ Pa and $P_L = 0$ Pa. The plastic viscosity $\mu_B = 5.0\ \text{Pa}\cdot\text{s}$. The yield stress is $\tau_0 = 0.5$ Pa. $\mu_\infty = 1e6\ \text{Pa}\cdot\text{s}$

Figure 1 shows the comparison between computed and analytical velocity profile for Bingham Flow.

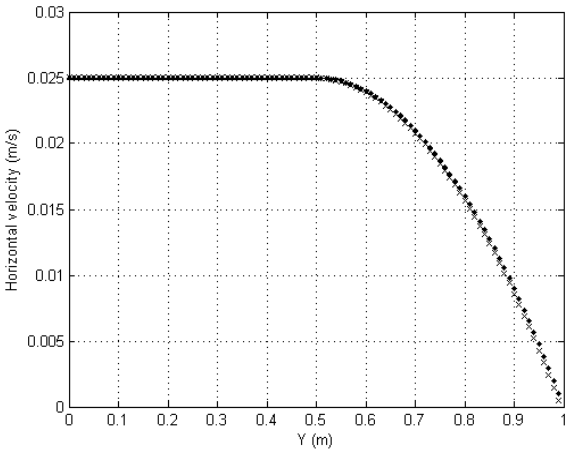

Figure 1 Comparison of the Velocity Profiles for Bingham Fluid. Diamond: Computed. Cross: Analytical.

3.2 Model Validation – Submerged Horizontal Jet

After validating with the analytical Bingham flow solution, the model is then utilized to study the benchmark problem of the submerged horizontal jet (Chatterjee et al., 1994). In their experiment, water entered the flume through a narrow slit of 2 cm in openness under water pressure. The inlet velocity was measured to be 1.56 m/s. The resulting 2D sheet of water flowed over a solid apron with 66 cm in length, and contacted a packed bed of sand bed 300 cm in length and 25 cm deep. The averaged density of sediment bed was measured to be 1709 kg/m^3. However, the Bingham yield τ_0, Bingham dynamic viscosity μ_B, and the maximum viscosity μ_∞ were not reported. In the numerical simulation, the μ_∞ is set to be $10^5\ \text{Pa}\cdot\text{s}$. From the numerical tests, we found that the final results is not sensitive to μ_∞ as long as μ_∞ is greater then $10^5\ \text{Pa}\cdot\text{s}$. The only parameter needs to be determined are τ_0 and μ_B. After trial and error method, the Bingham yield is found to be $150\ \text{N/m}^2$ and the Bingham viscosity $\mu_B = 0.08\ \text{Pa}\cdot\text{s}$. Figure 2 shows the experimentally observed bed profile and the simulation result from this study. The shape and the maximum scour depth of the predicted bed profiles compare very well to the experimentally observed sand bed. However, the downstream accumulation height is slight under predicted. This might require further fine tuning on the Bingham parameters.

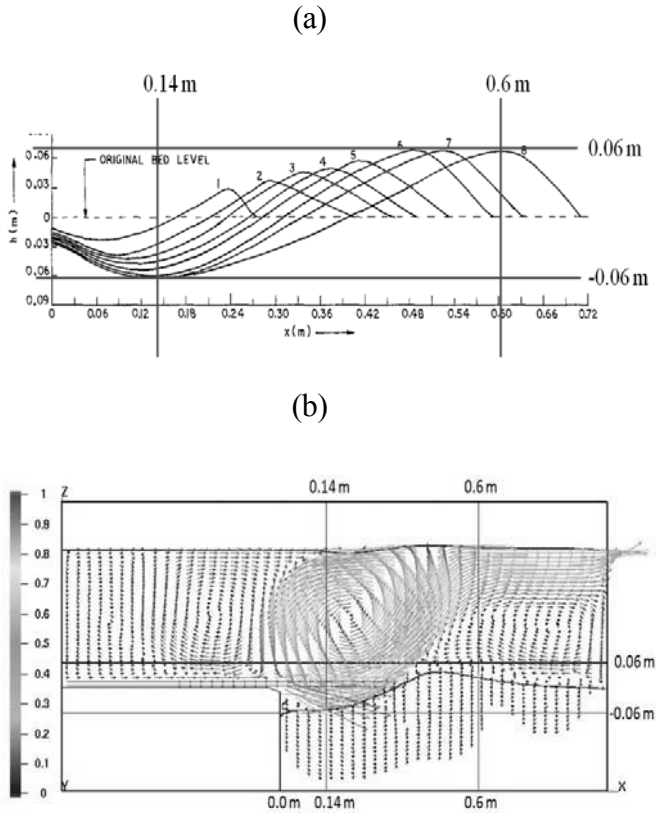

Figure 2 Comparison between computed and experimental scour profiles. (a) Experimental, (b) Numerical.

4. CASE STUDY – THE FAILURE OF SHUAN-YUAN BRIDGE

The validated scouring model is utilized to study the failure of Shuan-Yuan Bridge in the event of 2009 Typhoon Morakot. In this event, the flooding velocity was estimated and measured to be 8 m/s in the upstream direction of the bridge piles. The field measure also indicated that a 21 m scour depth right in front of the bridge piles might be the major cause to the bridge failure. The filed measure also indicated that a 15 m scour depth was measured 30 m away in the upstream direction. In this study, we shall simulate the 3D scour hole under the bridge pile. The Bingham parameters used in this case are $\tau_0 = 1600\ \text{N/m}^2$, $\mu_B = 10.0\ \text{Pa}\cdot\text{s}$, and $\mu_\infty = 1e6\ \text{Pa}\cdot\text{s}$. Figure 3(a) shows the over view of the setup and simulation results at

the quasi-steady state including the scour profile and free-surface. Figure 3(b) shows the local scour hole. The maximum scour depth is about 20.5 m which is very close the field measurement. The scour depth 30 m away from the bridge piles in the upstream direction is about 16 m which is close to the field measurement, too. Figure 3(c) shows the stream lines on the vertical cross-section. The stream lines shows that the flood causes the strong local scour right beneath the front row of the bridge piles. Figure 3(d) shows the overview of the local scour profile and the stream lines. Scouring mechanism can be seen clearly.

4. CONCLUSIONS

In this study, we proposed a new scour model by coupling the Bingham Rheological Model and the VOF-NS model. The plug area in the Bingham model is model as a high-viscous fluid. The viscosity is extremely high that makes the fluid behaves like a solid material. The implicit viscous solver is adopted to reduce the computational time. The newly developed scour model has no limitation on the number of Bingham materials, and is very suitable for simulating the field cases. This model is also suitable for simulating scouring problems under the strong floods in which the free-surface effect cannot be ignored. Because the Bingham model is used, only Bingham yield and Bingham viscosity are needed. Doesn't like the conventional sediment transport theory, the present model doesn't require other empirical or semi-empirical coefficients.

The model is validated with the analytical solution, 2D submerged jet problem, and 3D Shuan-Yuan Bridge scouring problem. Very good agreement can be seen while comparing the numerical solution to the analytical solution, experiment measurement, and field survey, respectively. The good results show the feasibility of using Bingham model on the scouring problems.

Abstract: The seismic mitigation effectiveness of insulation layer of LNG storage tank has been investigated through 3D finite element numerical models. LNG tanks are important facilities which are used to supply natural gas. Inner tank is much more sensitive to seismic effects and the design requirements of pile are fairly stringent. However, it is not considered that inner tank is protected by insulation layer and outer tank generally, and there are some thresholds beyond which the tank may not operate normally. The 3D finite element models are built for LNG tank with insulation layer and isolation bearings. A comparison between considering and without considering insulation layer has also been performed. Data reported and statistically sorted include tank wall stress, pile shear, global overturning moment, and wave height in the tank. The seismic mitigation effect is judged by these date. A common insulating material of LNG tank is used to evaluate influence of dynamic interaction. The results show that the insulation layer may not be neglected in the seismic design of LNG tank.

1. INTRODUCTION

LNG tanks are considered to be lifeline engineering due to the liquefied natural gas that they store. The volumes of these tanks are very large and have capacities about 160,000 m^3. LNG tank consists of inner steel tank, which contains the LNG, and outer concrete tank encasing and protecting the inner tank, with insulation placed between the two tank walls (Figure 1).

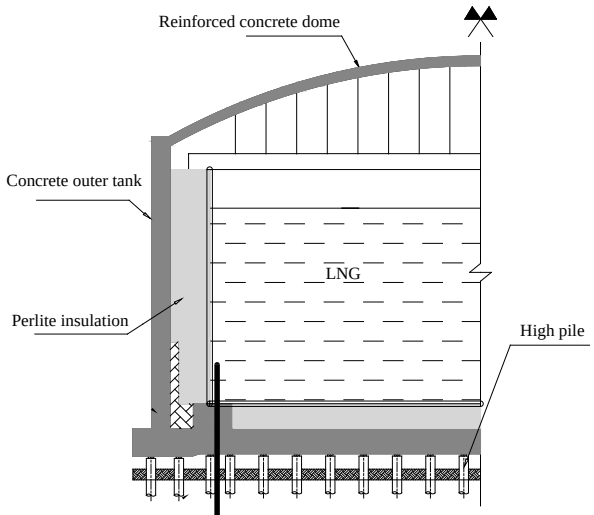

Figure 1 Schematic view of a modern LNG tank

The tanks could be damaged easily in the earthquake, which had been proved in many cases in last years. Typical damages of tanks during past earthquakes such as 1989 Loma Prieta, 1994 Northridge, Ji-Ji Taiwan and 1999 Kocaeli, were in the form of cracking at the corner of the bottom plate and compression buckling of tank wall (elephant foot buckling) due to uplift, sliding of the base, anchorage failure, sloshing damage around the roof, failure of piping systems and plastic deformation of base plate (Abali and Uckan 2009; Chalhoub and Kelly 1990). Originally, Housner (1957) developed a mathematical model in which the mass of liquid portion that accelerates with the tank wall together is called as the impulsive and the mass of liquid portion that causes sloshing motion of the free surface near the tank roof is called as the convective. A different approach to the analysis of flexible containers was developed by Veletsos (1974). He presented a simple procedure for evaluating hydrodynamic forces induced in flexible liquid filled tanks. Later, Veletsos and Yang (1976) estimated maximum base overturning moment induced by a horizontal earthquake motion by modifying Housner's model to consider the first cantilever mode of the tank. They presented simplified formulas to obtain the fundamental natural frequencies of liquid filled shells by the Rayleigh-Ritz energy method. Haroun and Housner (1980; 1981; 1983) modified the Housner's model and took into account the flexibility of the tank wall in the seismic analysis. In 2000, Malhotra et al. (2000) modified the mechanical analog proposed by Veletsos and Yang using only one convective mode. The procedure takes into account impulsive and convective (sloshing) actions of the liquid in flexible steel or concrete tanks fixed to rigid foundations.

A new approach developed by various researchers

proposes to use the isolation bearings to decrease the seismic response of tanks. Chalhoub and Kelly (1990) determined favorable effects of base isolation of liquid storage tanks through shake table tests on isolated and non-isolated tanks. In 2000, Bachmann and Wenk (2000) applied seismic isolation system to a liquid storage tank supported by short columns. They named this rehabilitation scheme as softening. As part of this "softening" approach, 26 high-damping bearings were incorporated into the structural system. Shrimali and Jangid (2002) investigated the seismic response of the liquid storage tanks isolated by lead-rubber bearings (LRB) for bi-directional earthquake excitation.

One of the original researches on seismic response of a base isolated LNG tank was conducted by Tsopelas et al. (1994). Seismic analysis of base-isolated LNG tank using the BE-FE-BE coupling technique was conducted by Kim et al. (2002). A project was investigated by Boduroğlu et al. (2006) to learn the dynamic behavior and weaknesses of these structures by site and laboratory tests and response analysis. To achieve these goals a study program including in-situ dynamic tests, shaking table tests and analytical analysis was followed. The results obtained showed that this type of structures is vulnerable to earthquake effects and the use of base isolation system is very effective in minimizing the earthquake effects. Christovasilis et al. (2008) study the utility of the simplified analogs for the analysis and design of liquid storage tanks constructed using conventional and protective systems. The Finite Element Method (FEM) is utilized to model the tank, as well as the contained liquid. Seismic isolation is implemented by introducing horizontal inelastic beam elements between the base and the ground. Zhang et al. (2010) present a LNG tank isolation system which is composed of annular damper reaction wall, viscous dampers, and lead rubber bearings mounted on the top of the piles in order to decrease pile shear and isolation displacement. The annular damper reaction wall which is not connected with the piles is embedded into the ground independently. However, dynamic interaction between the inner tank and outer tanks was neglected in these studies.

A simplified finite element model presented by Malhotra is used to judge the periods of inner tank. Data reported and statistically sorted include pile shear, Von Mises stress, wave height, and overturning moment. 3D finite element models are built for LNG tank with insulation layer and isolation bearings. The comparison between considering and without considering insulation layer is performed. Data reported and statistically sorted include tank wall stress, pile shear, isolation displacement, global overturning moment, and wave height in the tank. The seismic mitigation effect is judged by these date.

2. STRUCTURAL MODEL OF TANK

2.1 Malhotra Mechanical Model

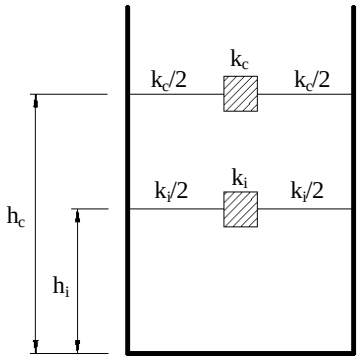

Figure 2 Mechanical analog proposed by Malhotra et al.

The procedure was based on the work of Veletsos and co-workers with certain modifications that included:

Combining the higher impulsive modal mass with the first impulsive mode and the higher convective modal mass with the first convective mode.

Modifying modal heights to account for the contribution of higher modes to the base overturning moment.

Generalizing the formula for the impulsive period so that it could be applied to steel and concrete tanks of various wall thicknesses.

The values proposed by Malhotra for the properties of the analog are presented in Table 1 and Eqs. 1 ~ 2, where t_s is the equivalent uniform thickness of the tank wall, E_s is the modulus of elasticity of the inner tank wall material, ρ_l is the mass density of the liquid, T_i and T_c are the periods of the impulsive and convective modes, m_i and m_c are masses of the impulsive and convective, m_l is the total liquid mass, and C_i and C_C are dimensionless factors, H is the height of liquid in the tank, r is the inner tank radius, and h_i and h_c are the heights of the centroids of the impulsive and convective hydrodynamic wall pressures.

$$T_i = C_i \frac{H\sqrt{\rho_l}}{\sqrt{t_s / r} \times \sqrt{E_s}} \tag{1}$$

$$T_c = C_C \sqrt{r} \tag{2}$$

Table 1 Properties of the mechanical analog (Malhotra 2000)

H/r	C_i	C_c	m_i/m_l	m_c/m_l	h_i/H	h_c/H
0.3	9.28	2.09	0.176	0.824	0.4	0.521

3	7.03	1.48	0.842	0.158	0.453	0.825

2.2 Governing Equations of Motion

The governing equations of motion of LNG tank may be expressed as:

$$m_c\left(\ddot{u}_c + \ddot{u}_b\right) + c_c\dot{u}_c + k_c u_c = -m_c\ddot{u}_g \tag{3}$$

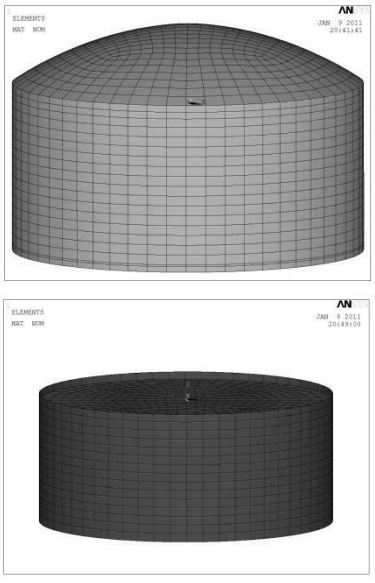
$$m_i\left(\ddot{u}_i + \ddot{u}_b\right) + c_i\dot{u}_i + k_i u_i = -m_i\ddot{u}_g \tag{4}$$

$$m_{ot}\left(\ddot{u}_{ot}+\ddot{u}_b\right)+c_{ot}\dot{u}_{ot}+k_{ot}u_{ot}=-m_{ot}\ddot{u}_g \quad (5)$$

$$m_{it}\ddot{u}_b+c_e\dot{u}_b-c_c\dot{u}_c-c_i\dot{u}_i-c_{ot}\dot{u}_{ot}+k_eu_b -k_cu_c-k_iu_i-k_{ot}u_{ot}=-m_{it}\ddot{u}_g \quad (6)$$

$$m_{it}=m_{iw}+m_b \quad (7)$$

where u_c is the displacement of the convective mass relative to bearing displacement in horizontal direction, u_i is the displacement of the impulsive mass relative to bearing displacement in the horizontal direction, u_{ot} is the displacement of the outer tank mass relative to bearing displacement in the horizontal direction, u_b is the displacement of the bearings relative to ground in the horizontal direction, c_c is the damping of the convective mass, c_i is the damping of the impulsive mass, c_{ot} is the damping of the outer tank mass, c_e is the equivalent damping of the isolation devices, k_c is the stiffness of the convective mass, k_i is the stiffness of the impulsive mass, k_{ot} is the stiffness of the outer tank mass, k_e is the equivalent stiffness of the isolation devices, $\ddot{u}_g$ is the earthquake ground acceleration, m_{iw} is the mass of the inner tank wall, m_{ot} is the total mass of the outer tank, m_b is the mass of the bottom plate and foam glass, m_{it} is the total mass of the inner tank and bottom plate.



2.3 Behavior of Lead Rubber Bearing

Nonlinear inverse force of the lead rubber bearing can be modeled with the bilinear hysteretic model. Here the Bouc-Wen model is used to facilitate the calculation.

The Bouc-Wen model has been extensively used to describe nonlinear hysteretic behaviors, particularly, in seismic isolation devices (Wen 1976).

3. NUMERICAL MODELS OF THE LNG TANK

3.1 Dimensions of the LNG tank

(a)

(b)

Figure 3 Finite element model of LNG tank: (a) outer tank, and (b) inner tank

A steel inner tank with a radius r of 40m and total height of 35 m is fully anchored to a concrete slab. The tank is filled with liquid to a height H of 33 m. The density of LNG in the inner tank ρ_l is 480 kg/m^3. The tank wall is made of three courses, and 10 m, 10m and 15m high. The lower course is 25mm thick, the middle course is 18mm and the upper course is 12mm thick. For steel, $E_s = 2\times10^{11}$N/m^2, $\rho = 7.9\times10^3$ kg/m^3.

The height of the outer tank wall L is 40m, the medium radius of the outer tank D_c is 41.45 m, the thickness of the outer tank wall t_c is 0.9 m, the density of the wall concrete ρ_c is 2500 kg/m^3, the modulus of elasticity of the wall concrete E_c is 3×10^{10} Pa, the poison's ratio of the wall concrete υ_c is 0.3.

The parameters of LRBs selected in SC_3 and SC_4 are shown in Table 2.

Damping is defined through a Rayleigh global damping matrix. The damping ratio for the impulsive mode is typically considered to be 2% of critical for a steel tank responding in the linear elastic range. The damping ratio for the sloshing mode is assumed to be 0.5% of critical (Haroun and Housner 1981; Veletsos 1984) per industry practice.

Scheme 1 (SC-1) is the LNG storage tank without considering insulation, and Scheme 2 (SC-2) is the LNG storage tank with perlite insulation. Scheme 3 (SC-3) is the isolated LNG storage tank without considering insulation, and Scheme 4 (SC-4) is the isolated LNG storage tank with perlite insulation. There are 360 piles are arranged under LNG storage tank. The flat and elevation diagrams of tank with isolators are plotted in Figure 4 and 5.

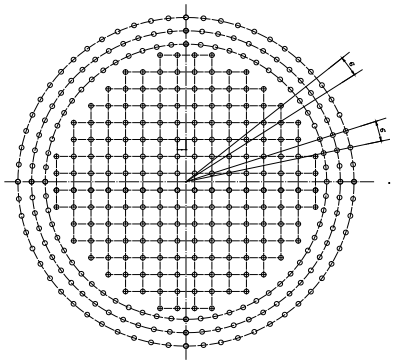


Figure 4 Flat diagram of tank with high piles

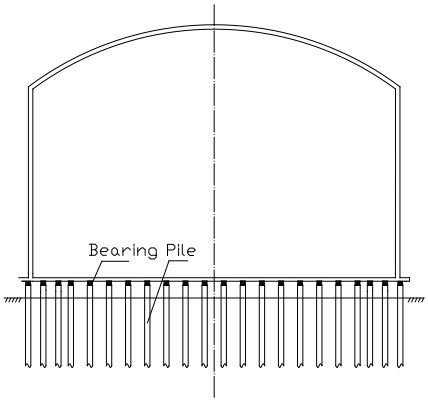

Figure 5 Profile diagram of tank with bearings

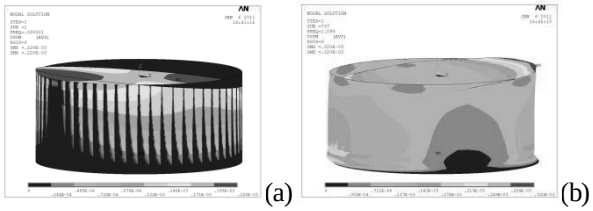
Table 2 Parameters of lead rubber bearings



type	Design capacity	yield force	Pre-yield stiffness	Post-yield stiffness	Equivalent stiffness	number
	kN	kN	kN/mm	kN/mm	kN/mm	
LRB600	4000	96.1	4.64	0.58	1.62	240
LRB650	5000	79.2	5.28	0.66	1.53	120

Notes: LRB650s are mounted on top of the outer piles and LRB600s are mounted on top of inner piles.

Modal analysis was performed in ANSYS using reduced method. Table 3 summarizes the eigenvalues obtained from Housner method and FE model, and Figure 6 illustrates the convective and impulsive modes of FE model for the inner tank. The convective mode shapes involve sloshing of the contained liquid. The natural periods predicted by the simplified model are very close to those predicted by ANSYS.

3.2 Seismic input

A LNG terminal project is located in the circum-Pacific seismic belt. The seismic acceleration of the operating basis earthquake (OBE) design is 0.16g and the seismic acceleration of the safe shutdown earthquake (SSE) is 0.30g. Artificial seismic waves are generated by design response spectrum which is suitable for the local field condition. Two of six simulated seismic waves are plotted in Figure 7 and 8 and design response spectrum curves are plotted in Figure 9 and 10. The parameters of seismic spectrum are shown in Eq. 10 and Table 4. Where β is spectral amplification factor, T is structural vibration period, γ is attenuation index, and $A_{\max}$ is acceleration amplitude.

$$\beta = \begin{cases} 1 & T \le 0.04s \\ 1+(\beta_{\max}-1)\dfrac{T-0.04}{T_1-0.04} & 0.04s < T \le T_1 \\ \beta_{\max} & T_1 < T \le T_2 \\ \beta_{\max}(T_2/T)^{\gamma} & T_2 < T \le 8.0s \end{cases} \quad (8)$$

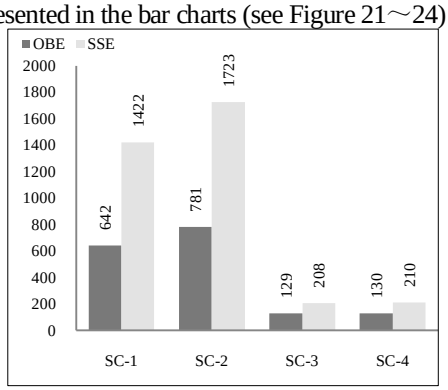

Figure 21 Single pile shear

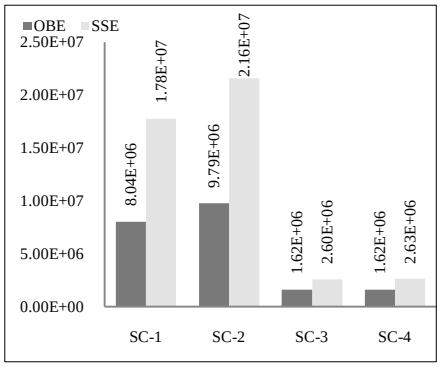

Figure 22 Overturning moment

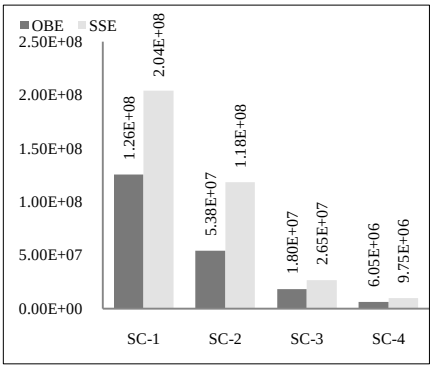

Figure 23 Von Mises stress

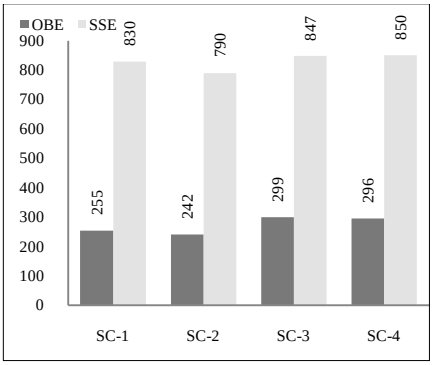

Figure 24 Wave height

The maximum responses of the numerical models for the 6 earthquake ground motions, scaled for both OBE and SSE shaking. Since the models are elastic, the SSE responses are about twice the OBE responses.

Contrast to the SC_1 and SC_2, indicators such as the shearing force of single pile and overturning moment are increased by SC-2 by considering the insulation. However, Von Mises stress and wave height is decreased by SC-2, especially Von Mises stress.

For the isolated LNG tank, the influence of insulation layer is limited except Von Mises stresses in the SC-3 and SC-4, but the seismic performance of the LNG tank is improved by seismic-isolated scheme.

4. CONCLUSIONS

A study has been made of the dynamic response of the LNG tank using four different schemes, when subjected to lateral seismic motion. A common insulating material of LNG tank is used to evaluate influence of dynamic interaction. Four schemes of LNG tank are anchorage tank without insulation layer (SC_1), with insulation layer (SC_2), and isolated tank without insulations (SC-3), with insulations (SC-4). Some key indicators are used to judge mitigation effect of different solutions. The following conclusions can be drawn from this study.

1. For four different schemes, it can be found that the maximum response of the tank always happen in the anchorage LNG tank.

2. Compare to SC_1, Von Mises stress of SC_2 can be decreased obviously. But some indicators such as the single pile shear and overturning moment are increased by SC-2, which means the shear and moment of the tank may be underestimated if not considering insulation layer for the anchorage tank.

3. Because isolators are mounted on the top of the high piles in the SC-3 and SC-4, the influence of insulation layer to the structural is limited except the Von Mises stress. So it is feasible for the design of the isolated LNG tank neglecting the insulation layer, which is conventional method.

Abstract: The use of externally bonded carbon fiber-reinforced polymer (FRP) systems in enhancing the behavior of gravity-load-designed building columns under lateral loading that may result from seismic actions was investigated in this study. The columns had a rectangular cross section with a high aspect ratio of 3.65. To improve the effectiveness of the FRP systems, the columns were enlarged at the short ends by circular segments, forming capsule-shaped sections, before they were bonded with FRP sheets. Seven half-scale column specimens, with concrete strength of 30 MPa, longitudinal steel ratio of 2%, and normal transverse steel reinforcement, were subjected to a constant axial load, and tested to failure under lateral loading. Test results indicated that the lateral load-carrying capacity increased with the provision of the circular segments, while the ductility of the columns increased with the number of ply of transverse FRP sheets in particular. The mode of failure changed from shear-compression to flexure with FRP rupture with the section enlargement and bonded FRP system. The test results are compared with analytical predictions based on conventional flexural and shear theories, which in turn could be compared with seismic demand capacity to determine the survivability of the columns under seismic actions.

1. INTRODUCTION

Inadequate lateral reinforcement and improper splicing of longitudinal reinforcement in the plastic hinge zone of columns have been featured as some of the main causes of building collapse during recent earthquakes. To enhance the axial load and shear capacities, as well as to increase the ductility and energy dissipation capacities, reinforced concrete columns could be confined using transverse fiber-reinforced polymer (FRP) systems. Recent studies have indicated that FRP confined square or rectangular columns with a cross-sectional aspect ratio of up to 1.5 exhibited significantly improved performance under cyclic or pushover loading.

In reality, many building columns are rectangular in shape with an aspect ratio of more than 1.5, and as large as 7, which may well be termed "wall-like" columns. The confinement effect of transverse FRP reinforcement on such rectangular columns is known to be insignificant. To increase the confinement effect, it is proposed that the short ends of the rectangular section be rounded off by adding circular concrete segments and thus forming a capsule-shaped section before applying the transverse FRP reinforcement.

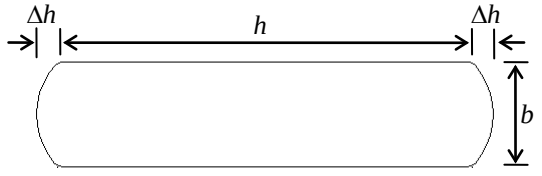
The present study was therefore carried out to examine the behavior of FRP-confined capsule-shaped reinforced concrete columns under lateral push-over loading, with focus on the effect of section geometry and the number of ply of transverse FRP sheets.

2. TEST PROGRAM

A total of seven half-scale column specimens were prepared and tested to failure under a constant axial load and a monotonically increasing lateral load.

2.1 Specimen details

The columns were designated as "L-*x*-*y*" where 'L' stands for laterally loaded specimens; '*x*' denotes the shape parameter, $\Delta h/b$, where Δh is the ratio of thickness of the cap at the two short sides and b is the width of column as shown in Figure 1; and '*y*' represents the number of ply of transverse carbon FRP (CFRP) sheets.



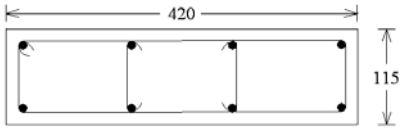


Figure 1 Capsule-shaped column

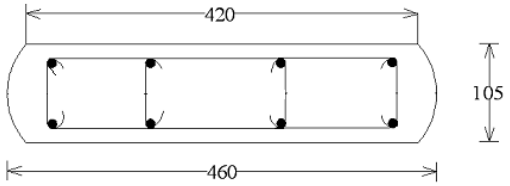
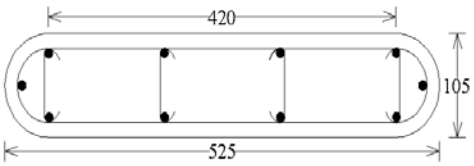
The seven columns were classified into three groups. Group A consisted of one specimen which had a



rectangular cross-section measuring 115 mm by 420 mm, with an aspect ratio of 3.65. Group B comprised three capsule-shaped columns with an overall dimension of 105 mm by 460 mm; while Group C included three other capsule-shaped columns with an overall dimension of 105 mm by 525 mm, as shown in Figure 2.

The height of the column specimens corresponded to the distance from the section of maximum moment to the point of contraflexure under lateral loading, and was taken as 940 mm.



For FRP-confined columns, the first ply was applied over the full height whereas the second ply was applied over the lower half of the column.

Group 'A' Column (L-0-1)
Area, A_g = 48,300 mm^2
Long. steel area = 1062 mm^2 (= 2.2%A_g)

Group 'B' Columns (L-0.19-0, 1, 2)
Area, A_g = 46,989 mm^2
Long. steel area = 1062 mm^2 (= 2.26%A_g)

Group 'C' Columns (L-0.5-0, 1, 2)
Area, A_g = 52,759 mm^2
Long. steel area = 1327 mm^2 (= 2.5%A_g)

Figure 2 Details of specimens (*all dimensions in mm.*)

2.2 Concrete

Ordinary Portland cement, natural sand (fine aggregate), crushed granite of 10-mm maximum size (coarse aggregate) and water were used in the proportion of 1 : 3.08 : 3.14 : 0.79 by weight for the concrete mix. The target cube compressive strength at 28 days was 30 MPa.

2.3 Internal steel reinforcement

The reinforcing cages were made using three types of reinforcing steel. Longitudinal reinforcement consisted of eight 13-mm diameter deformed bars in Group A and B columns, and ten 13-mm diameter deformed bars in Group B columns. The longitudinal steel ratio was thus maintained at between 2.2 to 2.5%.

The transverse steel reinforcement consisted of rectangular or capsule-shaped closed links and ties as shown in Figure 2. They were made of 6-mm diameter mild steel bars and spaced at 100 mm spacing in the longitudinal direction, which corresponded to nominal transverse reinforcement in gravity-load-designed building columns.

The average yield strength of 13-mm diameter high-yield deformed bars and 6-mm mild steel round bars was 460 MPa and 300 MPa respectively.

2.4 FRP system

Carbon FRP (CFRP) sheets were used. The primary properties as provided by the manufacturer are shown in the Table 1. A three-part resin was used to bond the FRP sheets on to the specimens and the mix proportion of the resin is shown in Table 2.

Table 1 Properties of Carbon FRP Sheet

Design Thickness (per ply)	0.176 mm
Fibre weight	300 g/m^2
Elastic modulus	240 kN/mm^2
Tensile strength	3800 N/mm^2
Elongation at rupture (%)	1.55

Table 2 Mix proportion of resin

Components	Weight (per m^2 of CFRP sheet)
Main	600g/m^2
Hardener	300g/m^2
Powder	600g/m^2

2.5 Fabrication of specimens and test set-up

The reinforcement cage for the column and the column base, which measured 350 mm by 1000 mm on plan and 300 mm in thickness, was assembled and placed in the formwork. Holes were provided through the thickness of the base to facilitate the anchoring of specimen to the strong floor using long anchor bolts. The specimen was cast and formwork was removed after one day. The specimens were then cured by covering with damp gunny sacks for a week. They were then left in the laboratory under ambient conditions. Accompanying cubes for the determination of concrete compressive strength were cast and cured in the same manner.

About three weeks after casting, all specimens

except L-0.19-0 and L-0.5-0 were bonded with carbon FRP systems. A week after this, the specimens were placed and anchored to the workshop floor via a strong beam as shown in Figure 3.

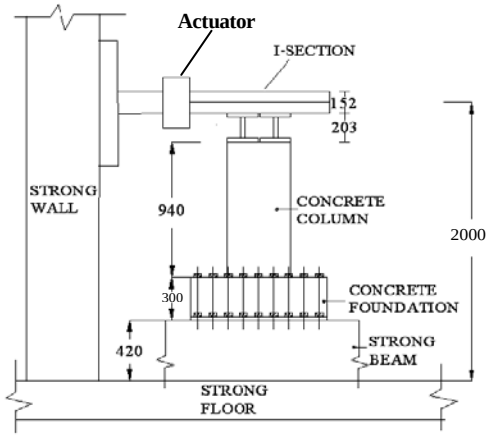


Figure 3 Test set-up

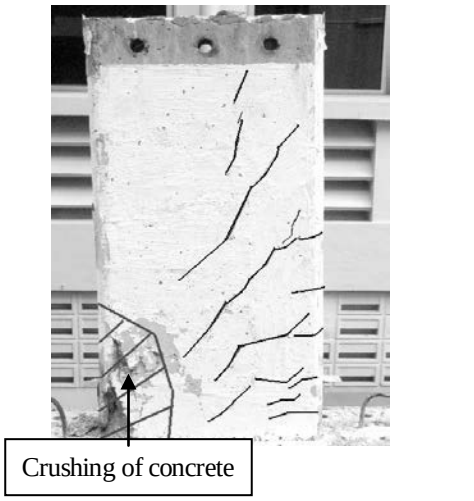
Two cross-beams were placed on top of the column specimen, which was then loaded axially using prestressing strands placed through and anchored on the cross-beams at the top and the strong beam at the bottom, to simulate the axial force from the upper stories. A total of eight seven-wire strands were used. Each strand had a diameter of 12.9 mm, nominal cross-sectional area of 100 mm^2, breaking load of 130 kN and Young's modulus of 195 GPa. For all columns, the axial load ratio ($N_u / f'_c A_g$) was 0.3.

Another I-beam was bolted to the cross-beams, and a 65-ton capacity actuator fixed on a strong wall was used to apply the lateral load on the beam assembly on top of the specimen.

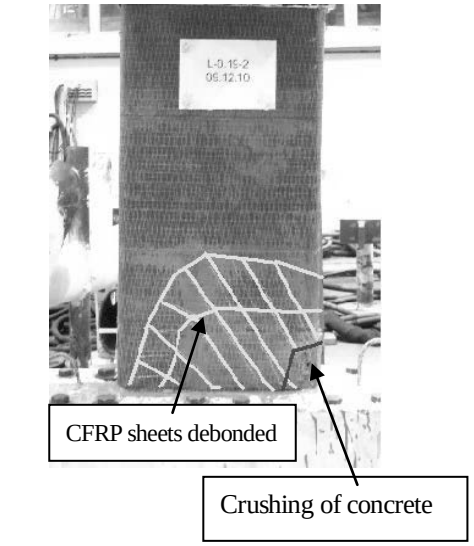
2.6 Test procedure

The columns were subjected to monotonically increasing lateral pushover load after applying the axial load. The strains in the strands were monitored to ensure no significant drop in preload. The specimens were also instrumented for lateral deflection measurements at the top end, and strain development in the transverse and longitudinal steel reinforcement as well as in the externally bonded CFRP system.



The lateral load was applied using displacement control method. The initial rate of loading was 0.15 mm/min. After first yielding of the internal longitudinal steel, the loading rate was increased to 0.3mm/min and kept constant up to the failure of column.

3 TEST RESULTS



3.1 Behavior and mode of failure

In unconfined specimens L-0.19-0 and L-0.5-0, fine cracks were observed near the base (foundation) on the tensile side of the column at a load of 40 to 50 kN. The first horizontal flexural cracks were observed to propagate from the tension side of the column at a height of 150 mm from the base at 70 kN and 80 kN for L-0.19-0 and L-0.5-0 respectively; and successive flexural cracks were formed at intervals of about 150 mm up to a height of 600 mm.

Inclined shear cracks started to form in the columns near the top of the column at 90 to 100 kN. The number and widths of inclined cracks increased gradually and the cracks propagated in a converging manner towards the compression face of column at the base as shown in Figure 4(a). The outermost longitudinal steel bars first yielded in tension at a load of 97 kN and 116 kN, respectively, for L-0.19-0 and L-0.5-0.

(a) Unconfined column

(b) Confined column

Figure 4 Typical failure patterns

Final failure occurred in unconfined columns due to concrete crushing on the compression side. The load at which the load started to drop and concrete crushed simultaneously was taken as the ultimate lateral load. The corresponding displacement was noted as the ultimate

displacement. The test results are shown in Tables 3 and 4.

Cracks could not be observed in the case of confined columns due to the presence of FRP system. However, a change in color in the FRP system was observed within the plastic hinge zone, which indicated the separation of fiber sheets from the concrete surface as crushing of concrete started. This was confirmed by tapping on the FRP systems using a metal rod or a coin.

Near the failure load, sounds of breaking of the hardened epoxy within the plastic hinge zone were increasingly heard, and final failure occurred with the rupture of CFRP sheets and crushing of concrete at the compression face of column near the base as shown in Figure 4(b).

Table 3 Ultimate lateral load

Speci-men	f'_{co} (MPa)	$P_{u\text{-}pred}$ (kN)		$P_{u,test}$ (kN)	$\frac{P_{u,test}}{P_{u,pred}}$*
		$P_{u,sh}$	$P_{u,fl}$		
L-0-1	24.2	254	96	116	1.21
L-0.19-0	25.2	108	100	122	1.22
L-0.19-1	25.6	263	121	142	1.16
L-0.19-2	24.6	418	133	147	1.10
L-0.5-0	26.6	129	136	142	1.04
L-0.5-1	23.9	306	156	178	1.14
L-0.5-2	27.2	484	180	203	1.12

Note: f'_{co} = cylinder strength; $P_{u,pred}$ * = Predicted ultimate lateral load = smaller of ($P_{u,sh}$, $P_{u,fl}$) ; $P_{u,sh}$= Predicted ultimate lateral load based on shear capacity; $P_{u,fl}$ = Predicted ult. lateral load based on flexural capacity; $P_{u,test}$ = Maximum observed lateral load.

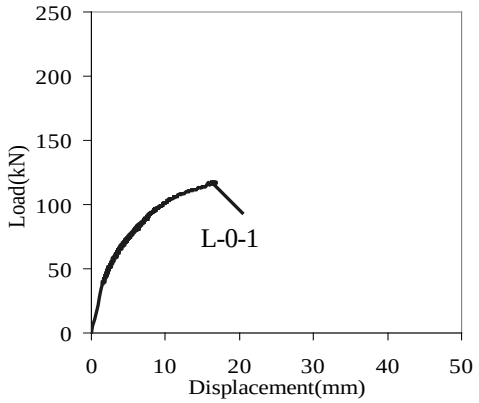


Table 4 Displacement ductility and drift ratio

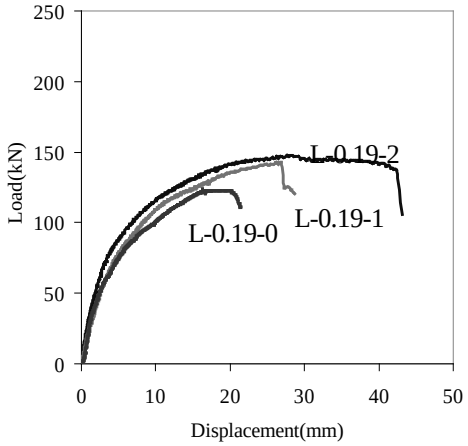
Specimen	Δ_y (mm)	Δ_u (mm)	μ_Δ	Δ_u / L (%)
L-0-1	5.9	16.0	2.7	1.7
L-0.19-0	9.1	20.3	2.2	2.1
L-0.19-1	8.2	26.9	3.3	2.9
L-0.19-2	7.6	42.3	5.6	4.5
L-0.5-0	6.4	14.0	2.2	1.5
L-0.5-1	6.3	22.1	2.9	2.3
L-0.5-2	6.3	31.7	4.9	3.4



Note: Δ_y = Yield displacement; Δ_u = Maximum lateral displacement; μ_Δ = Displacement ductility factor; L = Height of column; Δ_u / L = Drift ratio.

3.2 Load-displacement response

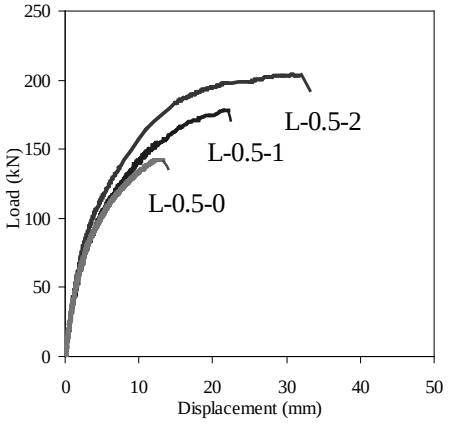


Figure 5 shows the load vs. lateral displacement characteristics of all specimens. For Group A column, the yield and maximum lateral displacement were observed as 5.9 mm (at 80 kN) and 16 mm (at 116 kN). The displacement ductility, defined as the ratio of maximum lateral displacement to the yield displacement, was thus 2.7.

(a) Group A specimen

(b) Group B specimens

(c) Group C specimens

Figure 5 Load-displacement characteristics

For Group B specimens, the yield loads were 97 kN, 100 kN and 104 kN for columns L-0.19-0, L-0.19-1 and

L-0.19-2, and the corresponding displacements were 9.1 mm, 8.2 mm and 7.6 mm respectively. The ultimate lateral displacements at which the load began to drop significantly were 20.3 mm (at 122 kN), 26.9 mm (at 142 kN) and 42.3 mm (at 137 kN), respectively.

The displacement ductility was calculated as 2.2, 3.3 and 5.6 for L-0.19-0, L-0.19-1 and L-0.19-2 respectively which showed that the ductility was increased by 50% and 154% with 1 ply and 2 plies of transverse CFRP sheets. Also, it may be noted that the lateral load capacities of L-0.19-1 and L-0.19-2 were 16% and 20% higher than L-0.19-0.

The yield displacements of L-0.5-0, L-0.5-1 and L-0.5-2 (Group C specimens) were 6.4 mm (at 116 kN), 6.3 mm (at 122 kN) and 6.3 mm (at 125 kN) respectively. The ultimate lateral displacement were on the other hand 14.0 mm (at 142 kN), 22.1 mm (at 178 kN) and 31.7 mm (at 203 kN) respectively. Thus, the displacement ductility was calculated as 2.2, 2.9 and 4.9 for L-0.5-0, L-0.5-1 and L-0.5-2 respectively. The lateral load capacity of L-0.5-1 and L-0.5-2 was 25% and 43% higher than L-0.5-0.

To evaluate the effect of effect of section geometry, the load-displacement characteristics of L-0-1, L-0.19-1 and L-0.5-1 are compared in Figure 6. Both the ultimate lateral load capacity and the ultimate lateral displacement increased with the shape factor $\Delta h/b$. The ultimate lateral load increased from 116 kN to 142 kN and 178 kN as the shape factor increased from zero to 0.19 and 5 respectively, as shown in Table 3. This was partly due to the enlarged concrete areas which led to an increase in shear and flexural resistance.

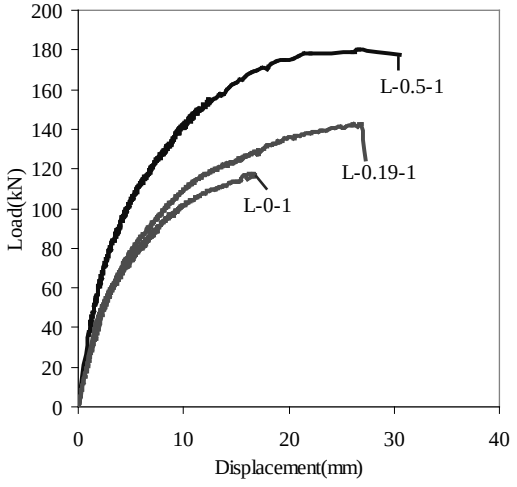

Figure 6 Effect of section geometry

On the other hand, however, the displacement ductility increased from 2.7 to 3.3 and 2.9 respectively as the shape factor increased from zero to 0.19 and 0.5 respectively. Similarly, the drift ratio increased from 1.7 to 2.9 and 2.3 percent respectively. It therefore appeared that Group B specimens with a shape factor of 0.19 were more efficient in terms of ductility.

4. THEORETICAL PREDICTIONS

The ultimate lateral load capacity was determined as the smaller of the lateral load that would result in shear or flexural failure of the column.

4.1 Shear Capacity

The theoretical calculation of shear capacity of FRP confined columns is based on the consideration that there should not be large dilation strains in loading direction; because a large dilation strain implies the degradation of aggregate interlock action which is the most essential component to protect the column in case of unexpected overload during earthquake. Hence, the maximum permissible dilation strain has been proposed as 0.004 by Seible et al. (1997).

The shear capacity of confined columns (V_{shear}) in this study was therefore calculated using the following equation as proposed in the work by Seible et al. (1997):

$$V_{shear} = V_c + V_s + V_{CFRP} = \left(1 + \frac{N_u}{14A_g}\right)\frac{\sqrt{f'_c}}{6} b_w d + \frac{A_v f_{yv} d}{s} + 2t_{CFRP} D\left(0.004 E_{CFRP}\right) \quad (1)$$

where V_c, V_s and V_{CFRP} = contribution to shear capacity from concrete, transverse steel stirrups and CFRP sheets, respectively; N_u, A_g, f'_c, b_w, d are the applied axial load, gross cross-sectional area of column, unconfined cylinder compressive strength of concrete, and width and effective depth of column respectively; A_v, f_{yv} and s are the cross-sectional area, yield strength and spacing of stirrup respectively; t_{CFRP}, E_{CFRP} and D = thickness of CFRP sheets, modulus of CFRP, and column dimension in the loading direction, respectively. For capsule- shaped columns, the term $b_w d$ was taken as equal to the area up to the outermost tensile longitudinal steel bar.

The predicted shear capacities of the test columns are given in Table 3. It can be seen that the CFRP sheets led to significant increase in the shear capacity of rectangular and capsule-shaped columns.

4.2 Flexural Capacity

The externally bonded transverse CFRP sheets confine the plastic hinge region of columns by restraining the lateral expansion of the concrete, thereby retaining the integrity of the core concrete and facilitating higher compressive stresses and strains to be sustained by the compression zone of column section before rupture of CFRP sheets occurs. By equating the strain energy capacity of the transversely wrapped CFRP systems as it is strained to peak stress to the increase in energy absorbed by concrete resulting from confinement, the ultimate confined compressive strain was determined by Priestley et al. (1996) as

$$\varepsilon_{cu} = 0.004 + 2.5\frac{\rho_{CFRP} f_{uj} \varepsilon_{uj}}{f'_{cc}} \quad (2)$$

where ε_{uj} is the hoop strain of FRP at failure, ρ_{CFRP} is the volumetric ratio of confining CFRP systems, f_{uj} is the tensile strength of CFRP systems and f'_{cc} is the confined compressive strength of concrete.

Initially, Equation (2) was proposed for circular columns only. For rectangular columns with a cross-section aspect ratio of 1.5, an effectiveness factor of 0.5 was proposed based on test results by Priestley et al. (1996).

In the present study, Equation (3) was used with the effective hoop strain ε_{uj} equal to 0.004, which correspond to 0.26 times the rupture strain of the CFRP system (ε_{fu}) which is 0.004. Thus, the modified ultimate confined compressive strain is given by

$$\varepsilon_{cu} = 0.004\left[1 + 2.5\frac{\rho_{CFRP} f_{uj}}{f'_{cc}}\right] \quad (3)$$

The maximum flexural capacity of capsule-shaped column was calculated by section analysis using Equation (3) and the following stress-strain model for FRP-confined concrete (ACI 440 2008):

$$f_c = E_c\varepsilon_c - \frac{(E_c - E_2)^2}{4f'_{co}}\varepsilon_c^2 \quad (\text{for } 0 \le \varepsilon_c \le \varepsilon'_t) \quad (4)$$

$$f_c = f'_{co} + E_2\varepsilon_c \quad (\text{for } \varepsilon'_t \le \varepsilon_c \le \varepsilon_{cu}) \quad (5)$$

$$E_2 = \frac{f'_{cc} - f'_{co}}{\varepsilon_{cu}} \quad (6)$$

$$\varepsilon'_t = \frac{2f'_{co}}{E_c - E_2} \quad (7)$$

where f_c and ε_c are the stress and strain, respectively; E_c is the elastic modulus of concrete; f'_{cc} and f'_{co} are the confined and unconfined concrete strength respectively.

Also, the confined concrete strength f'_{cc} was obtained from:

$$\frac{f'_{cc}}{f'_{co}} = 1 + k_1\varepsilon_{fe}\frac{f^*_l}{f'_{co}} \quad (8)$$

$$f^*_l = k_e\left(\frac{b+h}{bh}\right)E_{FRP}t_j \quad (9)$$

in which the value of $k_1\varepsilon_{fe}$ was taken as 0.0379 and k_e assumed to be equal to 0.7, based on a separate study on the confinement effectiveness of CFRP systems in capsule-shaped columns.

The predicted lateral load capacity based on the flexural moment capacity of the critical base section for the test columns in this study is given in Table 3. A nominal increase in the ultimate load capacity is noted.

4.3 Comparison with test results

The predicted ultimate lateral load capacity of the columns and failure mode corresponded to that which gave the lower ultimate load. Table 3 shows that all specimens except L-0.5-0 would fail in flexure while L-0.5-0 would fail in shear. This is in agreement with experimental observation except for L-0.19-0 which failed in shear-compression instead of flexure. This was because the predicted values were close to each other for L-0.19-0. The observed ultimate load capacities were between 4 and 22% higher than the predicted values.

5. CONCLUSION

The behavior of axially loaded FRP-confined capsule-shaped RC columns under lateral pushover loading was investigated. Test results indicated that the lateral load-carrying capacity of rectangular columns increased with the enlargement of the sections at the short ends using circular segments. The ultimate lateral displacement of such capsule-shaped columns increased with the application of transverse carbon FRP sheets. The displacement ductility and drift ratio was found to be largest in columns with an intermediate shape parameter value of 0.19.

Also, an analytical model to predict the lateral load-carrying capacity based on shear and flexural capacities was proposed and found to agree with the observed test results reasonably well.

SEISMIC PERFORMANCE OF A COUPLED WALL WITH HIGH PERFORMANCE FIBER REINFORCED CONCRETE

Chung-Chan Hung

Assistant Professor, Dept. of Civil Engineering, National Central University, Taiwan
cchung@ncu.edu.tw

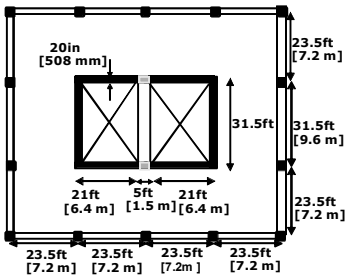
Abstract: High performance fiber reinforced concrete (HPFRC) possesses a unique strain hardening behavior in tension that translates into enhanced shear and bending behavior at the structural level. This paper investigates the seismic performance of an 18-story coupled wall system in which HPFRC is used to replace the traditional reinforced concrete (RC) in coupling beams and the plastic hinge regions in shear walls. System performance is evaluated using various parameters, such as deflection curves, inter-story drifts, maximum response, and shear deformation. The effectiveness of using HPFRC in the coupled wall system to enhance the seismic performance of the system is discussed in light of the results from nonlinear dynamic analysis.

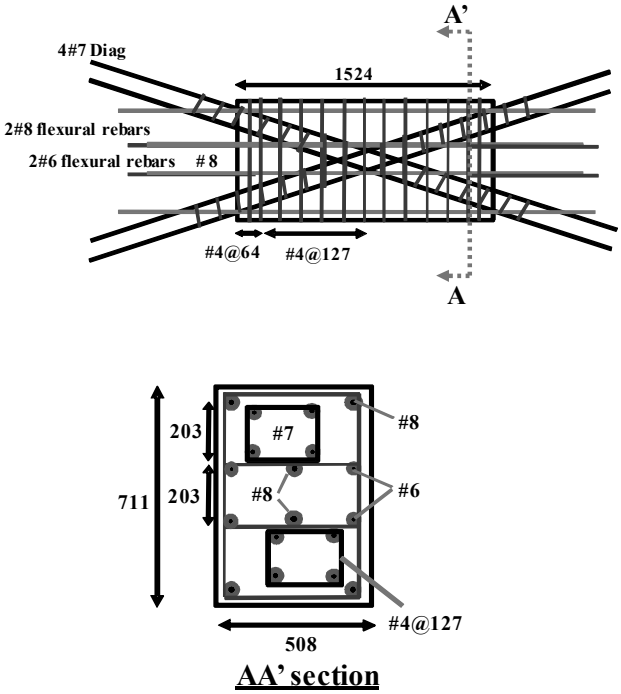
1. INTRODUCTION

High performance fiber reinforced concrete (HPFRC) is a class of materials that have properties that are attractive to structural engineers. These materials are characterized by pseudo-ductile tensile strain hardening behavior after first cracking accompanied by multiple cracks and large energy absorption prior to crack localization (Hung and El-Tawil 2010; Li 2003; Naaman 2006). HPFRC has the potential to serve as highly damage tolerant and energy absorbing materials under severe loading conditions, especially seismic loading. This paper numerically studies and compares the performance of a traditional 18-story RC coupled wall system with another similar system in which the coupling beams and plastic hinge regions are HPFRC instead of RC.

2. SYSTEM DESIGN

The theme system considered herein consists of a 94 ft (28.7 m) by 78.5 ft (23.9 m) (in plan) steel moment resisting frame surrounding a 47 ft (14.3 m) by 31.5 ft (9.6 m) (in plan) core wall system. The plan view of the prototype structure is given in Figure 1. The total height of the structure is 219 ft (66.7 m). The first floor's height is 15 ft (4.6 m) and typical floors are 12 ft (3.7 m) high. The thickness of the wall is 20 in (508 mm) and the total structure's weight is 20,831 kips (9449 tons). Two different prototype wall systems are designed. The first is a traditional RC system. The second prototype has HPFRC coupling beams. In addition, HPFRC is used in the first four floors of the wall piers.





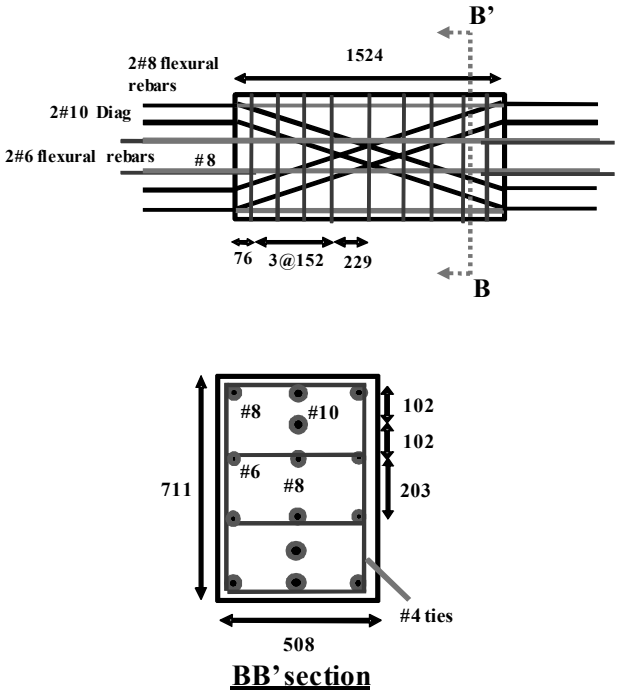


Figure 1. Plan view of prototype structural system.

Detail of the reinforcement design for RC coupling beams is shown in Figure 2(a), in which diagonal reinforcement cages with dense confining reinforcement are used. For the HPFRC coupling beams, reinforcement detailing design suggested by Canbolat et al. (2005) is used here that results in a single layer of diagonal reinforcement consisting of 2 #10 bars without confining reinforcement. The dimension and the amount of vertical reinforcement for the HPFRC beams are the same as that for the RC beams, while the horizontal reinforcement is reduced for the HPFRC coupling beams as shown in Figure 2.

The RC wall design details are compliant with (ACI 318 2008) and are shown in Figure 3, Table 1, and Table 2; where tw is the thickness of the wall, and Lbe is the length of boundary zone. The flexural and horizontal reinforcement of the HPFRC walls is reduced from that of the RC walls to take into account the additional tensile and shear capacity that HPFRC can provide.

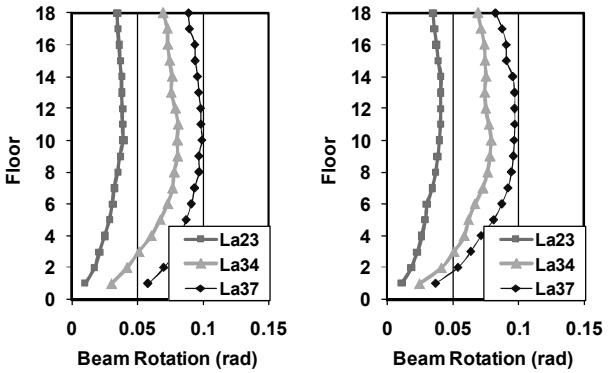
3. ANALYSIS RESULTS

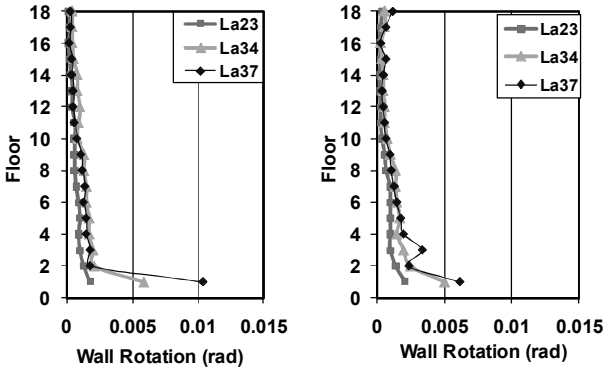
Performance of the systems is evaluated using nonlinear dynamic time history analysis. Three simulated time history ground motion records, LA23, LA34, and LA37 representing the seismic hazard level with probability of exceedance of 2% in 50 years (2/50) are used. The ground motions, which were developed by the SAC (Acronym for *Structural Engineers Association of California* 'SEAOC', *Applied Technology Council* 'ATC' and *California University for Research* in Earthquake Engineering 'CUREe') steel project, have a PGA of 0.42g, 0.68g, and 0.71g for LA23, LA34, and LA37, respectively. To reduce the computational effort, only the strong motion duration of the ground motion record is adopted for seismic excitation. The strong motion duration is defined as the time segment in which 90 percent of the seismic energy is delivered (Hassan 2005).



Details of component responses, drawn at the time corresponding to the occurrence of maximum system response (as determined by roof drift) during each earthquake, are plotted in Figures 4-6. Figure 4 shows the story drift of the two systems under each prescribed motion. The figure indicates that the story drifts of both systems are approximately the same along the building height. The drift limits in (ASCE 7 2002) imply that a maximum interstory drift of 2% shall not be exceeded at the Lift Safety performance level, while this criterion does not need to be observed at Collapse Prevention level. Nevertheless, the maximum interstory drifts of both prototype structures are around 2% during the 2/50 events, implying that the two systems can deliver similarly good performance.

(a) RC system (b) HPFRC system

Figure 4. Interstory drift of the systems



Coupling beam rotations in both systems are plotted in Figure 5. Clearly both systems have similar coupling beam rotation demands in spite of the reduced reinforcement amount and detailing in the HPFRC system.

(a) RC system (b) HPFRC system

Figure 5. Beam rotation levels at peak drift.

Wall rotations are plotted in Figure 6. It is clear that plastic hinges forms at the base of both systems when the peak displacement is reached. While both systems yield similar wall rotations along the height of the building under LA23 and LA34, LA37 results in a maximum wall base rotation of 0.01 for the RC system, which is about two times larger than the maximum response of the HPFRC system. This is taken to imply that the HPFRC system is capable of providing improved flexural behavior compared to conventional RC systems.

(a) RC system (b) HPFRC system

Figure 6. Wall rotation levels at peak drift.

4. CONCLUSIONS

The effectiveness of using HPFRC material to replace conventional RC material in the critical portions of an 18-story coupled wall system was discussed. Two coupled wall systems were considered: the first was a traditional RC design, while the second was a modified design in which HPFRC was used in the plastic hinge regions of the wall piers and in the coupling beams. The latter system was designed with less steel and relaxed detailing than the former in recognition of the beneficial effects of HPFRC. The responses of both systems subjected to strong seismic events with a 2% probability of exceedance in 50 years were then

compared. Comparisons of seismic response were made using story drift, wall rotation, and rotation of the coupling beams. The performance parameters studied suggested that both systems deliver similar performance in spite of the reduced reinforcement quantity and relaxed detailing in the HPFRC system compared to the RC system. This study was conducted using 3 seismic events with probability of exceedance of 2% in 50 years. The authors are currently expanding the study to investigate system responses in a stochastic manner, using a battery of seismic inputs representing various hazard levels.

Abstract: This paper introduces a rapid recovery technique using UHP-SHCC for damaged RC column, which involves only spraying of UHP-SHCC. Any formwork and additional reinforcement are not required. It might be helpful to reduce a construction process that is corresponding to reduction of cost. Cyclic loading tests were conducted for the column specimens repaired by UHP-SHCC and ordinary polymer cement mortar. It was confirmed experimentally that the developed technique using UHP-SHCC improve not only ultimate load but also ductility of recovered specimen. It seems that the prevention of buckling of longitudinal reinforcement, which was constrained by UHP-SHCC, imparts the mechanical improvement to the column specimens.

1. INTRODUCTION

For concrete structures such as super structures in highway, development of rapid recovery method[1)] is a very important issue and required in terms of business continuity plan (BCP).

Ishibashi[2)] has investigated recovery method on damaged RC column under cyclic loading. In the case of severe damage having spalling of cover concrete and buckling of longitudinal reinforcement, both crack injection and patching repairs were effective to recover the mechanical performance of the column. The thickness of patch repaired layer was larger than cover concrete thickness, and it means nominal cross sectional area of the column was increased.

There are a wide variety of methods such as jacketing with steel plate, continuous fibers and RC. However, these methods involve many construction processes such as manufacture of parts in steel jacketing, formwork and arrangement of steel reinforcement in RC jacketing. The many construction process gives longer downtime of the infrastructure.

Ultra High Performance-Strain Hardening Cementitious Composites (UHP-SHCC)[3)] is one of the fiber reinforced composites and has high strength in both compression and tension, high strain capacity in tension with pseudo strain hardening behavior. And spraying technique with UHP-SHCC has been also developed[4)].

This paper presents the experimental investigation on the developed rapid recovery technique using UHP-SHCC for damaged RC subjected to seismic loading. The column specimen repaired by UHP-SHCC was tested, and load carrying capacity and ductility were evaluated comparing to the specimen repaired by ordinary Polymer Cement Mortar (PCM).

2. CONCEPTUAL IDEA ON RAPID RECOVERY TECHNIQUE AND ITS ADVANTAGES

As shown in Fig. 1, UHP-SHCC is sprayed to a damaged part without any additional reinforcement. Both the novel material properties (i.e. high strength and high strain capacity) and spraying technique enable to develop the rapid recovery technique, and followings are feature of the developed technique including its advantages.

- A damaged structure for this recovery has buckling of longitudinal reinforcement with spalling of cover concrete.
- Load carrying capacity including ductility after the recovery is as well as that before the repair.
- Cross sectional shape after the recovery is the same as that before recovery. It means that the damaged concrete corresponding to cover concrete is replaced by the repair material (UHP-SHCC). It is possible to apply the other strengthening (e.g. steel plate jacketing) later.
- No additional reinforcement is utilized in the recovery.

- No formwork is required because of spraying technique.

3. OUTLINE OF EXPERIMENTAL PROGRAM

3.1 Procedure of Experiment

Outline of this experiment is summarized in Fig. 2. In this study, a cyclic loading was carried out in order to induce initial damage for column specimen (namely initial loading). After that, repair of the damaged column was conducted using two kinds of repair materials; one was ordinary PCM, and the other was UHP-SHCC. After the curing of the repaired specimens for 7days, a cyclic loading was conducted again (second loading).

3.2 Specimens

Shape of column specimens and reinforcement arrangement in the specimens are shown in Fig. 3. Sixteen longitudinal reinforcements (D13, SD345, f_y=368MPa) were used, and hoop reinforcement (D13, SD295A, f_y=360MPa) were also arranged at intervals of 80mm. Reinforcement ratio of longitudinal tensile reinforcement was 0.44%. In order to measure the strain of reinforcement and concrete, strain gages having the gauge length of 2mm and 30mm were attached, as shown in Fig. 3. Two specimens were prepared in this study, because different repair materials were adopted.

Material properties of concrete at the age of 28days and reinforcements are tabulated in Tables 1 and 2, respectively.

3.3 Loading Manner

As mentioned above, a cyclic loading was adopted to the column specimens in both initial loading and second one. Axial load of 160kN (nominal axial stress: 1MPa) was adopted. Displacement at yielding of reinforcement (δ_y) was 6.9mm in initial loading. The loading was terminated, when the load was decreased up to yielding load after the peak.

4. INITIAL LOADING TO INDUCE DAMAGE

4.1 Relationship between Load and Displacement

Figure 4 shows the relationship between load and displacement of the specimen in initial loading. Yielding of longitudinal reinforcement was occurred at load of 160kN and displacement of 6.9mm (δy). Horizontal load was significantly increased until 2δy. However, the curve represents plateau after 2δy. The peak load of the first specimen was 205kN at the displacement of 41.4mm (6δy), and the peak load of the second specimen was 200kN at displacement of 48.3mm (7δ_y). Note that, the first and second specimens were used for the repair using PCM and UHP-SHCC, respectively. After that, softening behavior was observed in both specimens, and loading was terminated when the load was same as yielding load

29.3	32

Table 2 Material Properties of Reinforcement

Longitudinal		Hoop	
Yield strength (MPa)	Young's modulus (GPa)	Yield strength (MPa)	Young's modulus (GPa)
368	186	360	190

(164kN). Eventually, both specimens exhibited similar load-displacement response, as shown in Fig. 4.

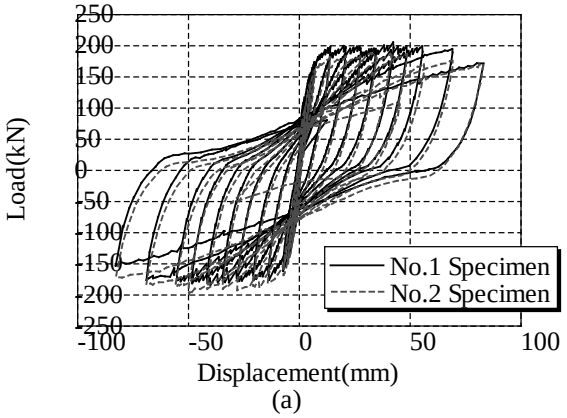
4.2 Induced Damage

Crack patterns during initial loading tests are given in Fig. 5. Flexural cracks occurred and propagated at hinge part of the column specimens mainly, and the number of cracks increased until the displacement corresponding to 1δy. After that, the number of crack was not increased, however, each crack opened wider.

On the side face of the column specimens, shear cracks occurred within 1D height (D: effective depth) from footing. And spalling of cover concrete was observed partially. Finally, buckling of longitudinal reinforcement was observed after spalling of cover concrete. In addition, fracture of core concrete was also obtained.

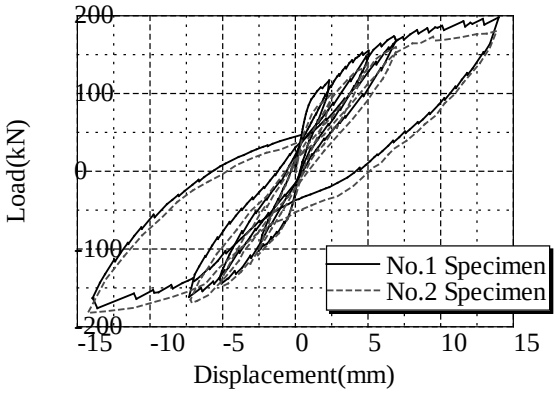
4.3 Strain Distribution

Figure 6(a) shows strain distribution of longitudinal reinforcement (left side of the column specimen) at each loading level, and Fig. 6(b) shows that of hoop reinforcement. Note that the loading direction was plus direction, as shown in Fig. 6.



Regarding the longitudinal reinforcement, strain value at hinge part of column specimen was increased with increasing of loading cycles up to displacement of 20.7mm (3δy), the higher strain region was corresponding to the damaged area mentioned in previous section. In the bottom of the column specimen, tensile strain was measured at final stage. It seems that elongation of the longitudinal reinforcement due to plastic strain was increased.

For the hoop reinforcement, the strain value became higher with increasing of loading cycles, and the higher strain region also agreed with the damaged area having a spalling of cover concrete. However, yielding of hoop reinforcement was not observed.



5. APPLICATION OF RECOVERY TECHNIQUE

5.1 Repair Materials

As described in Section 3.1, two kinds of cement

based materials were used in this study; one was ordinary PCM (premixed type) for plastering, and the other was UHP-SHCC for spraying. Where used PCM is not for this usage generally (i.e. no reinforcement is used).

Table 3 tabulates the material properties of each repair material at the age of 7days, which is corresponding to the loading age of second loading. Compressive strengths of PCM and UHP-SHCC were 23.2MPa and 79.7MPa, respectively. The compressive strength was obtained from the cylindrical specimens having the size of 50mm in diameter and 100mm in length. Figure 7 illustrates the tensile test results of UHP-SHCC dumbbell shaped specimens (5specimens), which were made by spraying. Note that tested cross section was 30x13mm. Averaged tensile strength of UHP-SHCC was 7.7MPa, and pseudo strain hardening and multiple fine cracking were observed, in addition to higher strain capacity over 1%.

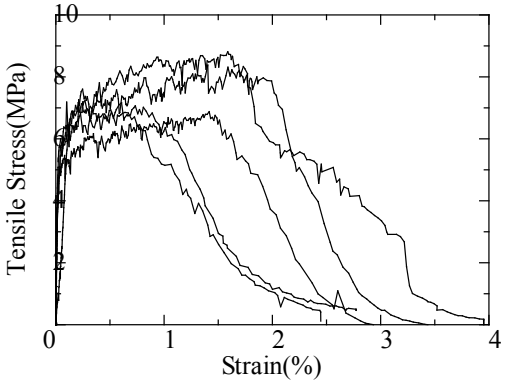

Figure 7 Tensile Stress-strain Curves of UHP-SHCC

5.2 Repair Method

The target of recovery was the damaged column specimens that were brought to the original position (residual displacement: 0mm). The damaged cover concrete was removed by using a hammer. And water spraying was also applied to prevent the water absorption of repair material itself.

PCM was applied by using plaster finishing. Note that the finished cross section was almost the same with un-damaged one (i.e. 400mm x 400mm).

Regarding UHP-SHCC, it was only sprayed to the damaged part, as shown in Fig. 8.

After the repair, curing was conducted for 7days,

Figure 8 Spraying of UHP-SHCC

and cyclic loading was carried out again for repaired specimens.

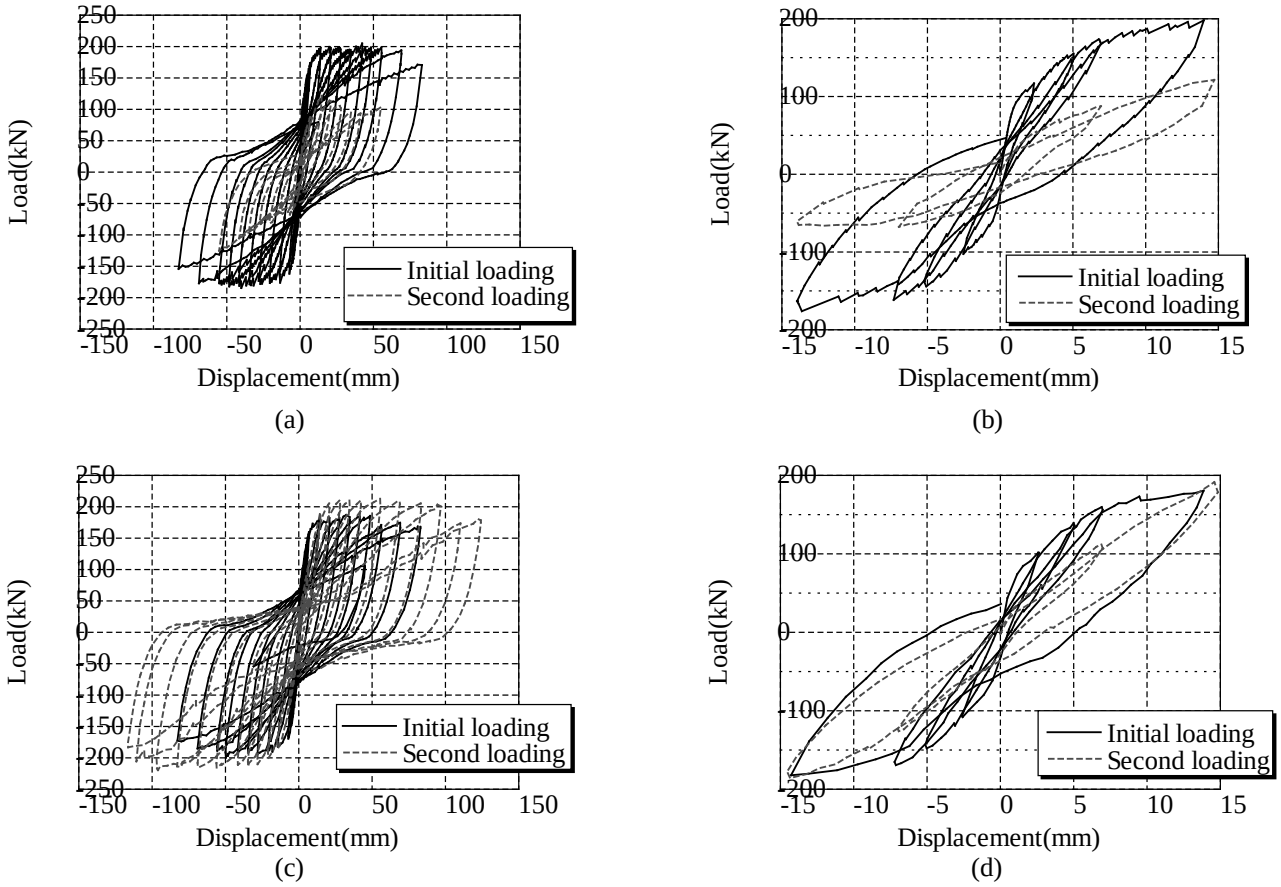

Figure 9 Load-displacement Curves of Each Repaired Specimens: (a) PCM (Overall), (b) PCM (Zoom Up), (c) UHP-SHCC (Overall), and (d) UHP-SHCC (Zoom Up)

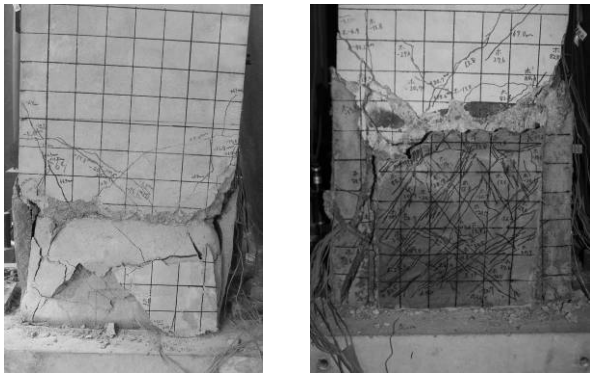

6. SECOND LOADING FOR REPAIRED SPECIMENS

6.1 Load-displacement Curves and Failure Behavior

Figures 9 (a) and (b) show the load-displacement curves of the specimens repaired by PCM and its zoom up one, respectively. Maximum load was about 120kN and it was dramatically decreased comparing to that of initial loading. Ductility of the specimen was also decreased significantly. In the initial loading stage (up to 2δy), splitting cracks occurred adjacent to longitudinal reinforcement of tensile side, and the cracks induced the buckling of reinforcement under compressive stress.

Figures 9 (c) and (d) illustrate the load-displacement curves of the specimens repaired by UHP-SHCC and its zoom up one, respectively. Maximum load was about 210kN, and it was higher than that of initial loading. Load was significantly decreased at 12δy, and ductility of the specimen was increased comparing to that of initial loading, eventually. As indicated in Fig. 9(d), initial stiffness was not recovered because of the crack located at the joint between column and footing.

Photos of the damaged part of the specimen with PCM and UHP-SHCC are shown in Figs. 10(a) and (b), respectively. In the case of specimen with PCM, splitting cracks were observed along longitudinal reinforcement,

(a) (b)

Figure 10 Photo of Damaged Specimen in Second Loading (Front View): (a) PCM, and (b) UHP-SHCC

and repaired part was crushed and spalling. Regarding the specimen with UHP-SHCC, however, diagonal multiple cracking was observed in the front side. No crashing of the UHP-SHCC was observed. However, concrete just above the interface between UHP-SHCC and concrete was damaged finally.

Regarding the side surface that is perpendicular to loading direction, although multiple cracking was expected, no crack was observed.

6.2 Relationship between Vertical and Horizontal Displacement

Figure 11 shows relationship between vertical and horizontal displacement of the columns repaired by PCM and UHP-SHCC. In the case of PCM, it was indicated that vertical displacement of second loading was decreased with increasing of loading cycles, because buckling of longitudinal reinforcement progressed. It seems that PCM could not resist against buckling of the longitudinal reinforcement.

Regarding the specimen with UHP-SHCC, vertical displacement was increased with increasing of loading cycles. It means that UHP-SHCC imparts higher resistance against buckling of the longitudinal reinforcement to the column specimen.

6.3 Energy Absorption Capacity

Figure 12 shows the relationship between loading cycle and energy absorption. In the case of specimen with UHP-SHCC, although energy absorption was slightly lower than that of initial loading in early stage, it became larger than that of initial loading finally. In the case of specimen with PCM, energy absorption was dramatically decreased comparing to other cases.

7. CONCLUSIONS

The rapid recovery technique using UHP-SHCC for damaged RC column was developed, and cyclic loading tests were conducted. Following conclusions were obtained;

(1) The rapid recovery technique involves only spraying of UHP-SHCC. Any formwork and additional reinforcement are not required. It might be helpful to reduce a construction process that is corresponding to reduction of cost.

(2) It was confirmed experimentally that the developed technique using UHP-SHCC improve not only ultimate load but also ductility of recovered specimen. It seems that the prevention of buckling of longitudinal reinforcement, which was constrained by UHP-SHCC, imparts the mechanical improvement to the column specimens.

Abstract: Deterioration of anchorage of reinforcement in RC structures can be caused by ASR or chloride ion induced corrosion. In this study, structural behaviors of deep beams with deteriorated anchorage of main reinforcement were investigated by experimental work. With bond deterioration of main reinforcement near the supports, the stiffness after the generation of diagonal cracks was remarkably reduced and the maximum load was also remarkably reduced. In experimental work, the effects of stirrups were investigated. When stirrups with small diameter were distributed, the stiffness after diagonal cracking was improved, and the maximum load was increased. Experimental results were numerically simulated by 3D FEM. Deterioration of bond was modeled by joint element, and experimental results were simulated well when appropriate shear strength of joint element was determined. Verification of analysis was conducted through load-displacement relationship, deformation, and strain distribution of main reinforcement.

1. INTRODUCTION

Due to the rupture of bending portion of re-bars by Alkali Silica Reaction , and due to the corrosion of re-bars at the ends of girders by de-icing agent, the deterioration of anchorage can be caused in actual concrete structures. The corrosion of re-bars by chloride ion will induce longitudinal cracking along re-bars which will cause bond deterioration. The deterioration of anchorage and bond can cause catastrophic failure of members.

The deterioration of bond near the anchorage of main re-bars adversely affects structural behaviors especially in deep beams. However, many past researches examined the effects of bond deterioration without the existence of stirrups.

In this research, the reinforcing effects of stirrups will be investigated in deep beam with initial deterioration of bond near the anchorage of main re-bars. Static loading of deep beams will be conducted where the adverse effects of bond deterioration and the reinforcing effects of stirrups with different arrangement will be investigated. 3 dimensional FEM simulation was conducted to understand the mechanism.

2. EXPERIMENTAL PROGRAM

2.1 Details of Specimens

The section and the shape of the specimens are shown in Figure 1. The width is 200mm and the height is 300mm. The effective depth is 260mm and the shear span is 450mm, and therefore a/d is 1.73. The length from the support to the bent portion of hook of the main re-bar was made long enough as 310mm. To obtain shear failure of the beams, the ratio of shear capacity to the shear force at flexural capacity was made lower than 1.0. Niwa's equation (JSCE, 2007) was used to calculate shear capacity.

Information about the specimens is summarized in Table 1. The properties of re-bars are shown in Table 2. Two specimens were made for all the cases to check reproducibility. As main re-bars, three D22 bars were arranged. When the effect of initial bond deterioration was examined in specimens N, ST6, ST13, the bond of main re-bars was removed in the range of 460mm from the bending portion of the hook. To remove bond, wax was filled in between the ribs of re-bars and the surface was made flat, and furthermore, the surface of that bond deterioration area was coated by grease and polyvinyl tape.

ST6 and ST13 specimens had stirrups, and in both cases the stirrup ratio was 0.422%. This satisfies the minimum reinforcement ratio in JSCE code and is almost equal to the reinforcement ratio of normal beams of road bridge piers. In ST6 specimens, stirrups of D6 were distributed with the spacing of 75mm. In ST13 specimens, D13 stirrups were coarsely arranged with the spacing of 300mm. D13 stirrups were arranged to cross the arch to connect the loading plate and the support as shown in Figure 1. For ST6 and ST13 specimens, compressive re-bars of D6 were arranged and stirrups were anchored to them.

2.2 Loading Method and Measurement of Displacement and Strain

2 points monotonic loading was statically applied. Steel plates with 100mm width were used for loading plates and supports. Up to diagonal cracking, loading was conducted in load control with 10kN step. After diagonal cracking, displacement control was used. The vertical displacement at the center of the span and the strains of main re-bars and stirrups were measured.

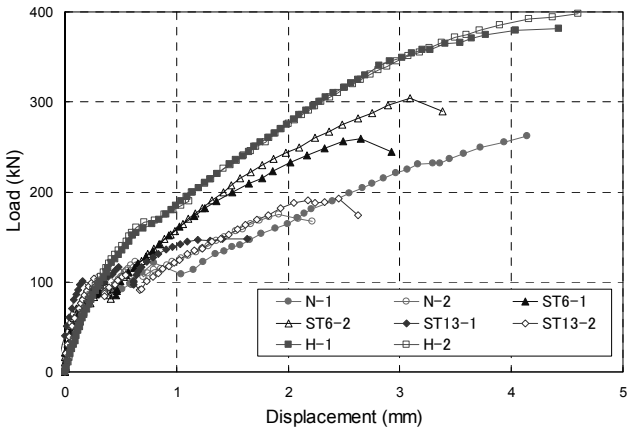

Figure 2 Load – Displacement Relationships

3. EXPERIMENTAL RESULTS

3.1 Stiffness after Diagonal Cracking

Figure 2 shows the relationships between load and the displacement at the center of the span. The beams H without initial bond deterioration show apparently higher diagonal cracking load and higher stiffness after diagonal cracking.

ST6 specimens with distributed stirrups showed higher stiffness after diagonal cracking and higher maximum load than N specimens without stirrups. Just after diagonal cracking, crack width was visually investigated. Diagonal crack width of ST6 was apparently restrained compared to that of N, which was caused by stirrups in the shear span.

ST13 specimens with coarse arrangement of stirrups showed almost the same behavior with N specimens. In terms of stiffness and failure pattern, the reinforcing effects

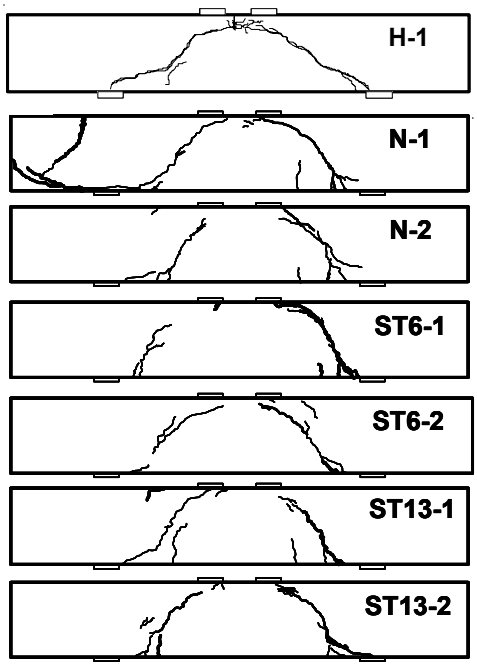

Figure 3 Crack Conditions

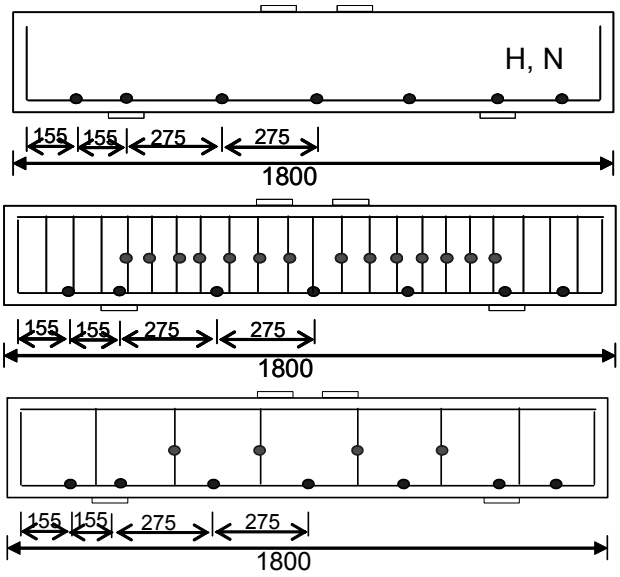

Figure 4 Locations to Measure Strain of Re-bars

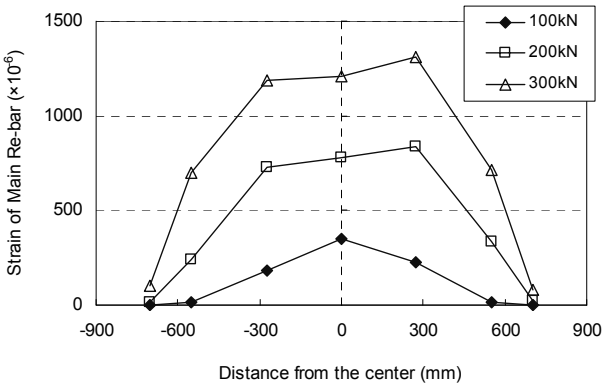

Figure 5 Strain Distribution of Main Re-bar (H-1)

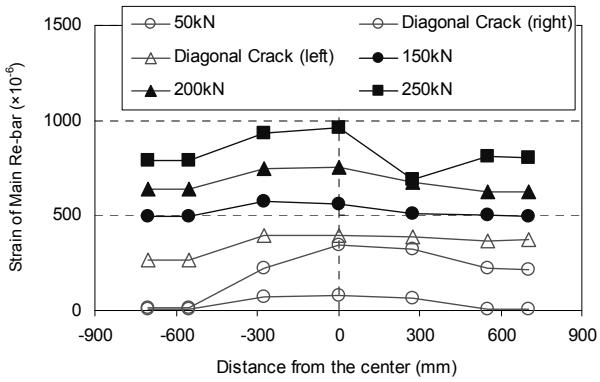

Figure 6 Strain Distribution of Main Re-bar (N-1)

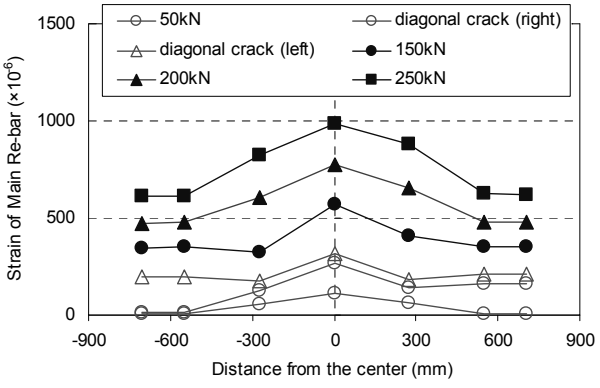

Figure 7 Strain Distribution of Main Re-bar (ST6-1)

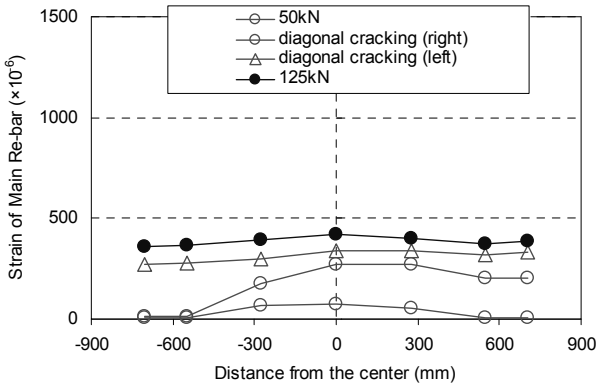

Figure 8 Strain Distribution of Main Re-bar (ST13-1)

of stirrups were not observed.

3.2 Crack Pattern and Failure Mode

Figure 3 shows the conditions of diagonal cracks after loading. In all the specimens with initial bond deterioration, diagonal crack developed from around the end of bond deterioration zone (460mm from the bending portion of hook of main re-bar). The origin of diagonal crack was the bending crack that was generated at the end of bond deterioration zone.

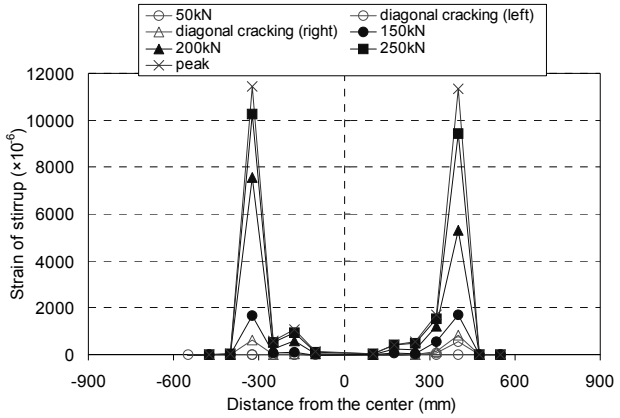

Figure 9 Strain Distribution of Stirrups (ST6-1)

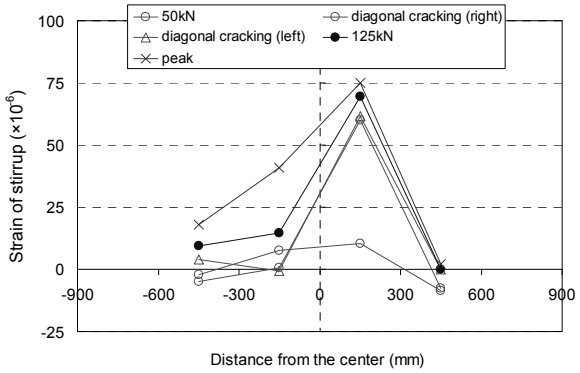

Figure 10 Strain Distribution of Stirrups (ST13-1)

In the case of H specimens, load increased after diagonal cracking, and diagonal cracks developed to go under the loading plates, and then finally failed with crushing of concrete in the bending compressive zone.

In the case of N-2 specimen, diagonal crack penetrated to the upper end of the beam beside the loading plate, and then showed shear compression failure. On the other hand, N-1 specimen carried larger force because diagonal cracks developed under the loading plates. N-1 specimen finally showed anchorage failure due to the slip of main re-bars with the appearance of vertical cracks at the upper portion of the beam.

ST6 specimens showed small distributed cracks near diagonal cracks which were not observed in H nor N specimens. This was due to bond effect of stirrups.

In ST13 specimens, diagonal cracks which developed from around the ends of bond deterioration zone crossed only small parts of stirrups coarsely arranged in the shear span.

The maximum loads in this experiment were varied a lot depending on the location of diagonal cracks, etc. When diagonal cracks penetrated to the upper end without going under the loading plates, maximum loads were relatively lower resulting in apparent shear failure with clear failure sound. In the next section, investigation by FEM simulation will be conducted where the stiffness after diagonal cracking rather than maximum load will be focused on.

3.3 Strain Distribution of Re-bars

Figure 4 shows the location to measure the strain of re-bars. Figures 5-8 show the strain distributions of main re-bars measured at 7 points along the longitudinal direction. Figures 9-10 show the strain distributions of stirrups.

From Figures 6-8, it can be seen that in all the specimens with bond deterioration, after diagonal cracking, strain of main re-bars in the bond deterioration area was started to increase.

In the case of N specimens, the strains of main re-bars at 7 points became almost uniform after diagonal cracking. This means that main re-bars from the bending portion of hooks to the center of the re-bars became uniform tension ties of arch mechanism. The beam load carrying mechanism before diagonal cracking shifted to arch mechanism where main re-bars carry almost uniform tensile force along the longitudinal direction.

In the case of ST13 specimens, the strain distributions of main re-bars had almost the same shape as that of N specimens. Judging from this result, the reinforcing effect of stirrups in ST13 was hardly achieved.

In the case of ST6 specimens, the strains of main re-bars near the center of the beam was increased after diagonal cracking, which was different from N specimens. Looking at Figure 9, the stirrups in the center of the shear span showed considerably large strain and got yielded. Stirrups carried shear force, and the strain of main re-bars was restrained, which resulted in larger stiffness after diagonal cracking than that of N specimens. This mechanism will be further investigated in the next section.

Before conducting this experiment, the authors expected that the slip of main re-bars might be restrained by friction caused by the stirrups surrounding main re-bars with bond deterioration. However, ST13 specimens showed almost no reinforcing effect, therefore we concluded that such kind of confining effect of stirrups was not observed.

4. FEM SIMULATION OF EXPERIMENTAL RESULTS

4.1 Outline of FEM Simulation

In this research, FEM program, "COM3" (Maekawa et al. 2003) was used which adopted constitutive laws based basically on smeared crack model. Simulation was conducted with axis-symmetric model as shown in Figure 11 (the model for specimen N). COM3 categorizes concrete elements into two types, such as RC elements and PL(Plain Concrete) elements (Maekawa et al. 2003). In RC elements, bond effect to distribute cracks is considered, and in PL elements a crack is localized without bond effect. In this research, main reinforcing bars were modeled as pure reinforcing bars without concrete, because joint elements were inserted between concrete elements and re-bar elements to express slipping due to bond deterioration by assuming appropriate shear stiffness of joint elements (Figure 14).

Main re-bars were modeled with pure re-bar model, and bond effective area was modeled as RC element. The

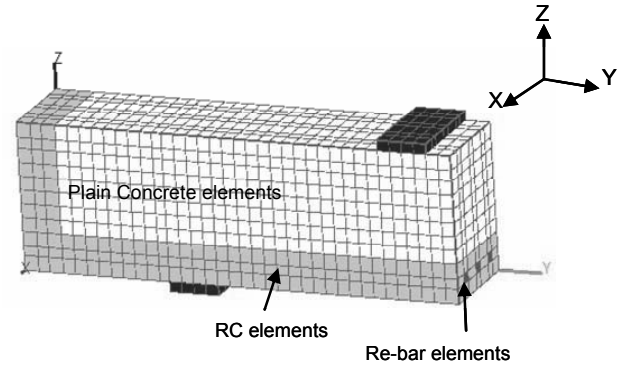

Figure 11 Analytical Model (N)

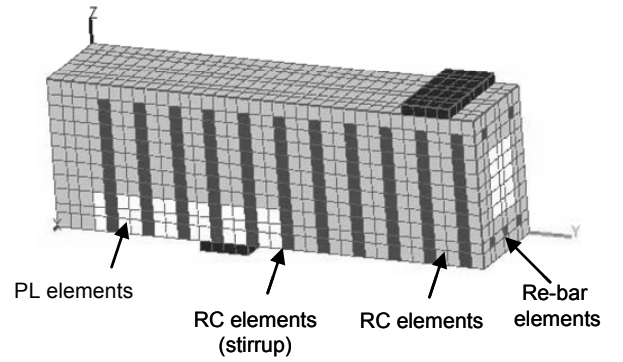

Figure 12 Analytical Model (ST6)

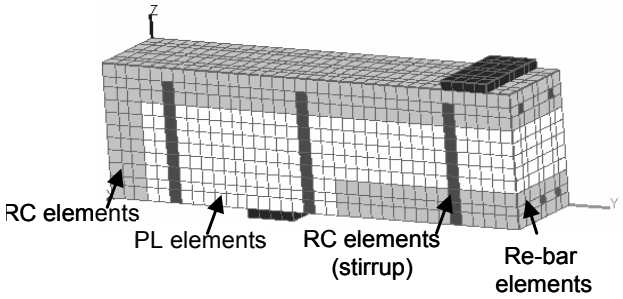

Figure 13 Analytical Model (ST13)

models for ST6 and ST13 were shown in Figures 12 and 13. In the case of ST6, considering the dense arrangement of stirrups, the width of RC zone was set as twice of cover thickness in X direction (Tsuchiya et al. 2001), and was set as the spacing of stirrups in Y direction. In the case of ST13, considering the coarse arrangement of stirrups, the width of an element including a stirrup was set as 25mm, and only that element with a stirrup was set as RC zone both in X and Y directions. In RC zones, the tension softening factor was set as 0.4 both for X and Y directions. In PL zones, the tension softening factor was decided considering fracture energy (Maekawa et al. 2003).

Bond deterioration of main re-bars was modeled using joint elements around pure re-bar elements. The length of bond deterioration and material properties of joint elements such as shear stiffness and opening/closing stiffness were set as shown in Figure 14 and Table 3 referring bond deterioration range by Okamura et al.(1991).

The bond property in non-deteriorated healthy area

Table 3 Material Properties of Joint Element

Healthy Bond Area		Bond Deterioration Area	
Shear Stiffness	Opening/Closing Stiffness	Shear Stiffness	Opening/Closing Stiffness
$N/mm^2/mm$	$kN/mm^2/mm$	$N/mm^2/mm$	$kN/mm^2/mm$
25	100	0	0

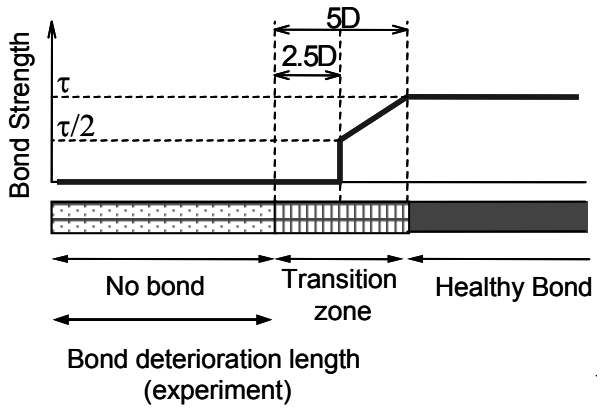

Figure 14 Modeling of Bond deterioration

were identified by the results of comparisons of numerical simulation and uni-axial tension tests by Tamai et al. (1987). The shear stiffness of joint elements of non-deteriorated area was decided to obtain almost the same behavior as the behavior of uni-axial tension tests. The behavior of reinforced concrete around tensile main re-bars is similar to that of uni-axial tension test. The same shear stiffness $25N/mm^2/mm$ was set for joint elements regardless of the location along healthy main re-bars. That value seems reasonable referring the value shown by Suzuki et al.(2005).

4.2 Results of FEM Simulation

The results of FEM simulation were shown in Figures 15 to 18. Figure 15 shows the relationships between load and displacement at the center of the span. Figure 16 shows the strain distribution of main re-bars. Figure 17 shows the strain distribution of stirrups. Figure 18 shows the contour of stress.

Regarding N specimens, the load at the generation of diagonal crack and the stiffness after diagonal cracking was evaluated appropriately. Looking at the strain distribution of main re-bars in Figure 16, the strain distribution was flat in the bond deterioration area, which was observed in N specimens as shown in Figure 6. This flat distribution leads to larger slip near the anchorage, and compressive stress tends to flow from the loading plate to the bending portion of anchorage of main re-bars (Figure 18). This will be the reason of lower stiffness after diagonal cracking than that of healthy deep beam.

Regarding ST6, the load – displacement relationship was predicted with sufficient accuracy including the stiffness after diagonal cracking. As shown in Figure 16, the strain of main re-bars of ST6 specimens was lower than that of N specimens at the same load. The shape of strain distribution of ST6 was sharp compared to flat distribution of N

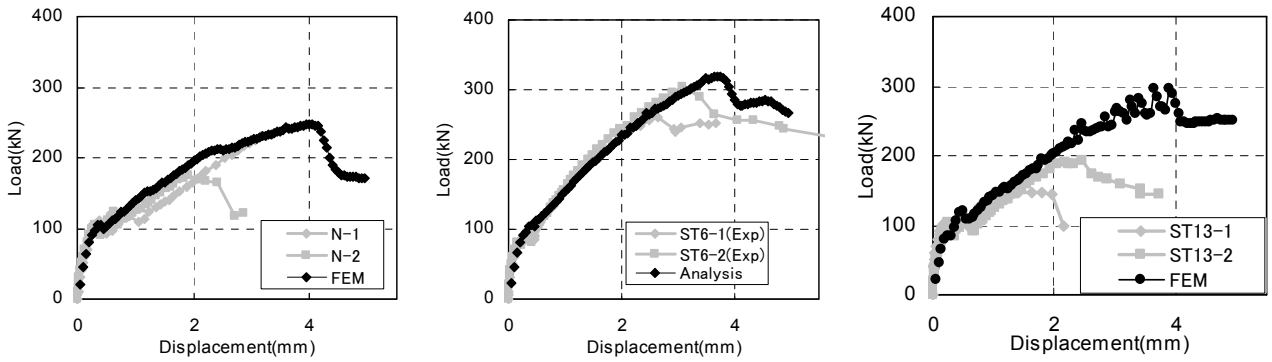

Figure 15 Load – Displacement Relationships (FEM)

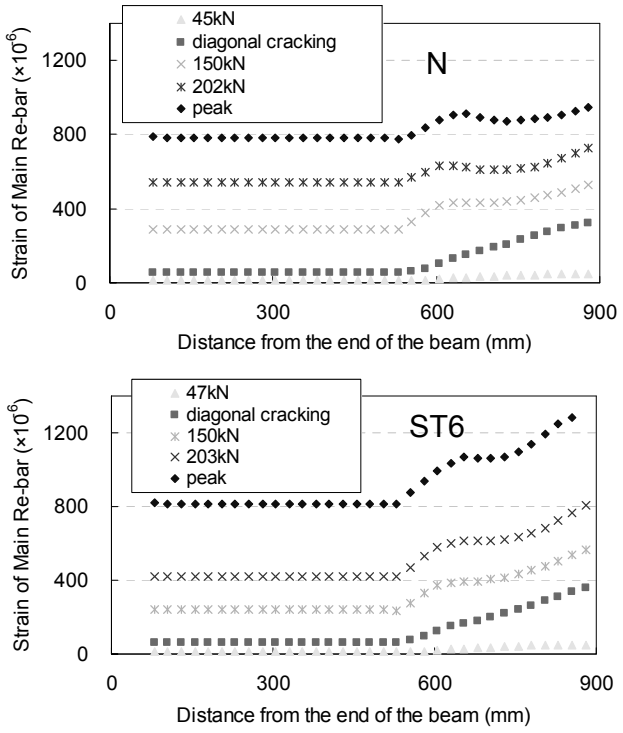

Figure 16 Strain Distribution of Main Rebar (FEM)

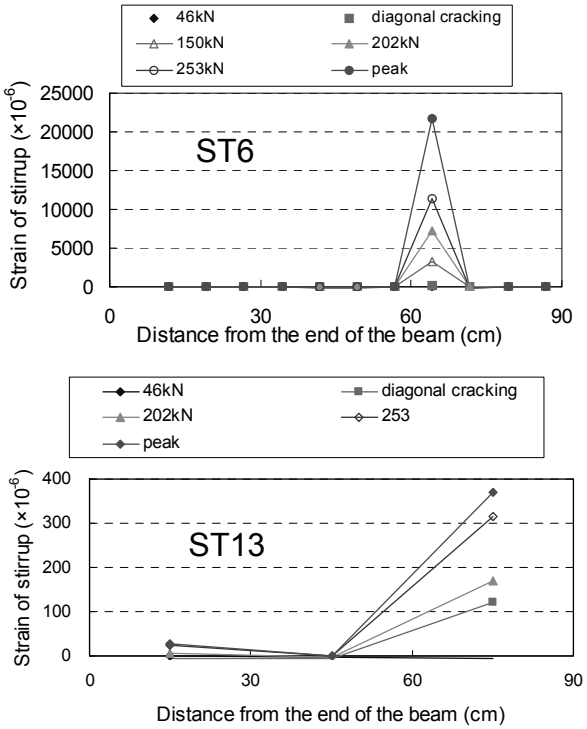

Figure 17 Strain Distribution of Stirrups (FEM)

Figure 18 Contour of Stress (FEM)

specimens. These were caused by the effect of stirrups.

The authors think that the effects of stirrups are to carry shear force, to improve shear transfer by restraining diagonal crack width, to distribute compressive stress in the strut by confinement effect, and to increase dowel action of main re-bars. From Figure 17, it is clear that the stirrups carry sufficient shear force in ST6. Figure 18 shows that compressive stress in diagonal direction is more distributed in ST6.

N and ST6 specimens show clear difference in the stiffness after diagonal cracking, which must be caused by the effects of stirrups. In the case of N, after diagonal cracking, the slip in the bond deterioration area caused further opening of diagonal crack, which led to lower stiffness than the beams without initial bond deterioration. On the other hand, in the case of ST6, due to the effects of stirrups, the opening of diagonal crack and the slip in the bond deterioration area were restrained, which led to increasing the stiffness of tied arch.

Regarding ST13, the maximum load in simulation was much higher than the experimental results. The reason is clearly shown in Figure 17, which shows the carrying of shear force by stirrups different from experiment. The simulation in this research could not reproduce a localized behavior, winding away of diagonal crack from a stirrup

near the loading plate, which was caused by the coarse arrangement of stirrups. The stiffness of ST13 after diagonal cracking was simulated well, because in the simulation only the stirrup just under the loading plate carried shear force and therefore diagonal crack width in the shear span was not restrained.

5. CONCLUSIONS

The adverse effects of bond deterioration of main re-bars and the reinforcing effects of stirrups were investigated in RC deep beam. The following results were obtained from experiment and 3D FEM simulation.

1) Due to bond deterioration near the anchorage of main re-bars, the load of diagonal cracking, the stiffness after diagonal cracking, and the maximum load were apparently reduced.

2) Distributed stirrups improved the stiffness after diagonal cracking in deep beam with initial bond deterioration. Due to the existence of distributed stirrups, the width of diagonal crack was restrained and the slip of main re-bars in the range of bond deterioration was restrained.

3) Coarsely arranged stirrups did not show reinforcing effect in deep beam with initial bond deterioration. Diagonal crack did not cross stirrups in the shear span, which could not be simulated well by 3D FEM.

4) Initial bond deterioration was appropriately modeled in FEM using joint elements around re-bar elements. The structural behaviors of deep beam with initial bond deterioration of main re-bars were simulated with sufficient accuracy. The effects of distributed stirrups were also well simulated.

Abstract: This research includes an experimental investigation to evaluate the residual structural performance of RC beams having partially corroded longitudinal reinforcing bars. The acceleration corrosion was applied to the RC beams which were subsequently used in the loading test. From measurement instruments embedded in the web concrete of RC beams, the minimum principle strain which is calculated by measured strain in the concrete is significant along with the diagonal crack in the shear span. Finally, the experiment results for the failure mode of RC beams can be classified according to the location, range and degree of the steel corrosion of the longitudinal reinforcement in the RC beams.

1. INTRODUCTION

An appropriate method for the maintenance of existing structures has been required to keep the structures having their initial required performance. Deteriorations such as steel corrosion due to the permeation of chloride ions should be considered as one of the durability problems of reinforced concrete (RC) structures. With the deteriorated RC structures, it is required to evaluate the residual performance of the structures in a maintenance system, and hence an analytical tool to evaluate the performance of the structures is keenly needed. In the analysis for these structures, not only the material deteriorations itself but the interaction between concrete and steel reinforcement will be considered. This is because of that both the cross-section of the reinforcement and the bond property due to the expansion pressure by the corrosion products decrease when the steel corrosion occurs in the RC structures. Consequently the safety and serviceability of the structures is affected by the corrosion of steel reinforcement.

Since the shear failure suddenly occurs without any notice and results in a complete loss of structural capacity, it is certainly important to assess the shear carrying capacity of RC structural members accurately. However, it is difficult to formulate a phenomenon of RC behavior in shear which depends on variables, including the bond property between concrete and longitudinal reinforcement. Ikeda and Uji (1980) have been proposed a unified concept for the influence of bond on the shear behavior of RC beams based on their experiment and analysis. Matsuo et al. (2004) conducted the loading tests on the RC beams with or without stirrups having corrosion of reinforcements. The acceleration corrosion procedure by means of applying electric current was used to make corrosion in the steel reinforcement. The RC beams had longitudinal reinforcements with somewhat uniform condition in the shear span as compared to that observed in actual structures. It should note that the corrosion conditions of reinforcement in the actual structures may vary spatially since the surface condition of concrete structures and the environmental actions subjected to the structures depend on the site.

The final goal of this research framework is to establish a method to evaluate the performance of the RC structures using given information for the deterioration due to steel corrosion (Miki and Takeuchi 2010). To achieve this goal, the aim of this study is to evaluate the residual performance of RC beams having partially corroded longitudinal reinforcement by means of the experimental research. In the experiment, a developed measurement instrument embedded in the web concrete of RC beams is used to obtain the internal strain distribution in the concrete being affected by the corrosion condition of reinforcement.

2. TEST PROGRAMS

2.1 Specimens

The test program consisted in a total number of six RC beams. Details of the beam geometry and reinforcement layout are presented in Figure 1 and Table 1. Two series of the beam size is used in the experiment. As it can be seen from the figure, there are no stirrups in the shear span. The reason for such a reinforcement layout is that we want to evaluate the shear carrying capacity of the concrete itself without the help of shear reinforcement. For each concrete mix in Table 2 beams with the dimensions of length, 1200

20	64.9	45.0	179	276	886	945	414

mm or 1800 mm and a cross-section of 200 × 150 mm have been cast. In this study, a concrete with a designed compressive strength of 30 N/mm^2, obtained from uniaxial compression tests at 14 days, was considered. Maximum size of coarse aggregate was 20 mm. Early-strength Portland cement was used with an air entraining agent in the concrete mixes.

A series of test specimens are summarized in Table 3 and illustrated in Figure 2 except specimen No.6. The experimental parameters were set to be a location, range and degree of the steel corrosion in longitudinal reinforcements. The accelerated corrosion area was located at the middle of shear spans (No.2, No.5 and No.6), ranged from the middle of a shear span to the beam end (No.3 and No.4), as shown in Figure 2. As for the specimen No.4, in the anchorage zone from the support to the beams end, the current was applied additionally. The specimen No.5 had initial simulant cracks at the middle of shear spans where the accelerated corrosion was locally applied. These cracks were formed by means of thin stainless plates which are set there before concrete casting of the beam and removes after the removal of forms. The crack width was 0.2 mm. The specimen No.6 has similar to specimen No.2 with respect to the condition of the steel corrosion in the longitudinal reinforcement but different size of the beam.

2.2 Accelerated Corrosion Tests

Accelerated corrosion tests have been used successfully to determine the susceptibility of steel reinforcement to corrosion. The accelerated corrosion setup used in this investigation consisted of a DC power supply, plastic tanks, electrolytic solution (3% sodium chloride, NaCl by the weight of water) and stainless plates in each tank, as shown in Figure 3. The RC beam soffit was partially attached with a plastic sponge of which other side is immersed in the electrolytic solution of NaCl. The range and location of corrosion in the longitudinal reinforcement was controlled by the ones where the plastic sponge was attached with the soffit of the beams. During the accelerated corrosion test, the cumulative current per unit corrosion area ($A*day/m^2$) applying with a current which is set from 0.7 to 1.7 A was controlled to induce the expected corrosion degree.

2.3 Loading Tests

To obtain the shear carrying capacity of the RC beams, a four point loading test was carried out. A 2000kN universal test machine was used. During the loading test, the load, displacements at both supports and midspan, steel strain of longitudinal reinforcement, and strain in the web concrete

explained detail in following section were measured. For the purpose of the friction reduction at each support, a set of Teflon sheets lubricated with grease was used.

2.4 Measurement of Strain in the Web Concrete

The internal strain in the web concrete within the shear span of a RC beam was measured during loading tests. Six triaxial rosette strain gages attached on an acryl plate (Tadokoro et al., 2005, Miki and Takeuchi 2010) which was formed and fabricated to firmly behave with surrounded concrete were embedded in the beam. This instrument with strain gages was fixed to the reinforcements for the preparation of concrete casting. For the specimens No.3 to No.5, two fabricated acryl gages, so that 12 measuring points was set were used in the both shear spans of the RC beams. In the specimen No.6, two layers of the fabricated acryl gage was installed to measure the distribution of strain in the height direction. Figures 4 and 5 illustrates details of the acryl attached strain gages and their location set in the specimen No.6, respectively. The material properties of the acryl used in the test are summarized here; a density of 1.18 g/cm3, a tensile strength of 60 MPa, a yield strain of 4.5% and a Young's modulus in tension of 3000 MPa.

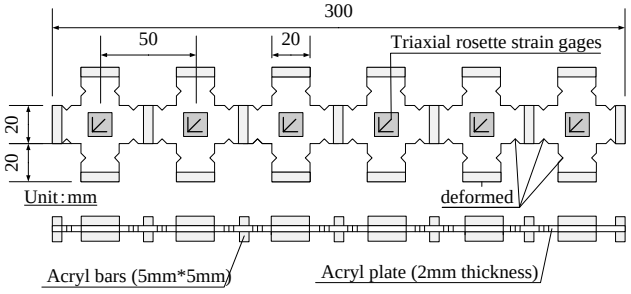

Figure 4 Details of a fabricated acryl gage

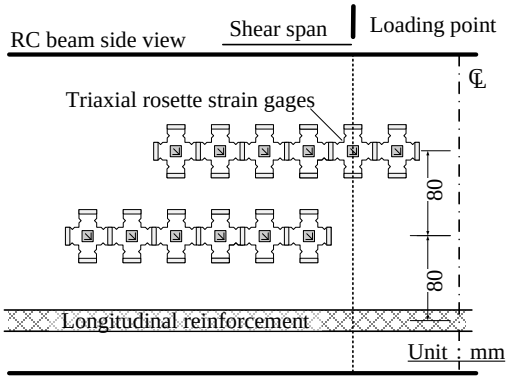

Figure 5 Location of the gages in specimen No.6

2.5 Procedure to Determine the Degree of Corrosion

The degree of corrosion was determined by the weight reduction of the steel reinforcement. In this study, the ratio of cross-sectional loss of reinforcing bar due to corrosion is defined as a ratio of the weight-loss of corroded reinforcing bar from its initial weight to that of non-corroded reinforcing bar. Tensile reinforcement was taken from the demolished RC beams after loading tests. To remove the rust on the steel reinforcement, the reinforcing bars were immersed in the 10% solution of diammonium hydrogen citrate at room temperature for 3 days. Then all reinforcing bars were divided into samples with the length of 50 mm. The ratios of cross-sectional loss were measured for each sample, and the distributions of the ratios of cross-sectional loss of reinforcing bar were measured. Therefore, the amount of corrosion can be estimated by using Eq. (1) as follows;

$$C = \frac{\Delta w}{w} \times 100 \tag{1}$$

where, Δw: weight difference between the samples of non-corroded and corroded reinforcing bars (g/mm), w: weight of non-corroded reinforcing bar (g/mm)

3. TEST RESULTS AND DISCUSSION

3.1 Load-Displacement Relationships

The load-displacement relationships of all specimens are shown in Figure 6. In addition, the results of loading test are summarized in Table 4. It should be mentioned that all specimens showed no yielding of longitudinal reinforcement during the loading test. The stiffness of all beams so that the inclination of the load-displacement curve decreased at 30 kN corresponding the flexural cracking load. The stiffness of the specimens having the corroded reinforcement is similar to the control specimen No.1 until 70 kN at which diagonal crack occurs except the specimens No.3 and No.6.

As for the behavior after diagonal cracking, clear difference between corroded and non-corroded specimens can be exhibited. The specimen No.1 indicated a diagonal tension failure so that the beam failed in brittle immediately after a decisive diagonal crack widely opened. On the other hand, the load of the specimens No.2 to No.6, which are the beams having the corroded longitudinal reinforcement, increased after the diagonal crack occurred, then the failure mode does not become brittle. From the results it can be expected that the failure mode changes with varying the condition of corrosion of the longitudinal reinforcement in the RC beams.

3.2 Crack Patterns of Tested Beams

The crack patterns of all beams after the loading tests are shown in Figure 7. In the figure an inclination angle of the decisive diagonal crack is also shown. Here, this

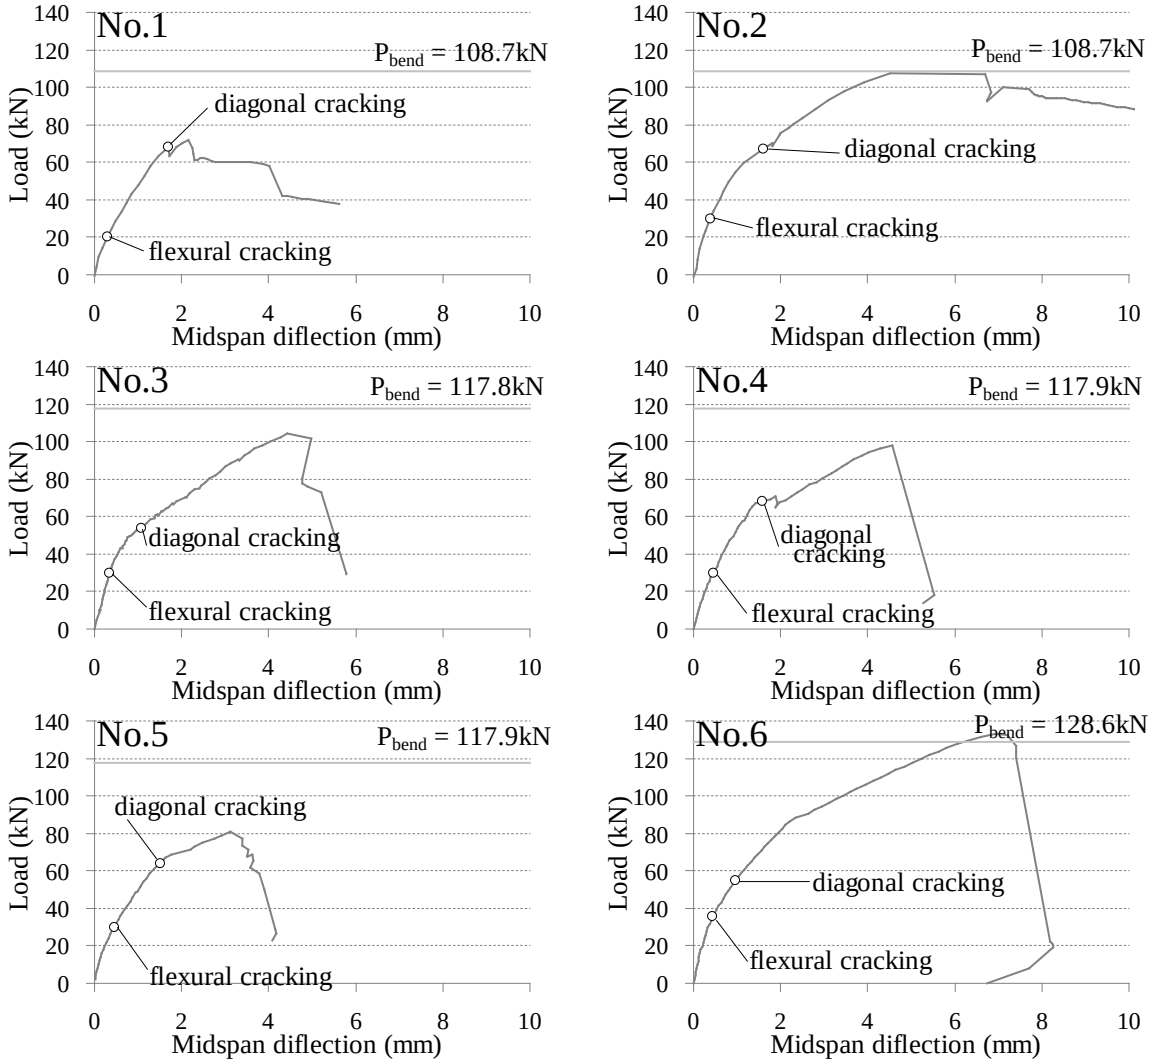

Figure 6 Load-displacement relationships

inclination angle is defined as that of a linear approximation between the loading point and a crossing point of the diagonal crack to the longitudinal reinforcement, as referred the previous study (Tsunoda et al., 2008). The values of θ in Figure 7 are mean values of the inclinations estimated in the shear spans of the beams.

The decisive diagonal crack in the specimen No.1 seems to be located along with a line connecting the support and loading point. On the other hand, the specimens having the corroded reinforcement have the steeper decisive diagonal crack than in the control specimen. With the specimens No.2 and No.6, diagonal cracks initially developed from the corrosion crack at an angle of around 33° and 39°, respectively to the horizontal axis. With further loading, it was observed that the existing corrosion crack had opened at the middle of the shear span. The final failure of the beam is caused by a crushing of the compression zone over the diagonal crack, as referred to a shear compression failure.

The specimens No.3 and No.4 had diagonal cracks propagated from the corrosion crack. This behavior is similar to one of the specimen No.2. The experiment for specimens No.3 and No.4 showed that in these beams the anchorage failure along with the end of the longitudinal reinforcement seemed to occur simultaneously with the crushing of concrete over the diagonal crack that is the vicinity of the loading point.

The specimen No.5 was able to carry additional load

Table 4 Results of loading tests

Beam ID	f_c' (MPa)	Diagonal cracking load (kN)	Max. load (kN)	Failure mode
No.1	23.3	68	71.9	Diagonal tens.
No.2	23.3	67	107.7	Shear comp.
No.3	33.2	54	104.1	Shear comp./ Shear tens.
No.4	33.4	68	98.1	Shear comp./ Shear tens.
No.5	33.4	64	80.9	Diagonal tens.
No.6	34.7	55	133.3	Shear comp.

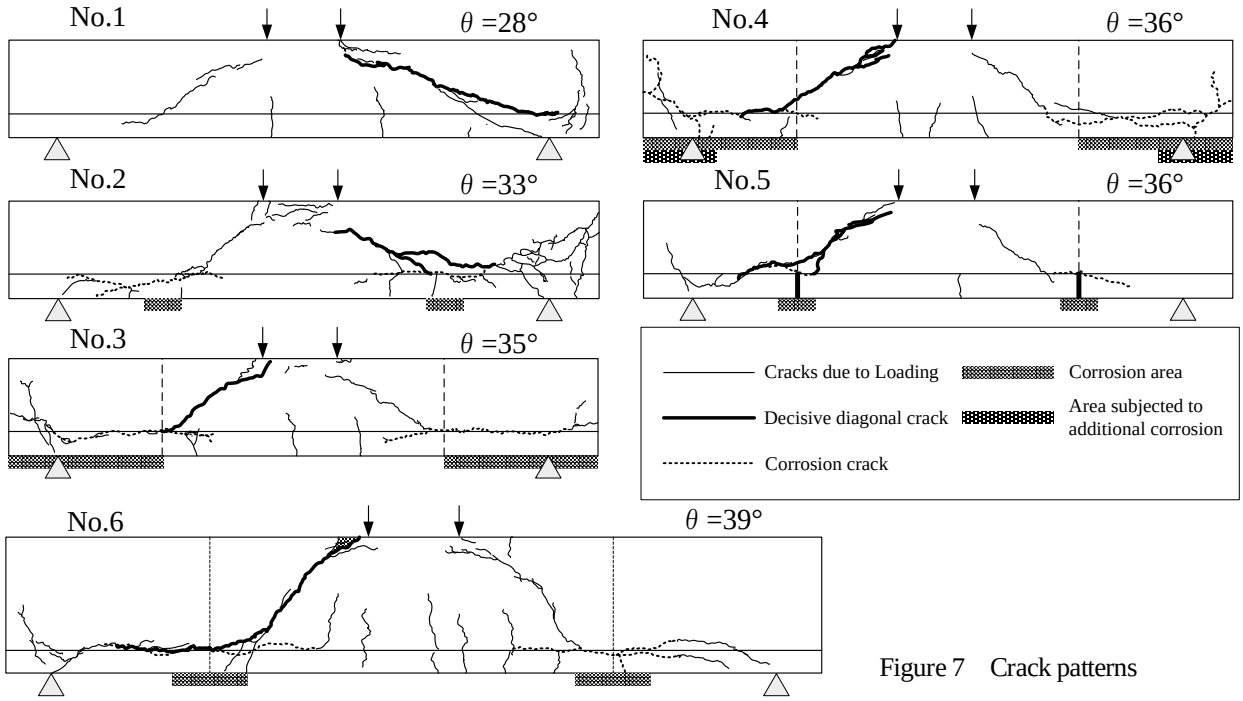

Figure 7 Crack patterns

after developing the diagonal crack at an angle of around 36°. This diagonal crack had propagated from the present corrosion crack at the middle of shear span. At ultimate stage the other crack whose angle was smaller than the former subsequently occurred. This crack propagated and opened gradually and consequently resulted in a diagonal tension failure.

3.3 Concrete Strain in the Web Concrete

As mentioned previously the internal strain in the web concrete within the shear span of a RC beam was measured during loading tests. Figure 8 indicates one of the results for the distribution of maximum and minimum principle strains in the specimen No.6. The results shown here were measured at the loads at the diagonal cracking (84.6kN) to the load carrying capacity (133.3kN) of RC beams, respectively. The length of lines in the figure corresponds to the magnitude of the maximum and minimum principle strains and its inclination indicates the direction of the principle strains. The measured location of the strain gages corresponds to a center point of this line. In the legend symbol, the length of the lines is corresponding to the strain value of $250*10^{-6}$. As can be seen in the figure, the minimum principle strain measured near the diagonal crack significantly increased until the maximum load after the diagonal cracking. This strain is the state of compression. In addition, the direction of the minimum principle strain corresponds to that of the decisive diagonal crack in the shear span. This behavior implies that the formation of the tied arch mechanism in the beam can be predicted. Moreover, the strut of concrete in the tied arch mechanism is formed along with the diagonal crack on its upper region.

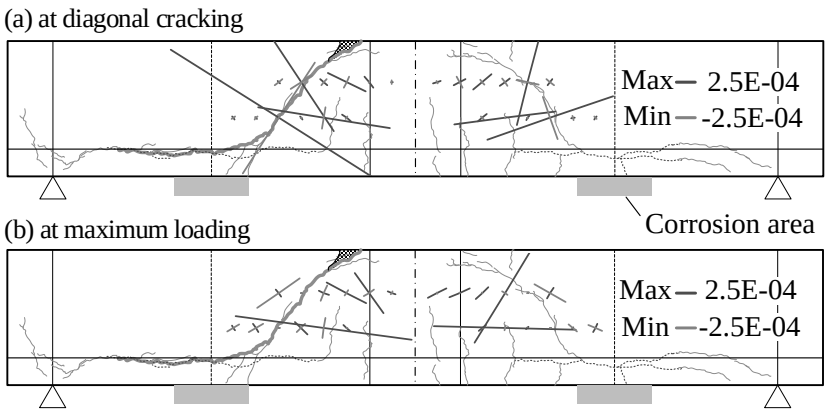

Figure 8 Distribution of maximum and minimum principle strains in the web concrete within the shear span of specimen No.6

3.4 Classification of the Failure Mode of RC Beams According to the Corrosion Condition in the Beams

The control RC beam (No.1) indicates the diagonal tension failure in which the beam failed in brittle immediately after a decisive diagonal crack widely opened. On the other hand, the load of the beams corroded in the longitudinal reinforcement increases after the diagonal crack occurs. The direction of diagonal crack of the corroded RC beams is steeper than that of the control beam. From the experiment, the failure behavior of these corroded RC beams can be classified as follows:

For the RC beams having the corrosion of longitudinal reinforcement in the anchorage zone (No.3, No.4), the diagonal crack propagated from the corrosion crack was observed. At the ultimate stage of these beams, the anchorage failure along with the end of the longitudinal reinforcement occurs simultaneously with the crushing of concrete over the diagonal crack that is the vicinity of the loading point.

On the other hands, the RC beams having the corrosion of longitudinal reinforcement in the shear span (No.2, No.6) suffers after the diagonal crack occurs. With further loading, the existing corrosion crack opens at the middle of the shear span. The failure of the beam is caused by a crushing of the compression zone over the diagonal crack, as referred to the shear compression failure. On the other hands, the RC beam corroded in the shear span but the rage of the crack due to corrosion products is localized because of the presence of a flexural crack shows different failure mode (No.5). The diagonal crack of this beam is propagated from the existing corrosion crack at the middle of shear span. At ultimate stage the other crack whose angle is smaller than the former subsequently occurs. This crack propagates and opens gradually and consequently results in the diagonal tension failure.

4. CONCLUSIONS

In this study the accelerated corrosion tests and loading tests was carried out for six RC beams with and without the corroded longitudinal reinforcement. A control RC beam with a shear span ratio a/d = 2.8 designed failed in shear. Using beams with same dimension to the control, loading test was carried out in order to evaluate the influence of the range and location of corrosion in the longitudinal reinforcement on the shear resisting mechanism of damaged RC beams. The conclusions obtained in the present study are as follows:

1) The carrying capacity of the RC beams having partially corroded longitudinal reinforcement increases compared to a non-corroded beam.
2) The experiment shows the influence of corrosion cracks that are locally observed in the shear span and occurred along with the longitudinal reinforcement on the initiation and propagation of the decisive diagonal crack due to the further loading.
3) Using the measurement instrument embedded in the web concrete, the maximum and minimum principle strains which are calculated by measured strain can be obtained. The distribution of the minimum principle strain indicates the formation of the tied arch mechanism in the beam. In addition, the strut of concrete in the tied arch mechanism is formed along with the diagonal crack on its upper region.
4) The failure mode of partially corroded RC beams can be classified according to the location, range and degree of the steel corrosion of the longitudinal reinforcement.

Abstract: Since low-grade material had been used for grouting of sheath in PC girder, some PC girders initially constructed in 1950s include sheaths being not fully filled by grout. The exposure of PC tendon in the sheath will corrode and break PC tendons, and reduce the load capacity of PC girders. This research focused on the interface bond between PC tendons and grout in sheath through the loading test and FEM analysis in order to explain the loading capacity of deteriorated PC girders.

1. INTRODUCTION

After the construction of first Daidogawa-bridge in 1954: the first post-tension prestressed concrete (PC) girder in Japan, more than 10,000 of post-tension PC girders have been constructed and used for Japanese railway. In such PC girders, the inside of sheaths should be filled with the grout to prevent the PC tendons from corrosion. The grout, however, does not completely fill inside the sheath by various reasons. (Mutsuyoshi 2006) As a results, the corrosion and broken of tendons have been reported. (Ishibashi, T. 2003) PC tendons in the post tension PC-girder are anchored at both ends in order to ensure the enough amount of the stress installed by tendons. Therefore, the corrosion of tendons will drastically change the mechanical performance of the PC girder and reduce the serviceability and the safety of the structure. Therefore, the mechanical performance of incompletely-grouted PC girders with broken tendons should be evaluated to execute the repairing and reinforcing according to it. (Coronelli et al. 2009)

If the grout is partially filled inside the sheath, the stress will transmit from tendons to concrete because the bond exists between tendons and grout after cutting the tendons. This means that the bond between the grout and tendons as well as the residual stress of the PC girder will be a key to evaluate the mechanical performance of the PC girder reasonably. There are several reports of the pull-out test of PC tendon from concrete by referring to the test for the reinforcing bar. (Korenaga and Watanabe 1999) The method, however, cannot duplicate the strain condition of broken-tendon.

The non-destructive evaluation system for understanding the existence the grout inside the sheath is now developing. The corrosion process of PC tendon also has been reported in the world. Integration of these research with the evaluation of the residual stress has a potential to evaluate the mechanical performance of the PC girder immediately.

The objective of this paper is to evaluate the bond between PC tendon and the grout inside the sheath, and the flexural load capacity of incompletely-grouted PC girder with broken tendons. In order to overcome the objective, we conducted a series of rupture tests of PC tendon by using the uni-axially prestressed specimens, and the bond characteristic of the PC tendon was assumed as a function of the PC-tendon type and the grout strength. Finally, the paper proposed the flexural load capacity of incompletely-grouted PC girder with broken tendons with the verification by the experimental results.

2. EVALUATION OF RESIDUAL PRESTRESS OF PC-GIRDERS WITH BROKEN TENDONS

2.1 Rupture Test of PC-Tendon in Uni-axial Specimen

Figure 1 indicates the outline of specimen. The specimen had a rectangular cross-section with 250×250 mm or 400×400 mm, and the hole was located at the edge of specimen in order to cut the PC tendon before loading. The

target compressive strength of concrete was 50 N/mm^2.

The grout was filled enough in the steel sheath, and four longitudinal re-bars were arranged in surrounding of the sheath, and stirrups with the nominal diameter of 13 mm were provided with an interval of 100 mm. In addition, the deformed re-bars having a series of strain gauges were installed along the sheath of the specimen.

Table 1 lists the parameter of nine specimens used in this study: the compressive strength of the grout (grout strength) and the type of PC-tendon. According to Korenaga and Watanabe (1999), both affect the bond characteristic between tendons and the grout. The age of installing the prestress force was 10 days, and the tendon was cut at 30 days after the casting.

2.2 Residual Stress Ratio

The magnitude of residual stress after cutting the PC tendon was measured by using the gauge arranged on the re-bars. Figure 3 shows the residual stress ratio, which can be calculated by comparing the strain measured before and after cutting the tendon.

Figure 3(a) compares the influence of the grout

Fig. 6 Calculation of residual stress in concrete and strain at PC tendon after cutting the tendon

strength on the residual stress ratio between experimental results of 1-2 and 1-3. The figure indicates that the bond strength between tendons and the grout increased with the increase in the grout strength, and the stress-decreasing region where the ratio indicate less than 1.0 became small.

Figure 3(b): the result of 1-8 and 1-9, shows the influence of the grout strength on the length of stress-decreasing region became large when the PC tendon was a round re-bar. In addition, Fig. 3(c), which compares the result of 1-9 using the round re-bar and 1-3 using strands as for PC tendon, informs that the length of stress-decreasing region also changed strongly depending on the type of

tendons.

Figure 3(d) indicates the PC tendon that consisted of two or more strands increased the length of stress-decreasing region because these strands contacting each other cannot attach to the grout.

2.3 Calculation of Residual Stress

Figure 3 implied that the relationship between the residual stress and the distance from the breaking position of PC tendon showed a linear in the stress-decreasing region. This means that inclination seems to be a linear relationship, so the bond stress was constant in the stress-decreasing region. This study calculated the bond strength with dividing the effective stress by the surface area of the PC tendon.

Based on the experimental results, Fig. 4 plots the bond strength as the function of the grout strength, of which tendency that the bond strength increases as the grout strength increases. This study assumed the relationship can be as a function of grout strength (f_g') by referring to Korenaga and Watanabe (1999).

The phenomenon of this research is the generation of bond force according to the stress releasing of PC tendon, on the other hands, Korenaga and Watanabe (1999) focused on the bond-slip displacement based on the pull-out test of PC tendon from concrete. Even these two phenomena will be different in the point of bond characteristic with grout according to the extension or the shrinkage of PC tendon, this study followed the function form of Korenaga and Watanabe (1999) in the range of this study.

In addition, Fig. 3(d) confirmed that the length of the stress-decreasing region was different between the specimens having one strand wire and two or more strand wires. Therefore, the bond strength of grout and PC tendon was provided respectively as a function of f_g' as Eqs. (1) and (2) according to the number of the strand wire. The calculation by Eqs. (1) and (2) are plotted in Fig. 4 to compare with the experimental results.

$$\tau_1 = 0.55\sqrt{f_g'} : \text{single strand} \tag{1}$$

$$\tau_2 = 0.30\sqrt{f_g'} : \text{malch strands} \tag{2}$$

The bond-slip relationship was expressed as bi-linear based on the bond strength by Eqs. (1) or (2).

Figure 5 shows the pattern diagrams of the strain distribution of concrete and PC tendon after the tendon is broken in the PC beam. The force balance in a certain section: the accumulation of bond force between PC tendon and grout is equals to the decreased force in the tendon in the section, derived the following Eqs. (3) to (6).

$$s_{n-1} = s_n + \left(\varepsilon_{pp} - \frac{\varepsilon_{pn} + \varepsilon_{pn-1}}{2}\right)\Delta x - \left(\varepsilon_{cp} - \frac{\varepsilon_{cn} + \varepsilon_{cn-1}}{2}\right)\Delta x \tag{3}$$

$$\tau_{cn-1} = \frac{E_c\left(\varepsilon_{cn-1} - \varepsilon_{cn}\right)A_c}{\pi D \Delta x} \tag{4}$$

Table 2 Specimen detail

$$\tau_{pn-1} = \frac{E_p(\varepsilon_{pn} - \varepsilon_{pn-1})A_c}{\pi D \Delta x} \quad (5)$$

$$\tau_{cn} = \tau_{pn} \quad (6)$$

The residual stress ratio of the specimen was calculated according to Eqs. (3) to (6), and plotted in Fig.3. Figure 6 indicates the stress-decreasing region based on experiment and calculation results. It confirmed that the calculation value can reproduce the test results. The stress-decreasing region and the magnitude of stress were calculated by the developed bond-slip relationship (t-s) and Eqs. (3) to (6).

3. EVALUATION FOR FLEXURAL LOAD CAPACITY OF INCOMPLETELY-GROUTED PC GIRDERS WITH BROKEN TENDONS

3.1 Bending Test of PC Girders with Broken Tendons

Table 2 lists the parameter of the specimen test and the material used in this study, Fig.7 shows the outline of the specimen. The PC tendon was a single strand (SWPR7BL: 12T12.7) with yield strength (f_{py}) of 1849 N/mm^2, the tensile strength of 2020 N/mm^2, and Young's modulus (E_p) of 194 N/mm^2. The longitudinal re-bar has the nominal diameter of 12.7 mm, the tensile yield strength (f_{sy}) of 370 N/mm^2, and Young's modulus (E_s) of 194 kN/mm^2. Stirrups has the nominal diameter of 15.9 mm, the tensile yield strength (f_{sy}) of 345 N/mm^2, and Young's modulus (E_s) of 194 kN/mm^2.

Steel sheath with the diameter of 65 mm was used. The inside of the sheath were filled by grout (the compressive strength of 34.1 N/mm^2). The bond between PC tendon and the grout had been removed in the range of 1000 mm from one-support of the beam by wrapping the tape around the tendon. Four specimens were prepared: 2-1 with no-broken tendon and 2-2 to 2-4 with 50 to 75 % of tendons being broken. PC tendons in 2-2 and 2-3 were cut before the loading test, and the tendon of 2-4 was gradually cut with applying the load of 620 kN.

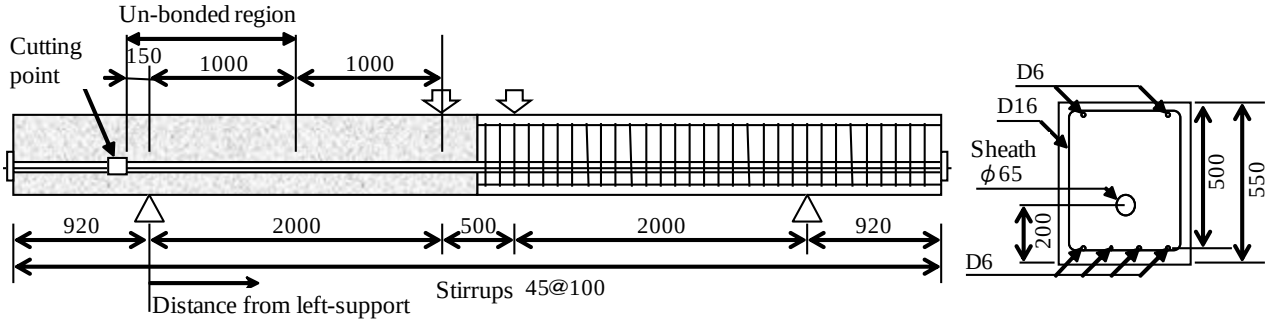

Fig.7 Specimen detail

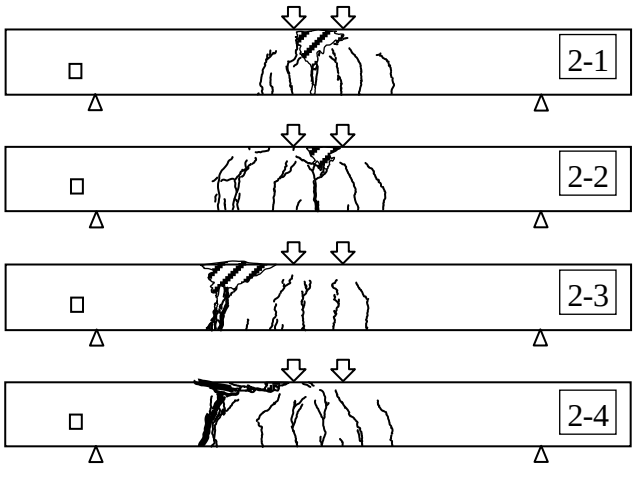

Fig.8 Failed specimens

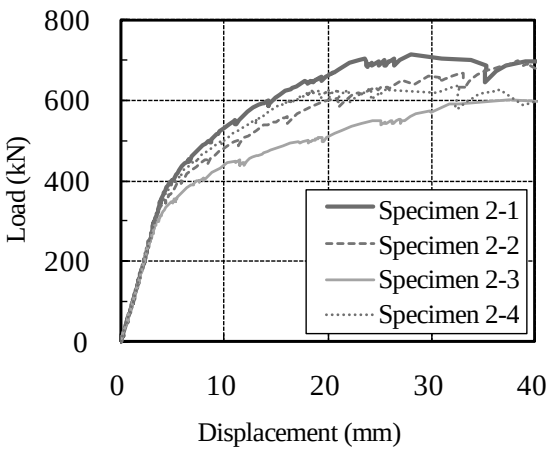

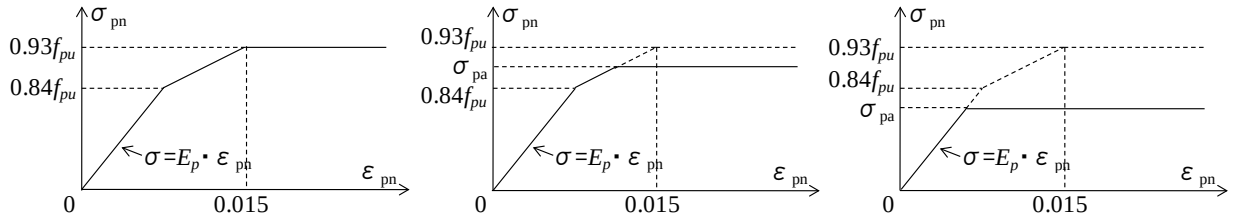

Fig.9 Comparison of load-displacement relationship

where, σ_{pa} : stress in PC tendon when the tendon slips (N/mm^2), $\sigma_{pa}=\tau_1 * \phi * \pi * L_a/A_{pn}$
L_a : Distance between failed cross-section and cutting point of PC tendon. (mm)

Fig. 10 Stress-strain relationship of PC tendon

Figure 8 shows the crack distribution of tested specimens. All specimens were failed in flexural with crashing the concrete at the top-edge. Table 2 summarizes the experiment and calculation results. The flexural crack generated at the load of 252 to 346 kN. The number of the crack increased with the increase in the amount of cutting the PC tendon.

According to the crack distribution of 2-2, some flexural cracks were observed in left side, and concrete at the middle span of specimen was crashed. This crashing position was transferred to the left side: 1300 mm from left support in the specimen 2-3. The number of flexural crack in the left span of 2-4 was increased as the PC tendon cutting, then concrete between 1200 to 1800 mm from left support.

Figure 9 compares the load-displacement relationship of all specimens. The load-carrying capacity and stiffness were depending on the number of tendon. Specimen 2-4 was not able to hold the load 620 kN when 67 % of wires were broken.

3.2 Evaluation of Flexural Load Capacity

The flexural capacity of PC beams with broken tendons was calculated according to the assumption of plane stress remained plane, and the balance force in the section as (RTRI 2004):

$$C' = \int_0^x \sigma'_c(u) \cdot b(u) du \quad (7)$$

$$T_p = \sum A_{pn} \cdot \sigma_{pn} \quad (8)$$

$$T_s = A_s \cdot \sigma_s \quad (9)$$

where, C' : compressive force carried by concrete (kN), T_p : tensile force carried by PC tendon (kN), T_s : tensile force carried by longitudinal re-bars (kN), σ'_c(u): compressive stress carried by concrete at the height (u) from neutral axis (N/mm^2), b(u): width of cross-section at the height (u) from neutral axis (mm), A_{pn}: cross-section area of PC-tendon at n (mm^2), σ_{pn}: stress of PC-tendon at n (N/mm^2), A_s: cross-section area of tensile re-bars (mm^2), and σ_s: tensile stress at centroid of longitudinal re-bars (N/mm^2).

The flexural capacity M_u was calculated by Eqs. (10) to (12) as:

$$N'_d = C' - T_s - T_p \quad (10)$$

$$M_u = C'(d_s - e_s - \beta_x) + T_s \cdot e_s + \sum A_{pn} \cdot \sigma_{pn} \cdot e_{pn} \quad (11)$$

$$\beta_x = x - \frac{\int_0^x \sigma'_c(u) \cdot b(u) \cdot u \cdot du}{C'} \quad (12)$$

where, N'_d: force in longitudinal direction (kN), M_u: maximum moment (kNm), d_s: distance from compressive edge to the centroid of tensile longitudinal bars (mm), e_s: distance between centroids of tensile longitudinal bars and cross-section (mm), e_{pn}: distance between between centroids of PC tendon at n and cross-section (mm), and x: distance between compressive flange and neutral axis (mm).

The tensile force carried by broken PC tendon was calculated by the tensile strain (ε_{pn}) estimated by considering the bond of PC tendon as Fig. 10.

3.3 Verification of Calculations by Comparing with Experimental Results

The flexural capacity of partially prestressed concrete beams was calculated by verifying the balance between the action and the resistance moments in all cross-section of the specimen. The checking position is corresponding to the position of failed cross-section section in the experiment.

Table 2 compares the maximum load capacity in the experiment and the calculation according to section 3.2. Based on the result of 2-4, the load-capacity of the specimen was assumed to be 620 kN when 67 % of the tendon was broken. The calculated results seem to be a similar to the experimental values. The ratios between both were 1.13 to 1.40; that became larger by cutting the PC tendon.

One of the reasons for the experimental values being larger than the calculation was considered as the influence of the moment action on the bond behavior. Even so, the proposed method in this study can evaluate the flexural load capacity of incompletely-grouted PC girders with broken tendons, and enable more reasonable method for repairing and reinforcing the deteriorated PC girders.

4. CONCLUSIONS

The influence of grout strength and a type of PC tendon on the length of stress-decreasing region was examined, and proposed the method for getting the residual stress in PC girders. Finally the method for evaluating the flexural load capacity of incompletely-grouted PC girders with broken tendons was proposed.

This research has been supported by the subsidy from Ministry of Land, Infrastructure, Transport and Tourism.

DEFORMABILITY MODELS FOR SHEAR CRITICAL REINFORCED CONCRETE MEMBERS

Sung-Gul Hong

Professor, Dept of Architecture, Seoul National University, Korea
sglhong@snu.ac.kr

Abstract: This paper presents how to estimate deformability of shear critical reinforced concrete members. This study focuses on ductility of reinforced concrete members which mostly depends on ultimate strain of concrete in compression. For ductile behavior of systems seismic design practices rely on formation of plastic hinge an intended region of flexural members. To guarantee and increase deformability of concrete in compression appropriate reinforcement details for confinement have been focused on. Most design provisions are supposed to suppress premature shear strength dependent on deformation cannot be avoided such as in deep coupling beams and beam-column joints even after flexural yielding for stable energy dissipation. Since most of ductility of limited ductility concepts have been introduced for flexural shear failure of columns and shear strength of walls of low aspect ratios. This study shows the utilization of failure mechanisms of strut-and-tie models for deformability. Crushing of compressive struts and bond strength degradation can be extended to the estimation of deformability of other shear critical members.

1. INTRODUCTION

Structural concrete in disturbed regions (D-regions) is characterized by geometric discontinuities, adjacency to holes, abrupt changes in the cross-section or direction, or statical discontinuities, which are regions near concentrated loads and reactions. Strut-and-tie models (STM) have been successfully used to detail structural concrete in D-regions, as these models illustrate the explicable force flows within D-regions (Marti 1985-1, Marti 1985-2, Muttoni 1997, Schlaich et al. 1987, MaGregor 1988, Schlaich et al. 1991). Inelastic deformations of shear-dominated walls, potential plastic hinges at the bases of columns, and coupling beams in such D-regions are associated with limited ductility and shear strength reduction (Paulay et al. 1992). In practical designs, it has been recommended that the contribution of the concrete to the shear strength is reduced for such shear critical members of limited ductility. Furthermore, when designing the squat wall according to the provision of NZS 3101(Standard Association of New Zealand 1982), the dependable displacement ductility capacity in the squat wall is assumed to be affected by the aspect ratio. However, questions remain as to why most shear transfer members that rely on diagonal struts and/or diagonal compression fields show brittle behavior or limited ductility even after the yielding of longitudinal reinforcements while under-reinforced flexural members show larger ductility.

Many researchers have analyzed the load-deformation curves and deformation capacity of structural concrete in continuity regions using compression field theory or the modified compression field theory in terms of the average stress and strain (Collins 1978, Vecchio 1986). The cracked membrane model (Kaufmann 1998, Kaufmann et al. 1998) further combines the basic concept of the modified compression field theory and the tension chord model that adopts a stepped, rigid-perfectly plastic bond stress-slip relationship to investigate problems related to the deformation capacity of both non-prestressed and prestressed concrete members. Subsequently, the tension chord model (Marti et al. 1998) was attempted to apply, along with the discontinuous stress field in disturbed regions, to determine the rotation capacity of plastic hinge regions and to evaluate the permissible moment redistribution in continuous members. Similarly, the deformation capacity of interior beam-column joints with plastic hinges at beams was proposed by the consideration of change in nodal zones and shear force transfer within joints (Hong et al. 2011-1). For practical reasons, however, the development of a more efficient method is needed to estimate the deformation capacity of structural concrete in a simple and direct manner without recourse to an iterative and incremental analysis using the modified compression field theory or the cracked membrane model.

One of the methods to estimate the deformation capacity of structural systems is a mechanism-based approach which considers admissible geometric configurations at the ultimate state. A mechanism-based approach (Paulay 1998, Paulay 2002) which considers admissible geometric configurations at the ultimate state was developed as a way to estimate the deformation capacity of structural systems (e.g., torsional behavior of asymmetric shear wall systems). The mechanism-based approach is a clear, rational method

for estimating system ductility taking into account the maximum deformation of critical components; that is, the ductility limit of the system depends on given ductility limits of the components of a static system. This study shows how this concept is extended to the estimation of the maximum deformation of structural concrete, which is controlled by the deformation capacity of compression struts, critical components that govern the failure mechanisms (Hong et al. 2011-2).

The objective of this paper is to introduce a simple, clear, and rational model to estimate the deformation capacity of structural concrete in D-regions in terms of direct shear transfer and indirect shear transfer. Failure mechanisms that are compatible with STMs are considered to determine the governing deformation patterns of the struts and bond failure. The proposed model addresses the effects of the aspect ratio, reinforcing degree, and ultimate compressive strain of concrete on the deformation capacity. The proposed model can serve as a deformation estimation tool for the D-regions of limited ductility such as joints, coupling beams and walls that are dominated by shear.

2. FUNDAMENTALS

2.1 Classification of Load Transfer for Shear

Shear force transfer has been explained by direct transfer via diagonal struts and indirect transfer via transverse reinforcement in a beam as shown in **Fig. 1**. In other words, direct transfer by strut action and/or arch action and indirect transfer by truss actions. Arch action relies on compressive strength of concrete and slope of struts while truss action on transverse ties with bond.

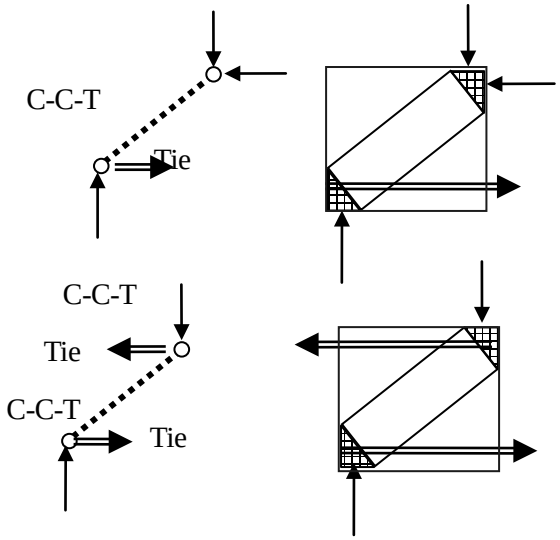

Fig. 1 Direct Shear Transfer

Typical indirect shear transfer can be explained by a uniform or smoothly varying stress fields (B-regions) such as in shallow beams in shear and it has been so-called truss action. The total shear strength relies on diagonal strut and fan or diagonal compression fields. Selection of fan or diagonal compression fields for indirect shear transfers depends on ways of shear acting on boundaries. For a concentrated load the diagonal strut is combined with fans while for distributed shear applied along the boundary the diagonal strut is combined with diagonal compression field as shown in **Fig. 2**. In case of distributed shear along the boundaries the maximum shear strength is developed by sum of diagonal strut action and truss action.

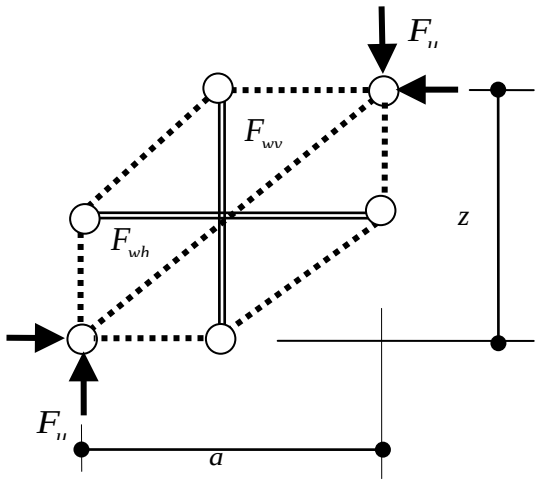

Fig. 2 Indirect Shear Transfer

2.2 Yield Condition and Assumption

The square yield locus with a zero tension cut-off in **Fig. 3** is used for the yield condition for concrete in this study. A reinforcing bar is assumed to resist in the axial direction only, and dowel action is neglected (**Fig. 3**). The effectiveness factors and for reinforcing steel and concrete relate the yield strengths of the idealized plastic material to the properties of the actual material and the factors generally depend on the strain environment.

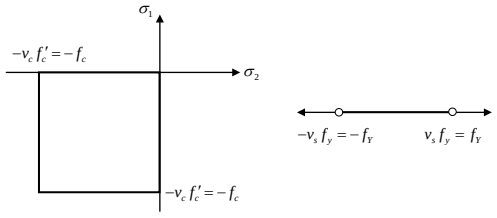

Fig. 3 Yield Conditions for Concrete and Steel

The change in geometry of the structure that occurs at the limit load is assumed to be negligible. The geometric description of the structure due to failure mechanism remains unchanged, so as to allow the formulation of displacement sets based on the original configuration. It is assumed that the displacements induced by the failure mechanisms equal the total deformations of limiting values as indicated in **Fig. 4**.

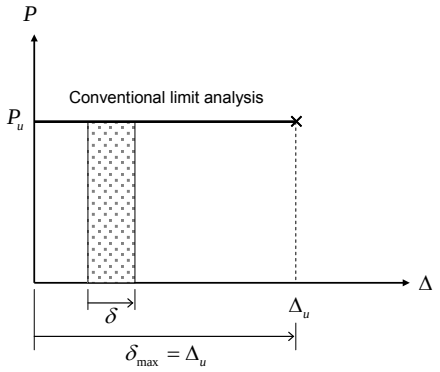

Fig. 4 Rigid-plastic Behavior

3. DEFORMABILITY FOR DIRECT TRANSFER OF SHEAR

3.1 Stress Fields and Failure Mechanisms

In order to understand direct load transfer for shear, consider a simple case where one concentrated force at the top in the right of half of deep beam is supposed to be transferred the support located at the left bottom of beam.

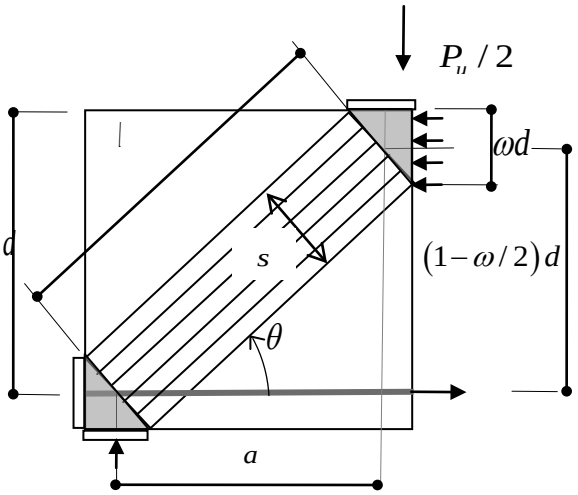

Fig. 5 Stress Field for Half of Simply Supported Deep Beam

The distances between the two points are *z* and *a* in the vertical and horizontal directions, respectively. A simple stress field for half of the deep beam of depth *d* and width *b* under two vertical loads on the top is considered, as shown in **Fig. 5**. The stress field consists of a strut of uniform width, a horizontal tie, and two bi-axially compressed nodal zones at the left loading point and the support. At the ultimate condition, the yielding of the tie provides the width of the strut *s* as

$$s = \omega d / \cos\theta \qquad (1)$$

where ω is defined as the reinforcement degree $(A_s f_Y)/(bdf_c)$, A_s is the sectional area of the longitudinal reinforcement, f_c is the effective compressive strength of the concrete, and θ is the inclination angle of the strut with respect to the horizontal axis.

The selection of possible failure mechanisms for this stress field depends on whether or not the chosen failure mechanism requires the yielding of a horizontal tie. Three well-known failure mechanisms for the crushing of a strut involve bending, translational, and rotational mechanisms involving a hyperbolic failure curve (Marti et al 1982, Ashour et al. 1996). The deformation of each failure mechanism is assumed to be limited by the ultimate compressive strain in the struts.

3.2 Deformation Capacity Models

The bending mechanism in **Fig. 6** involves the elongation of the horizontal tie and the rotation of the strut. The strut is assumed to rotate about the bottom corner of the bi-axially compressed nodal zone at the loading point.

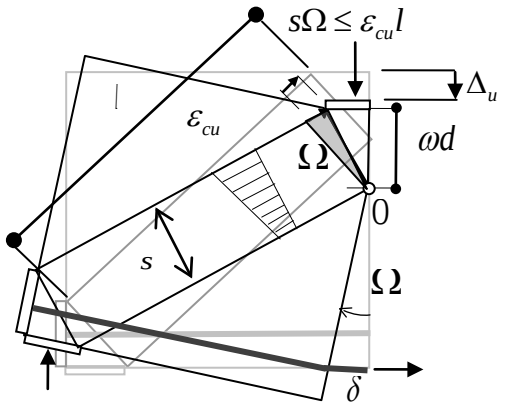

Fig. 6 Bending Mechanism

The deformation limit in this bending mechanism is expressed in terms of mechanical reinforcement ratio, *a/d*, and ultimate compressive strain of concrete.

$$\frac{\Delta_u}{a} \le \left[\frac{1}{\omega}\frac{a}{d} + \frac{(1-\omega/2)}{2}\frac{d}{a}\right]\varepsilon_{cu} \qquad (2)$$

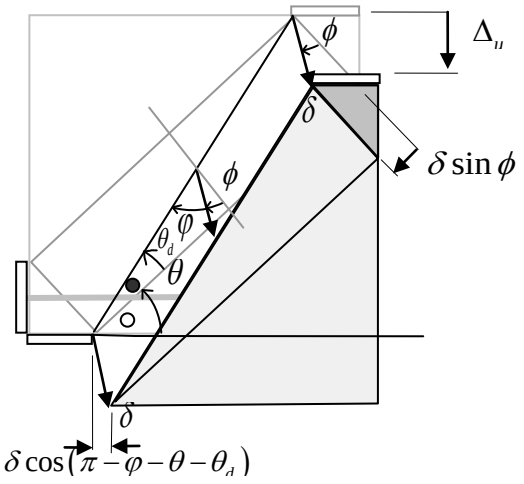

Fig. 7 Translational Mechanism

Next, consider a translational failure mechanism involving the straight diagonal failure crack in the strut as shown in **Fig. 7**. This translational mechanism for the deep beam accompanies the yielding of the horizontal tie depending on whether the horizontal displacement component of the horizontal tie across the diagonal failure crack occurs or not. Since the strut's shortening should be equal to the absolute difference of the movement of its ends, the translational displacement δ along the diagonal in the strut results in the shortening of strut.

$$\frac{\Delta_u}{a} \le \frac{1}{(1-\omega/2)}\left[\frac{a}{d}+\frac{d}{a}(1-\omega/2)^2\right]\varepsilon_{cu} \qquad (3)$$

Finally, consider the so-called hyperbolic failure mechanism, in which failure crack occurs along a hyperbolic curve within a strut as shown in **Fig. 8**. Due to this rotational mechanism, two rigid bodies are separated along a hyperbolic curve passing through two corner points of strut. In this case, the bottom rigid body is assumed to rotate about an instantaneous center of rotation located at any point along the diagonal of the strut. This failure mechanism results in a sliding surface that causes crushing of concrete in the strut.

To describe the hyperbolic curve and the corresponding displacement field, it is convenient to introduce a local *x*-*y* coordinate system with the origin at an instantaneous center of rotation to describe the hyperbolic curve and the corresponding displacement field. The *x*-axis runs parallel to the axis of strut.

This failure mechanism involves non-yielding of the horizontal tie, when the instantaneous center of rotation is located at the intersection point of the diagonal of strut and an extended line of the tie. On the other hand, when the instantaneous center of rotation is located at any other point along the diagonal, the crushing of the strut is combined with the yielding of the horizontal tie because the elongation of the tie due to the mechanism occurs as shown in Fig. 8.

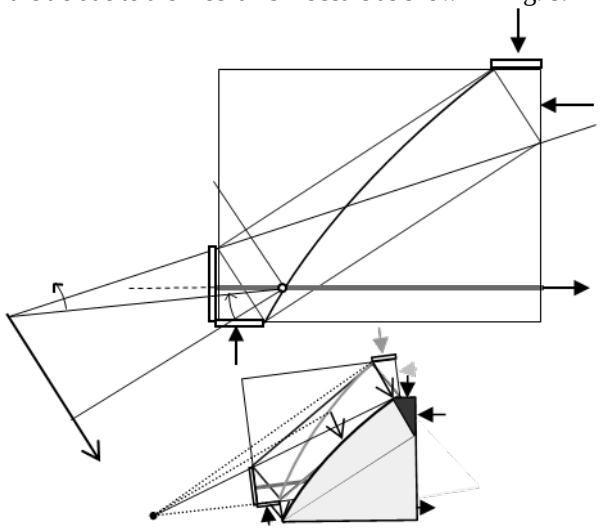

Fig. 8 Rotation Mechanism Involving Hyperbolic Curve

$$\frac{\Delta_u}{a} \le \left(1-\cos^2\theta+\cot\phi_b\sin\theta\cos\theta\right)\frac{1}{\sin\theta\cos\theta}\varepsilon_{cu} \qquad (4)$$

4. DEFORMABILITY OF INDIRECT SHEAR TRANSFER

4.1 Stress Fields and Failure Mechanisms

Shear transfer in a deep beam with stirrups has been treated as indeterminate strut-and-tie models in terms of arch action and truss action which is so called indirect load transfer for shear.

Distribution between arch action and truss action is assumed or can be determined using stiffness ratio, strength ratio, and the energy based methods. For example, the strength ratio gives a possible distribution between direct and indirect load transfer of shear. As **Fig. 2** indicates, the equilibrium conditions at nodes and strengths of vertical and horizontal reinforcement result in the ratio of shear strength by diagonal strut to the total shear strength F_u as

$$\zeta_0 = 1-\frac{F_{wv}}{F_u}-\frac{F_{wh}}{F_u}\frac{z}{a} \qquad (5)$$

where z denotes the arm length of flexural compression to the tension tie and a shear span length. The strength of intermediate vertical and horizontal ties denotes F_v and F_h, respectively.

We may consider two fan-shaped stress fields with diagonal strut for example of indirect load transfer as shown in **Fig. 9**, when the stress fields for combination of direct and indirect load transfer are constructed at onset of yielding of flexural reinforcements or partial loss of bond near the location of the maximum moment. After yielding or partial loss of bond along the longitudinal bar, the load transfer in deep beams begins to change due to the yield penetration or the loss of bond of longitudinal bar so that the stress fields are necessary to be modified.

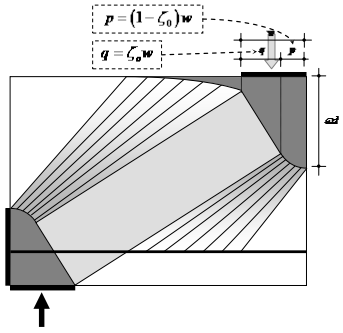

Fig. 9 Stress Field for Indirect Shear Transfer in a Simply Supported Deep Beam

The ultimate state of a STM involving direct transfer and indirect transfer is explained by yielding of one component

of each STM. The yielding of the horizontal tie induces the system to fail in flexural failure mode without yielding of other remaining components. If the yielding of the horizontal tie is combined with the yielding of the shear transfer components such as a diagonal strut and vertical ties, it is called flexural-shear failure.

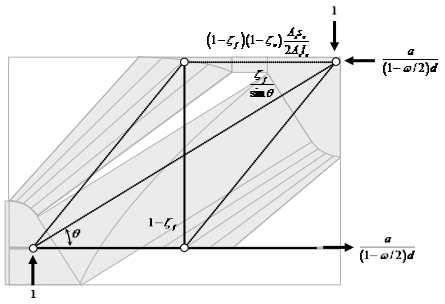

Fig. 10 Stress Field for Indirect Shear Transfer

In the post yield stage a partial yield penetration of longitudinal bars is developed accompanying the loss of bond along the bottom chord. The loss of bond results in no resistance of transverse ties in the segment of yield penetration of the bottom chord. Thereby, it is necessary to modify the initial strut-and-tie model for the maximum shear strength for flexural-shear failure as new one. As a result of the loss of bond along the bottom chord a horizontal strut along the top chord is developed as shown in **Fig.10**. The reduced shear resistance by transverse ties is compensated with diagonal strut.

Among possible failure mechanisms for deformability of limited ductility of a simply supported deep beam, we may select a rotational mechanism involving hyperbolic curve in the diagonal strut as shown in **Fig. 11**. If the center of rotation is selected at the intersection of diagonal with the extended line of longitudinal tie, this mechanism can exclude the extension of longitudinal tie anymore after yielding and consider the partial loss of bond. This failure mechanism enables us to explain the shear failure before or after the flexural failure.

4.2 Deformability Models

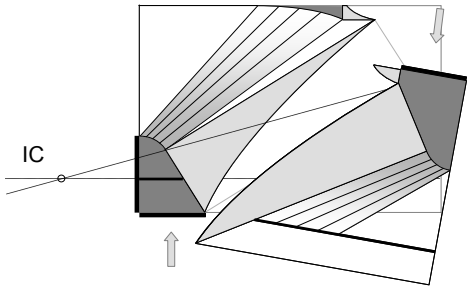

Fig. 11 Possible Failure Mechanism for Indirect Shear Transfer in a Deep Beam

In order to estimate the deformability of the simply supported deep beam with vertical ties, we need to consider possible failure mechanisms as displacement sets. One of displacement sets under the ultimate strength is considered as the rotational mechanism involving a hyperbolic curve as discussed for the deformability of a diagonal strut.

The main components contributing to the estimation of deformability is composed of the rotation of diagonal strut, horizontal strut, and the yielding of vertical tie. The displacement of each component is limited by the maximum rotation angle at which the crushing of diagonal strut is occurred.

For a deep beam with stirrups, the longitudinal reinforcement near the point at which the hyperbolic curve meets does not yield. Thereby, the instantaneous center of rotation is located at the intersection point of extended line of diagonal line GF and the extended line of longitudinal tie as shown in **Fig. 12**. The lower rigid body separated by the hyperbolic curve is assumed to rotate about O by Ω without elongation of longitudinal tie. It is convenience to introduce *x*-*y* coordinate system with the origin at the instantaneous center of rotation. The *x*-axis runs parallel with the direction along the diagonal strut and the *y*-axis is perpendicular to *x*-axis downwards.

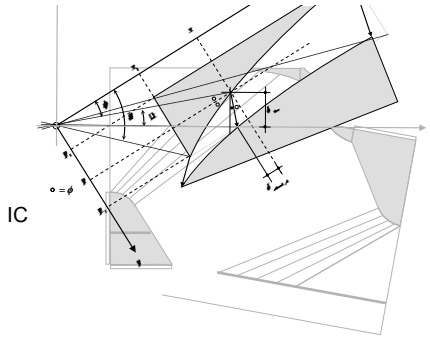

Fig. 12 Displacement Field for Diagonal Strut by Rotational Mechanism involving Hyperbolic Curves

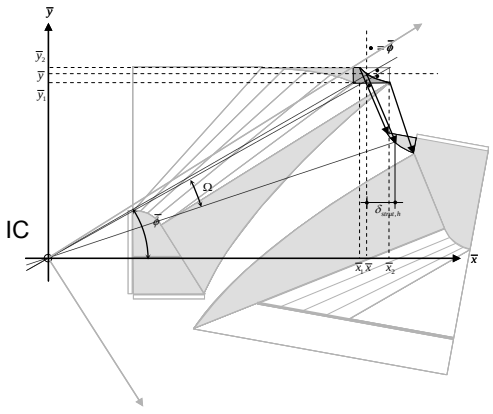

Fig. 13 Description of Displacement Field for Horizontal Strut

The horizontal strut shares the instantaneous center and the maximum rotation angle with the diagonal strut. It is convenience to introduce $\bar{x}$ - $\bar{y}$ coordinate system with the origin at the instantaneous center of rotation. The $\bar{x}$ -axis runs parallel with the direction along the longitudinal tie and the $\bar{y}$ -axis is perpendicular to $\bar{x}$ -axis upwards.

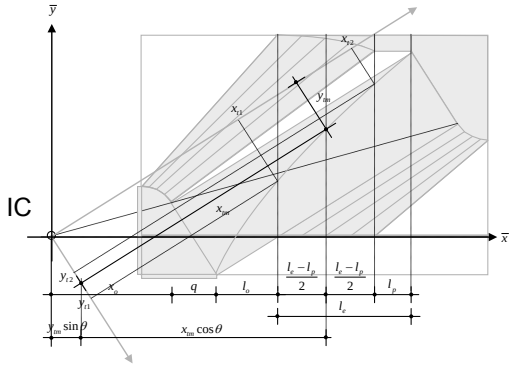

Fig. 14 Displacement Field for Vertical Stirrups

The equilibrium set under unit load and the displacement set by failure mechanism under ultimate load provides the deformability of deep beams with stirrups by virtual works. **Figs. 12**, **13**, and **14** illustrate the displacement set for the horizontal and diagonal struts and vertical ties. Application of the virtual work method for the equilibrium set and the displacement set based on the mechanism results in the deformability l expressed by equation (6) in terms of various parameters such as the length of plastic hinge, span-to-depth ratio, the ratio of flexural reinforcement, and the ratio of shear reinforcement.

$$\Delta_u \le \left(\frac{1}{2}(1-\zeta_o)(1-\zeta_f)\frac{\rho_h}{\rho_v}\frac{d}{l_e},\quad \frac{\zeta_f}{\sin\theta},\quad 1-\zeta_f \right) * \begin{pmatrix} \frac{1}{2}(2d-s) \\ \frac{1}{2}\left(2\frac{x_o}{\sin\phi_o}\sin(\theta-\phi_o)+\frac{r}{\cos\theta} \right) \\ \left(x_o+q+l_o+\frac{1}{2}(l_e-l_p) \right) \end{pmatrix} \Omega_{\max} \quad (6)$$

As the length of plastic hinge, the ratio of flexural and shear reinforcement increase, the ultimate deformation increase. The large shear span-to-depth ratio enlarges the deformability.

The deformability of deep beams with stirrups is mainly affected by the length of plastic hinge and the shear span-to-depth ratio. These are related to the geometry of the stress-fields which determine the width of the diagonal strut. The effects of the ratio of flexural and shear reinforcement is less than the other factors. Hence, the factors closely connected with the depth of diagonal struts influence on the ultimate deformation significantly.

4.2 Deformability of Truss Action

In this section, the deformation capacity models for diagonal compression fields are discussed. Consider a simply supported beam with shear span length *a*, internal lever arm length *jd*, width b_w as show in **Fig. 15**. The angle θ of inclination can be obtained by the energy methods. **Fig. 16** shows the failure mechanism. The maximum displacement is obtained as in Eq. (7).

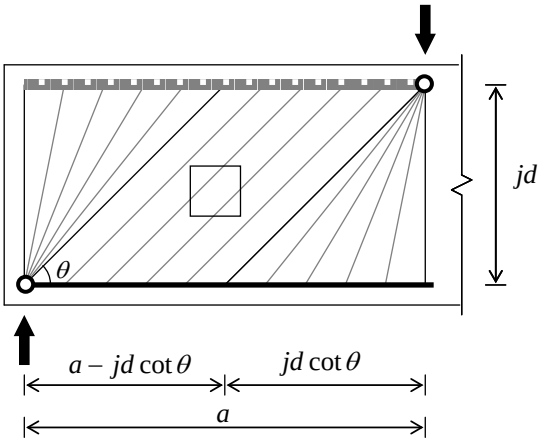

Fig. 15 Diagonal Compression Field between Fans

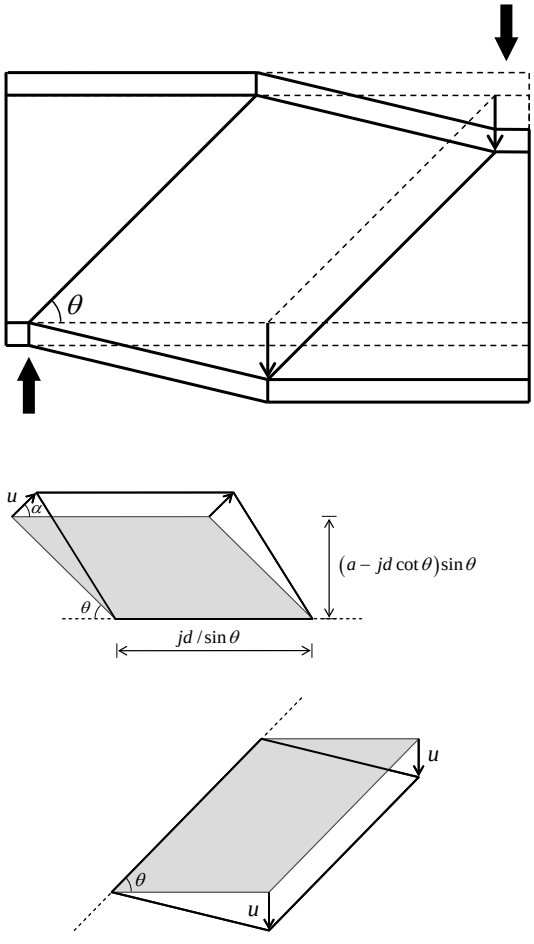

Fig. 15 Displacement Field for Vertical Stirrups

$$\frac{u_{\max}}{a} = -\frac{2}{(1-\cos\theta)}\left(\sin\theta - \cos\theta\frac{jd}{a}\right)\varepsilon_{cu} \qquad (7)$$

5. COUPLING BEAMS

The proposed concepts with along the procedure for a simply supported deep beam may be extended to the case of a coupling beam. After flexural yielding of a coupling beam, we need horizontal struts as in case of a simply supported beam. The dimensions of nodal zones can be determined by the equilibrium and ultimate stress states. The vertical dimension of top nodal zone is described by assuming that compression stresses reach compressive strength of concrete. We may have two different stress fields depending on force distribution along the longitudinal ties. The first one consists of horizontal struts after yield penetration (**Fig. 16**) and the second one is developed by bond along the fans (**Fig. 17**).

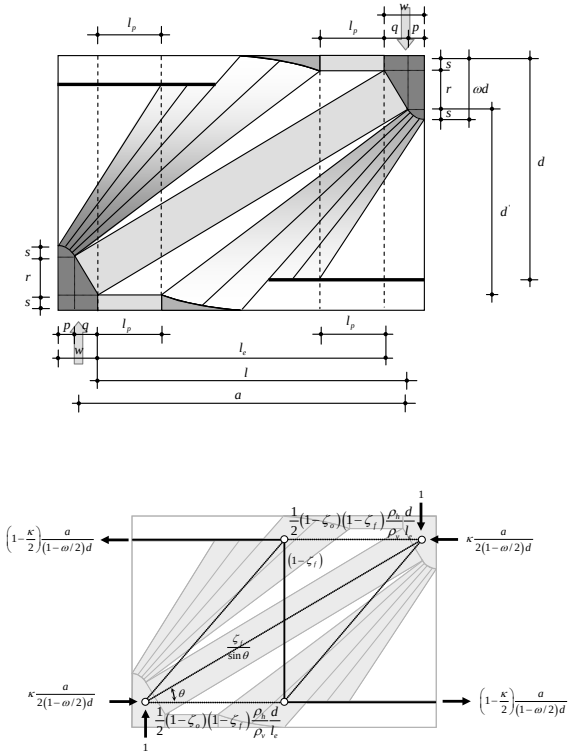

Fig. 16 Stress Field and Equilibrium System under a Unit Load with Yield Penetration along Longitudinal Bar

The stress fields including horizontal struts are considered with translational mechanism (Type I). The stress fields with longitudinal tie along entire length consider the bending mechanism (Type II) and translational mechanism (Type III).

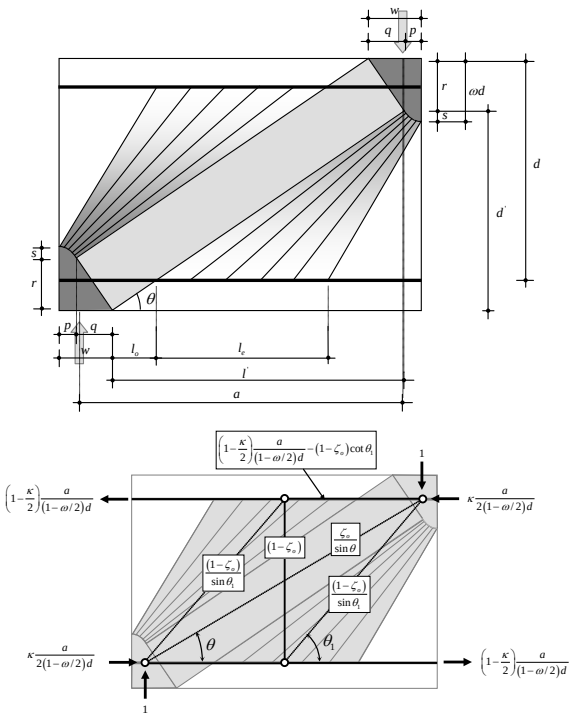

Fig. 17 Stress Field and Equilibrium System under a Unit Load Relying on Bond

5.1 Translational Failure Mechanism involving Horizontal Struts

After the stress fields which take the length of yield penetration into account is constructed, the possible failure mechanisms compatible with stress fields are considered. The stress fields including the horizontal strut and diagonal strut allows the translational failure mechanism as shown in **Fig. 18**. It is associated with the crushing of the horizontal struts in company with diagonal strut and the extension of the vertical ties. The horizontal struts share the displacement vector with the diagonal strut. The direction of displacement vector is defined by the normality rule satisfying in translational mechanism for horizontal and diagonal strut simultaneously.

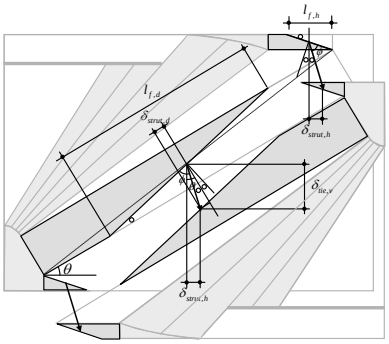

Fig. 18 Translational Mechanism for Coupling Beam with Diagonal and Horizontal Struts

$$\Delta_u \le \left(2\times\frac{1}{2}(1-\zeta_o)(1-\zeta_f)\frac{\rho_h}{\rho_v}\frac{d}{l_e} \quad \frac{\zeta_f}{\sin\theta} \quad 1-\zeta_f \right) * \begin{pmatrix} \sin\left(\theta+\frac{\phi}{2}-\frac{\pi}{4}\right) \\ \sin\left(\frac{\pi}{4}-\frac{\phi}{2}\right) \\ \cos\left(\theta+\frac{\phi}{2}-\frac{\pi}{4}\right) \end{pmatrix} \delta_{\max} \quad (8)$$

Using the same concept, we have the deformability for translational mechanism by Eq (8).

5.2 Translational Failure Mechanism

The fan-shaped stress fields have variable stresses in longitudinal reinforcements. In order to satisfy this stress fields, the diagonal strut must translate in the direction of perpendicular to longitudinal reinforcement. If diagonal strut moves in other direction, the longitudinal reinforcements yield near the strut and have uniform stress in the whole length.

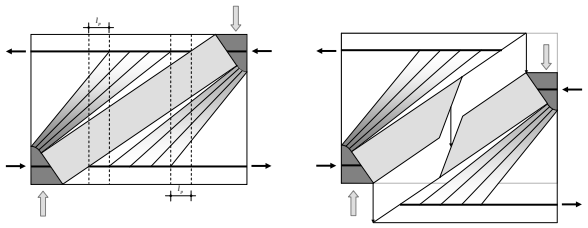

Fig. 19 Translational Mechanism for Coupling Beam with Diagonal Strut

Application of the procedure as discussed to the translational mechanism shown in **Fig. 19** results in

$$\Delta_u \le \left(\frac{\zeta_f}{\sin\theta} \quad 1-\zeta_f \right) \begin{pmatrix} \sin\theta \\ 1 \end{pmatrix} \delta_{\max} \quad (9)$$

where $\delta_{\max} = \frac{r}{\sin^2\theta}\varepsilon_{cu}$

5.3 Bending Failure Mechanism

In bending mechanism as shown in **Fig. 20**, the rotation of diagonal strut about point O by Ω makes the longitudinal reinforcement yield at point A. Bending mechanism consider only the shortening of the diagonal strut and the extension of the longitudinal reinforcement. The limit of deformation according to bending mechanism is determined by the crushing of diagonal strut

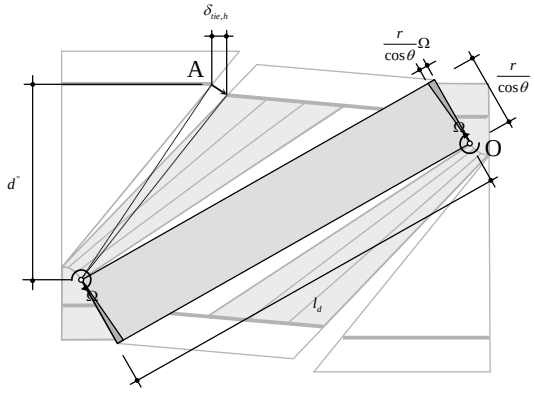

Fig. 20 Bending Mechanism for Coupling Beam with Diagonal Strut

$$\Delta_u \le 2\left(\left(1-\frac{\kappa}{2}\right)\frac{a}{(1-\omega/2)d} \quad \frac{\zeta_f}{\sin\theta}\frac{1}{2}\frac{r}{\cos\theta} \right) * \begin{pmatrix} d-r \\ 1 \end{pmatrix} \Omega_{\max} \quad (10)$$

6. APPLICATIONS

A squat shear wall under the horizontal shear is known as to have limited ductility. To construct shear and-flexural strength model, we need to set up stress fields such as arch action with tension and compression chords for flexure. Pure shear failure mode requires translational failure mechanism in the diagonal strut only while flexural failure mode requires crushing in compression chord with bending mechanism in the diagonal strut.

6.1 Deformability Models for Squat Walls

Consider a squat shear wall under the horizontal shear as shown in **Fig. 21**. To construct shear- flexural interaction curve, we need to set up stress fields such as arch action with tension and compression chords for flexure. Pure shear failure mode is considered as translational failure mechanism in the diagonal strut only and flexural-shear failure mode may be explained by crushing in compression chord with bending mechanism in the diagonal strut.
The deformability of squat wall subject to the horizontal shear is estimated by the translational mechanism. It is assumed that the main diagonal cracking from the top corner to the bottom corner of wall controls deformation capacity of wall in this study.

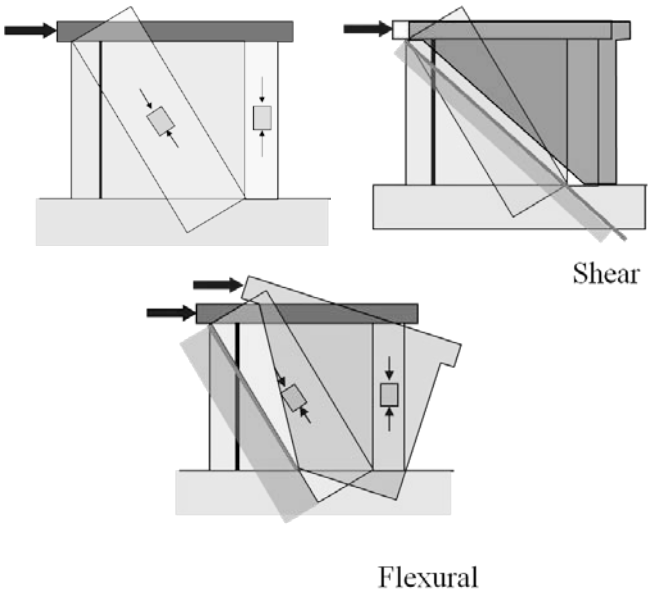

Fig. 21 Failure Mechanisms of Squat Walls

As a result of the horizontal displacement, the compressive strain in compression field of the inclination angle develops the ultimate compressive strain as shown in **Fig. 22**. The maximum displacement is limited by the ultimate strain of concrete in compression.

$$\frac{\Delta\cos(\alpha-\theta)}{\sqrt{l_w^2+h_w^2}} \le \varepsilon_{cu} \tag{11}$$

Based on the deformation models the maximum shear angle of wall is limited by

$$\frac{\Delta}{h_w} \le \frac{\varepsilon_{cu}\sqrt{(l_w/h_w)^2+1}}{\cos(\alpha-\theta)} \tag{12}$$

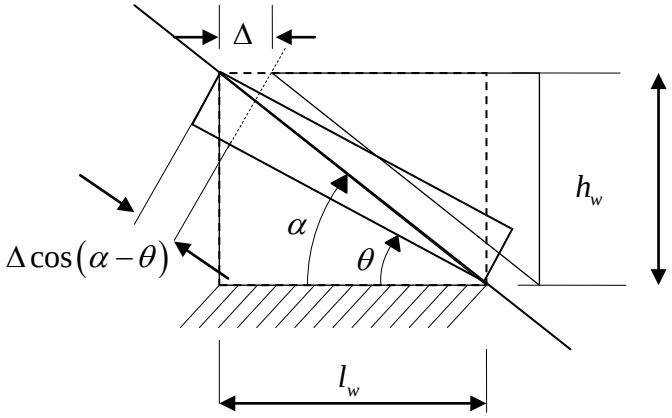

Fig. 22 Deformation Capacity of Squat Wall in Translational Mechanism

Traditionally, strength interaction curves have been constructed by lower bound approach, in which equilibrium conditions and yield conditions for components must be satisfied. Flexural-shear interaction curve for beams needs a truss action in web and relationship between slope angle of diagonal stress field and forces in top and bottom chords.

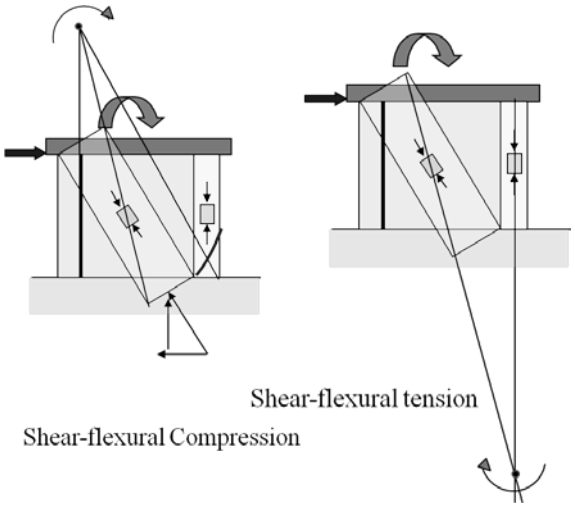

Fig. 23 Shear-flexural failure mechanism by rotational mechanism for diagonal strut

Instead of bending mechanism for the diagonal strut, rotational mechanism for the diagonal strut is applied to shear-flexural compression failure as well as shear-flexural tension. For an equilibrium system and failure mode by failure mechanism, we apply the virtual work method for derivation of interaction curves.

6.2 Deformability Models for Joints

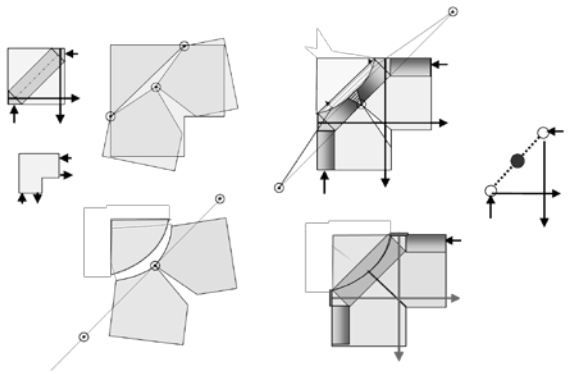

Fig. 24 Deformability of Opening Joint

The concept is extended to estimate the deformation of beam-column joints. Consider an opening joint as shown in **Fig. 24**. If the diagonal crack within the joint controls the ultimate state of the joint, the crushing failure of the diagonal strut is expected. The rotational mechanism involving hyperbolic curves and new flexural type failure mechanism may explain the failure mechanism with estimation of deformation in terms of ration angle of joint.

6.3 Verification

In order to verify the proposed deformability models, experimental data from literature and experimental program were compared with the theoretical results. The experimental data involve those from shear test of simply supported deep beams and coupling beams. The comparison showed good agreement with the calculation using the proposed models. Especially, the deformation limit of shear walls has been explained by the translational mechanism showing 0.6 % drift ratio in case of shear failure mode.

7. CONCLUSIONS

In order to estimate the deformation capacity of a typical structural concrete failure mechanisms compatible with their corresponding STM have been considered on the basis of basic concepts of limit analysis. The bending, translational, and rotational failure mechanisms of struts in crushing failure mode have been investigated as governing deformation patterns of STMs in D-regions. On the basis of this investigation the following main conclusion may be drawn:

1) The proposed models show the deformation capacity depending on whether each failure mechanism involves yielding of longitudinal tie or not. Both the bending and the translational mechanisms with yielding of longitudinal ties show larger deformation capacity than those by the other failure mechanism with non-yielding of longitudinal ties in the range of moderate mechanical reinforcement degree.

2) When deformation limits of struts in failure mechanisms alone are considered to control deformation capacity of structural concrete, the deformation capacity is expressed in terms of shear span to beam depth ratios, reinforcement degree of longitudinal ties and transverse ties, and an ultimate compressive strain of concrete. According to the proposed equation, the deformation capacity is directly proportional to an ultimate or limiting strain of concrete in compression.

3) The proposed model based on STM relying on a diagonal strut alone has predicted smaller deformation capacity than experimental results. Larger deformation capacity due to the web reinforcement is explained by the deformability models for indirect shear transfer.

Abstract: The configuration of a crack in high-strength concrete that has a strength that exceeds 100 N/mm^2 is much smoother than that in normal-strength concrete (under 45 N/mm^2), and results in a loss of shear-transfer ability across the crack. Tests were performed on reinforced concrete (RC) columns having concrete strengths of 40 N/mm^2 to 120 N/mm^2, axial load ratios of 0.1 to 0.28, and shear reinforcement ratios of 0.39% to 0.78% in order to study the influence of crack configuration, axial load, and shear reinforcement upon the hysteresis characteristics of the columns under cyclic shear loading. With an increase in axial load and a decrease in shear reinforcement, the shear slide in a closed smooth crack in high-strength concrete increases, and the solidity as an RC member is compromised. As a result, the hysteresis curves of high-strength concrete columns with higher axial load and less shear reinforcement show an asymmetric response between positive and negative loading as a result of large slippage in a closed shear crack. Finite element method analyses are carried out to examine the effect of the coefficient of friction when closing shear cracks.

1. INTRODUCTION

In recent years, the construction of super-high-rise apartment buildings has proceeded on a large scale in urban areas. As these apartment buildings require a structural rigidity that will resist strong winds and microtremors, as well as a degree of sound insulation to afford living comfort, they are typically built using a reinforced concrete (RC), for economic reasons. Furthermore, the design of the latest super-high-rise apartment buildings also requires that the cross-section of columns be reduced and the spacing among columns be increased to accommodate the idea of free planning to enable the use of the buildings for more than one generation, in addition to providing long-term durability. Therefore, high-strength concrete is absolutely indispensable for the construction of the columns of the lower stories that will support huge axial loads, and it is expected that there will be continuing demands for higher-strength concretes.

Concrete having a strength of more than 60 N/mm^2, which is outside the scope of the calculation criterion and the guidelines in the Architectural Institute of Japan (AIJ) standards, is used for the columns of the lower stories of super-high-rise apartment buildings. However, some problems have been pointed out with regard to the hysteresis characteristics of RC members that use high-strength concrete (Teraoka *et al*. 2003). For example, in the hysteresis characteristics of an ultra-high-strength concrete column, there is a tendency for the shear force under negative loading to be less than the shear force under positive loading. The reason is probably that the solidity (rigidity) of a member is degraded by a slide in a smooth crack surface, although a crack generated under positive loading is closed under negative loading.

We have investigated the shear transfer mechanism of smooth crack surfaces in ultra-high-strength concrete having a compressive strength in excess of 100 N/mm^2 (Hasegawa *et al*. 2004). In addition, we have carried out flexure-shear experiments and analyses of RC members using an ultra-high-strength concrete to study the effect of a smooth crack surface on the shear behavior of an RC member after shear-cracking (Shinohara *et al*. 2007). However, as a flexural yield precedence-type specimen that does not introduce an axial load was adopted, the hysteresis characteristics that destroy the symmetrical response under positive and negative loading could not be reproduced. This asymmetrical hysteresis characteristic is one of the problems of RC members made of ultra-high-strength concrete.

In this paper, a flexure-shear experiment is conducted on shear failure precedence-type RC columns to examine how crack surface behavior and an axial load influence hysteresis characteristics from the occurrence of shear-crack to the maximum shear strength. For this reason, this crack behavior is recorded under positive and negative loading, and we examine the asymmetry of hysteresis characteristics based on crack behavior. Moreover, finite element method (FEM) analysis taking account of the aggregate interlocking and shear friction in a crack surface is conducted, and the coefficient of friction of a smooth crack surface of an RC column that uses high-strength concrete is proposed.

2. OVERVIEW OF EXPERIMENTS

2.1 Details of Test Specimens

The specimen used in this study is about one-fourth the size of an actual column. The specimen configuration and the rebar arrangement are shown in Fig. 1. Common factors are the cross-sectional dimensions (200 mm × 254 mm), the shear-span ratio (1.2) and the main reinforcement (8-D16, σ_y = 1030 N/mm^2). The variable factors are the concrete strengths of two levels (Fc120, Fc30), the axial load ratios of two levels (0.10, 0.28), and the shear reinforcement ratios of two levels (0.39%, 0.78%). Specimen details are shown in Table 1. The specimen designation is expressed by the concrete strength (H, N), the shear reinforcement ratio (%), and the axial load ratio. The shear reinforcement consisted of four bars [four bars (legs) constitute one set of shear reinforcement (see Fig. 1).] (5.0 mm or 7.0 mm in diameter) positioned at intervals of 100 mm. All RC column specimens were designed to reach shear failure before the longitudinal reinforcement yield. For this reason, a high-strength steel reinforcement was used for the main reinforcement, and the ends were welded to an anchor plate. Moreover, additional rebars (D13) were fitted between shear reinforcements to prevent the columns from splitting as a result of bond failure. The stub concrete was widened by 10 mm on the right and left so that the edge of the steel stubs would not damage the specimens. The concrete was laterally poured in the specimen mould. After pouring and curing, the specimen was connected to the steel stubs using high-strength steel bolts embedded in the upper and lower stubs. The mix proportions of the concrete are shown in Table 2. Silica-fume cement is used for the high-strength concrete, and an air-entraining and high-range water-reducing admixture is added to it. Ordinary portland cement and an air-entraining and water-reducing admixture are used for normal-strength concrete. As the interlocking effect of the aggregate in a crack surface is the purpose of our research, the concrete is mixed so that the amount of coarse aggregates in high-strength concrete is the same as that in normal-strength concrete. The coarse aggregate is a land gravel that has a maximum diameter of 25 mm, a specific gravity of 2.61, and a water absorption of 1.1%. For high-strength concrete, the air content was 1.1% to 2.6%, and the slump flow was 50 cm to 63 cm. For normal-strength concrete, the air content was 4.1% to 4.3%, and the slump value was 19 cm to 20 cm.

2.2 Loading and Measuring Method

The loading device used in the experiments is shown in Fig. 2. The lower stub of the specimen was fixed to the loading main frame, and a loading beam was connected to the upper stub. Then, channel steel was attached to the upper stub to restrain any out-of-plane deformation. After introducing a predetermined axial load to the specimen using a 2000 kN hydraulic jack, a constant axial load was maintained using the controller until the completion of the test. Cyclic horizontal loading was applied by controlling 1000 kN and 500 kN hydraulic jacks with a controller so that the upper end of the specimen did not rotate, so that an antisymmetric flexural would occur in the specimen. The horizontal force was decreased when the rotation angle of

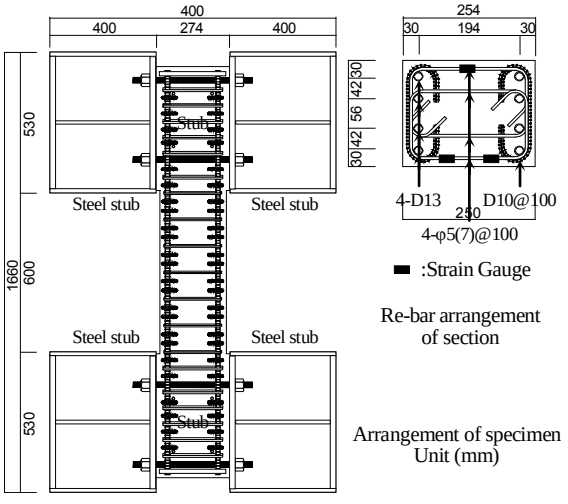

Figure 1 Appearance of specimen and re-bar arrangement

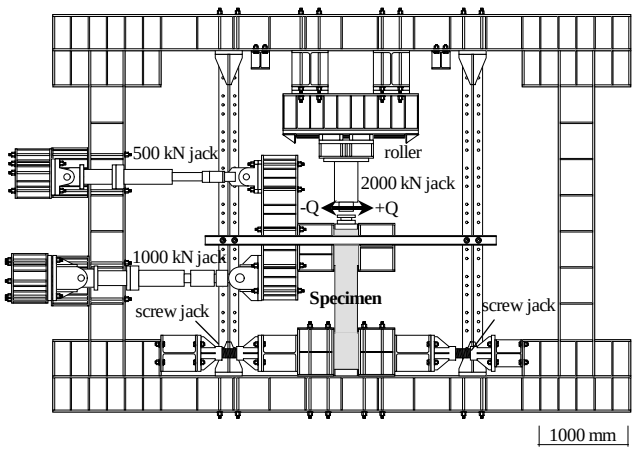

Figure 2 Loading apparatus

the column amounted to ±1/400, ±1/200, ±1/133, ±1/100, and ±1/67, until the peak load was reached. The relative displacement (horizontal and vertical) between the stubs was measured using a displacement-measuring jig attached to the upper and lower concrete stub. Strain on the main reinforcement was measured at the ends of the test section to ascertain the flexural yielding of the main reinforcement. To examine the correspondence to shear-crack behavior, the strain on the shear reinforcement was measured by attaching two strain gauges on the front bar and one gauge on the back bar of all reinforcements.

All shear-crack behavior was measured at peak and unloading in each cycle using a digital microscope with a resolution of 0.01 mm. After shear cracking, the displacements in the direction of depth (x axis) and height (y axis) of a specimen, and the angle (θ) between a shear crack and the x axis were measured at the intersection point of a shear crack and a line drawn every 50 mm symmetrically on the specimen facade (Fig. 3). The crack width, w, perpendicular and the crack sliding, δ, parallel to a crack surface were computed based on the above-mentioned measured value. Measurement of the shear crack was performed at all measuring points up to a rotation angle of R = 1/100 rad., in which crack damage by repeated loading does not influence measurement. For some main cracks, crack behavior in the loading progress was measured in the rotation angle of R = ±1/400 rad., ±1/200 rad., ±1/133 rad., and ±1/100 rad.

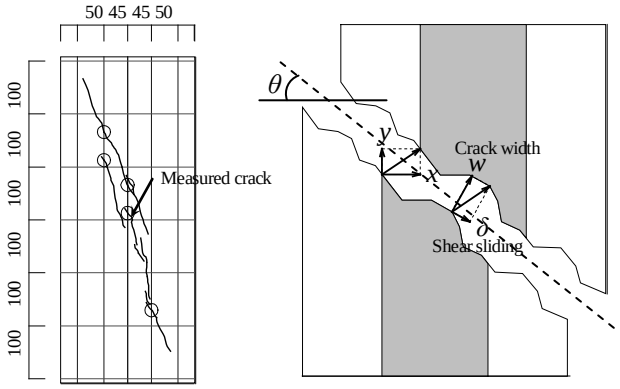

Figure 3 Definitions of crack displacements

3. EXPERIMENTAL RESULTS

3.1 Shear Force and Rotation Angle Curves

Figure 4 shows the shear force Q versus rotation angle R curves obtained from the experiments, where ◊ and ○ indicate the shear-crack strength and ultimate shear strength, respectively. In the case of specimens that use a high-strength shear reinforcement, the reinforcement did not yield to the maximum shear force, but the shear force declined as a result of the collapse of the concrete in the compression zone of a member end. In the case of specimens (HRC-0.39L-0.28 and NRC-0.39L-0.28), which permitted yielding of the shear reinforcement, the shear force declined by widening the shear crack in R = 1/100 cycles after the yielding of a part of the reinforcements (Fig. 4). As none of the main reinforcements yielded until they reached maximum strength, it was judged that all specimens caused shear failure. In the ultra-high-strength concrete specimens (HRC-0.39-0.28 and HRC-0.39L-0.28) that have few shear reinforcements and on which a high axial load acts, the positive and negative hysteresis characteristics differed greatly, and the strength difference increased after shear cracking. The HRC-0.39L-0.28 specimen reached maximum strength under positive loading in the first cycle of R = +1/133, after that, the shear crack occurred in the first cycle of R = −1/133, in the second cycle of R = +1/133, another crack caused by positive loading occurred, which might be derived from the crack generated under the negative loading just imposed. Although the crack strength and the shear

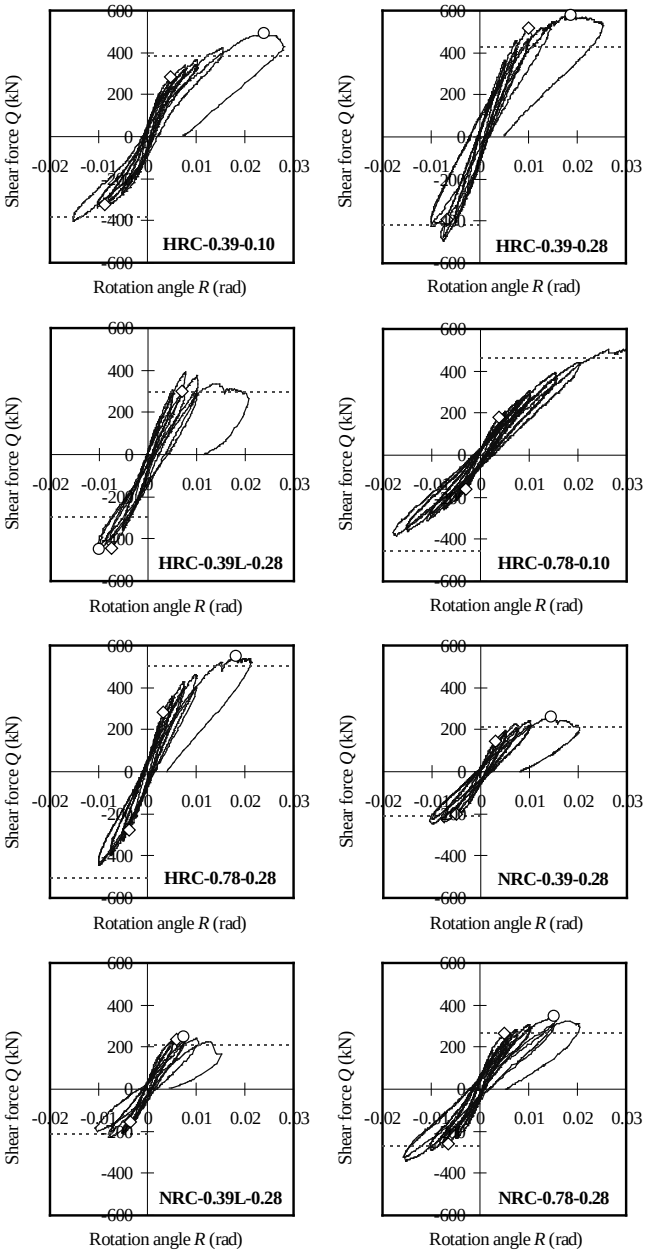

Figure 4 Q-R curves obtained from experiment

stiffness generally showed a tendency to decrease when the ratio of the axial load became low, the crack strength and the shear stiffness of the HRC-0.78-0.10 specimen are smaller than those of the HRC-0.39-0.10 specimen having the same concrete strength and axial load. This seems to be the influence of the crack caused by shrinkage before loading.

The envelope curves of positive loading and negative loading are compared and shown in Fig. 5 for specimens that have a ratio of axial load, a shear reinforcement ratio, and a concrete strength different from the HRC-0.39-0.28 specimen that exhibits asymmetrical hysteresis characteristics after shear cracking under a positive loading. Compared with the HRC-0.39-0.28 specimen in which the strength decreased by a little more than 20% in the negative loading cycle after shear cracking, a strength decrease in the specimens of a low ratio of axial load (HRC-0.39-0.10), a double shear-reinforcement ratio (HRC-0.78-0.28), and a normal concrete strength (NRC-0.39-0.28) is less than 10%. In high-strength concrete, the asymmetry of the hysteresis characteristics appears notably in the HRC-0.39-0.28 specimen that has a high ratio of axial load and low shear-reinforcement ratios. Moreover, comparing the HRC-0.39-0.10 and NRC-0.39-0.28 specimens with approximately the same axial load, the asymmetric hysteresis characteristics appear more clearly in high-strength concrete having a smoother crack surface. This indicates that the axial load, the amount of shear-reinforcement, and the crack surface configuration affect the asymmetry of the hysteresis characteristics of an RC column.

Table 3 shows the shear-crack strength, ultimate shear strength, bond splitting strength, and bending strength obtained from the calculation according to design guidelines (AIJ 1997) and the experiments. Plus and minus in an experimental value indicates positive and negative loading, respectively. The ultimate shear strength by experiment exceeds the calculated value for all the specimens. In the case of the HRC-0.39-0.28 and HRC-0.39L-0.28 specimens, which have high axial loads and few shear reinforcements, the shear crack occurred at a higher shear force than the ultimate strength determined by calculation. For this reason, the shear transferred by the arch mechanism before cracking increased greatly, and the ultimate shear strength by experiment exceeded the calculated value by 40% to 50%.

3.2 Shear Crack Behavior

The crack pattern at the maximum shear load of each specimen is shown in Fig. 6. In the figure, ○ and ◊ show the point that measured the crack under positive loading and negative loading, respectively, while ● indicates a main crack measured at a rotation angle of ±1/400, ±1/200, ±1/133, and ±1/100 in addition to at the peak load and the unloading of each cycle in order to study the progress of crack behavior. In the case of the HRC-0.39-0.28 and HRC-0.39L-0.28 specimens having few shear reinforcements and a high axial load, the shear crack occurred in an instant at a rotation angle of +1/100 under positive loading and at a rotation angle of −1/133 under negative loading, respectively, in the diagonal direction of a specimen with a loud splitting sound. As these two specimens decrease in strength in reverse-direction loading as described in the previous section, there were comparatively few cracks caused by reverse-direction loading, and the shear crack generated first behaved dominantly. Other specimens showed an increase in the number of cracks with an increase in shear force, and the cracks were localized as the amounts of shear reinforcement decreased and as the axial load increased. The average strain distribution of three gauges attached to the shear reinforcements with a close relation to shear-crack width is shown in Fig. 7 (Shinohara, *et al*. 2005). The strain on the reinforcement is large in the mid-height of a specimen not restrained laterally by a stub. If specimens having the same ratio of axial load are compared, the strain decreases and the crack width is controlled as the amount of shear reinforcement increases. Moreover, if specimens with the

same shear reinforcement ratio are compared, the strain increases with an increase in axial load, but as it is related to the shear slide of a crack, this is discussed in the next section. The maximum crack width was less than 1 mm except for the NRC-0.39L-0.28 specimen until a rotation angle of 1/100.

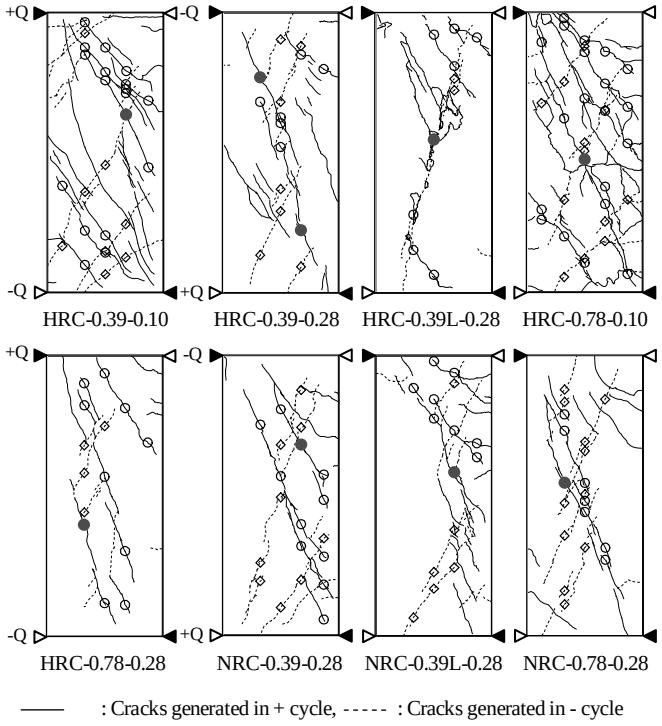

Figure 6 Final crack patterns and measured points

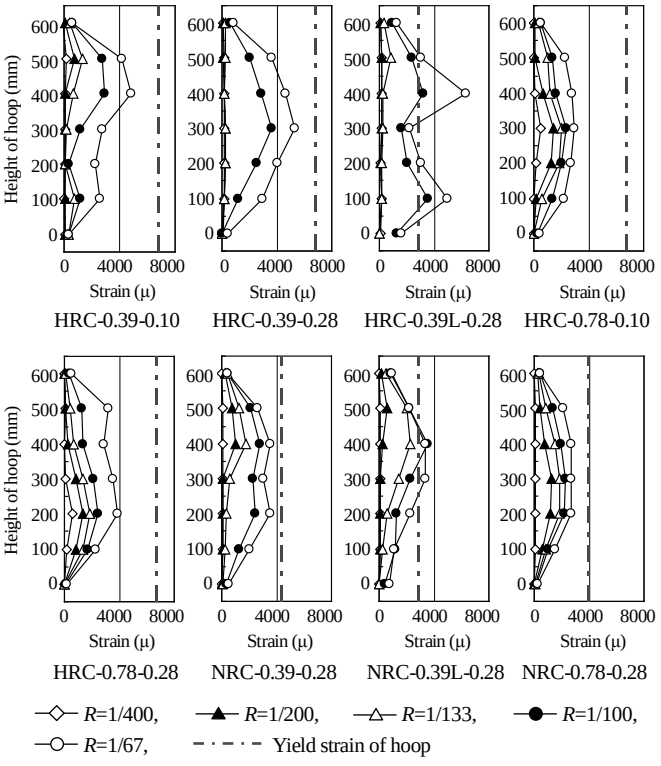

Figure 7 Strain distribution of shear reinforcement

4. SHEAR CRACK BEHAVIOR AND HYSTERESIS CHARACTERISTICS

A crack generated and opened in a certain direction of a loading is closed by a reverse-direction loading. To examine the effect of crack behavior on the hysteresis characteristics of an RC column, each crack is differentiated as an "opening crack" or a "closed crack" in this study. Figure 8 shows the relation between crack width and shear slide from the shear-crack generating until the cycle of R = 1/100 for a high-strength concrete column, where opening cracks are shown on the left and closed cracks on the right. A shear slide is displaced below in a load cycle from a peak to an unloading and a reverse-direction loading, as shown later in Fig. 10. All shear sliding displacements in Fig. 8 are shown by absolute value in order to study the relation between crack width and shear sliding displacement. In the figure, "●" and "×" indicate a shear crack generated under positive and negative loading, respectively. For the opening crack in the experiment on a high-strength concrete member that does not introduce an axial load, both the shear-crack width and the shear slide have been controlled by providing many shear reinforcements (Shinohara *et al*. 2007). When introducing an axial load, if specimens having the same ratio of axial load are compared, the shear-crack width tends to decrease as the amount of shear reinforcements increases, but if specimens having the same amount of shear reinforcements are compared, the crack width decreases as the axial load increases. Generally, if the shear reinforcement is doubled, the strain of reinforcement and the crack width is decreased by half (Shinohara, *et al*. 2009), but in the crack behavior of the HRC-0.78-0.10 specimen and the HRC-0.39-0.10 specimen, even if the amount of shear reinforcements is doubled, the crack width does not decrease as much as in the strain distribution of the shear reinforcement shown in Fig. 7. The reason is probably that the shrinkage crack before loading exerted an influence, as described in the Q-R relation shown in Fig. 5. Most shear slides of an opening crack are 0.2 mm or less, and a significant difference was not seen in a comparison with cases in which the amount of reinforcements was approximately doubled. On the other hand, a shear slide of closed cracks increases as the ratio of axial load increases and the amount of shear reinforcements decreases. In particular, the HRC-0.39-0.28 and HRC-0.39L-0.28 specimens, in which the strength difference of the positive and negative loadings was large, produced a shear slide of 0.6 mm or more at the reverse-direction loading peak. Although the width of an opening crack is small in specimens having a high axial load, the strain of a shear reinforcement is large because of the large amount of sliding in a closed crack. Thus, shear reinforcement functions to control not only shear-crack width but also shear slide (Shinohara, *et al*. 2009).

In the five high-strength concrete specimens and the NRC-0.38-0.28 specimen, the ratio of negative to positive shear force (the first drawing), the maximum shear sliding displacement in a closed crack (the second drawing), and an

axial displacement (the third drawing) are shown in Fig. 9 for the 1st cycle of each rotation angle. A shear sliding displacement is negative when displaced below, and an axial displacement is negative when contracted. Although a variation in the experimental result appears in the small rotation angle before shear cracking, the ratio, −Qp/+Qp, of the shear force of a positive and negative loading tends to

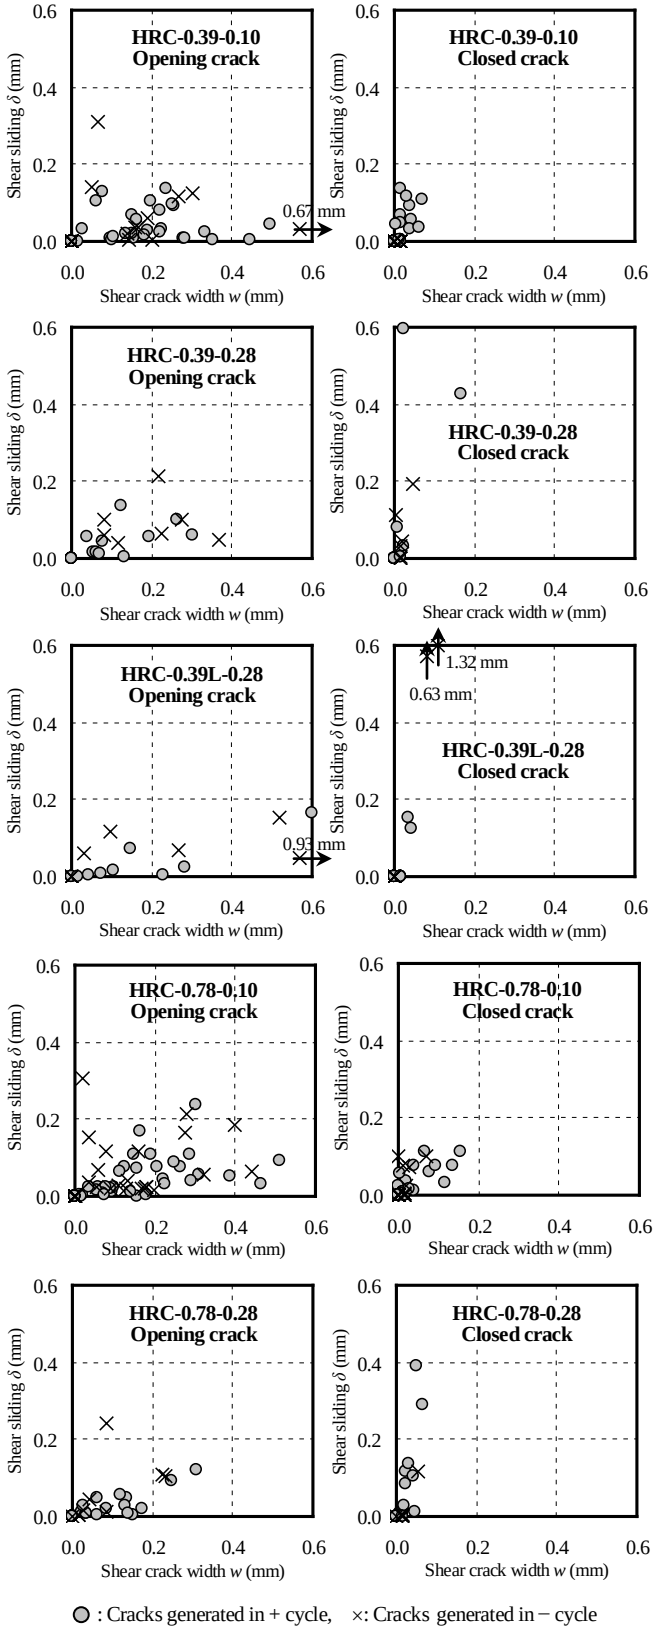

Figure 8 Relation between shear crack width and shear sliding at peak load in each cycle

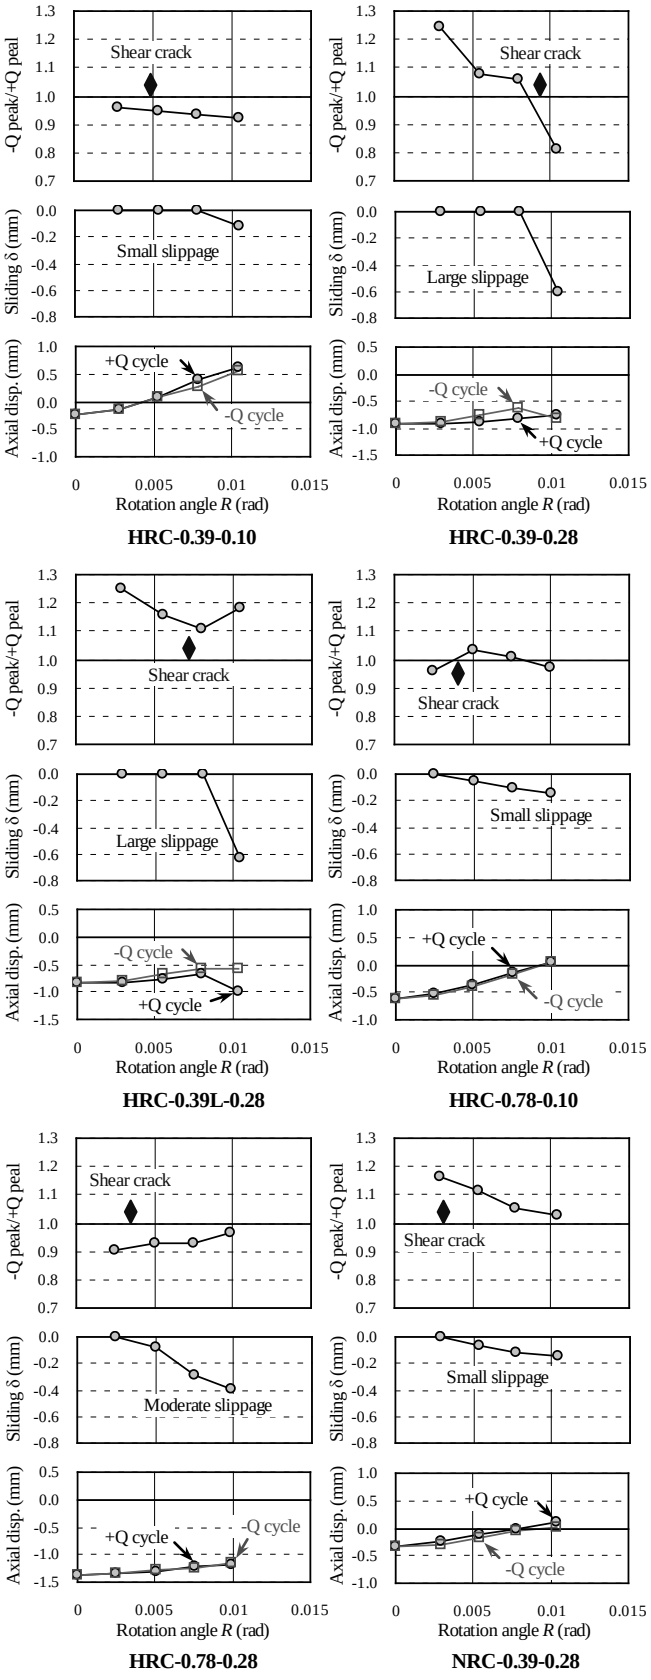

Figure 9 Relation between rotation angle and –Q peak/+Q peak ratio, sliding in shear crack, axial displacement

decrease as the shear slide increases. In the case of the HRC-0.39L-0.28 specimen, as the shear force of the positive loading decreases by sliding in a shear crack generated under negative loading, the ratio of −Qp/+Qp increases after shear cracking. In particular, in the case of the HRC-0.39-0.28 and HRC-0.39L-0.28 specimens showing a significant asymmetry of the skeleton curve, when a crack that is generated with a loud splitting sound closes during reverse-direction loading, the shear slide increases along with axial contraction, and its solidity (rigidity) as a member is degraded. The ratio of the negative to the positive shear force, −Qp/+Qp, changes sharply as a result of the deteriorating shear stiffness of RC members. In contrast to the above-mentioned specimen, a specimen having a small ratio of axial load and/or thicker shear reinforcements has a shear slide of less than 0.2 mm (HRC-0.78-0.28 specimen less than 0.4 mm), the variation of −Qp/+Qp and the axial

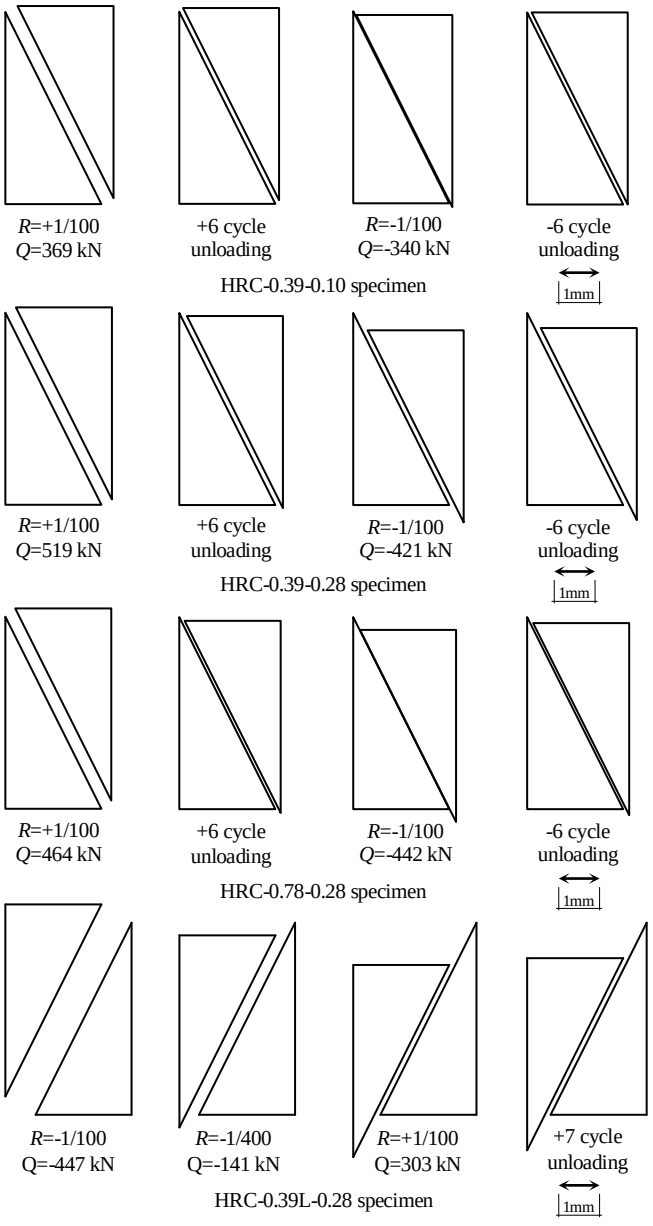

Figure 10 Comparison of crack behaviors between specimens with different axial load and shear reinforcement

contraction after shear cracking reduces, and the hysteresis characteristics under positive and negative loading becomes symmetric. A normal-strength concrete specimen also has symmetrical hysteresis characteristics under positive and negative loading provided the shear reinforcement does not yield.

The crack behavior from the +6 cycle (the first cycle of R = +1/100) to −6 cycle (the first cycle of R = −1/100) in the measuring point (● symbols in Fig. 6) that recorded maximum displacement is expanded and shown in Fig. 10 using the same multiplying factor. However, the crack behavior of the HRC-0.39L-0.28 specimen that the shear crack generated under negative loading is shown from the −6 cycle to the +7 cycle (the second cycle of R = 1/100). Here, "unloading" means Q = 0 kN of each cycle. Although the crack width exceeds 0.3 mm at the peak of R = +1/100 cycles in the HRC-0.39-0.10 specimen, its opening is mostly closed and the shear slide is small during the process of subsequent unloading and negative loading, so that the shear force of the peak load of R = −1/100 cycles is hardly reduced. On the other hand, although the crack behavior at the peak of R = +1/100 cycles in the HRC-0.39-0.28 specimen having a high axial load is almost the same as that of the HRC-0.39-0.10 specimen, the shear slide to the slanting lower part caused by a high axial load during the progress of unloading and negative loading increases substantially. As a result, the shear force of the peak load of R = −1/100 cycles is reduced by 20%, and the majority of shear slides remain even after unloading. Moreover, in the case of the HRC-0.39L-0.28 specimen, as the shear reinforcement yields in part in R = −1/100 cycles (Fig. 7), the crack width approaches 1 mm and the shear slide in subsequent unloading progress also increases remarkably. As the +7 cycle is the second cycle of R = +1/100, the peak shear force declines 30% or more, the residual shear slide exceeds 1 mm, and the solidity as a member is degraded greatly.

5. COEFFICIENT OF FRICTION OF CRACK SURFACE OBTAINED FROM ANALYSIS

To examine the coefficient of friction in the smooth crack surface of an RC column made of high-strength concrete, FEM analysis incorporating the aggregate interlocking and shear friction in a crack surface was carried out. Although the analysis included a stub part, the FEM of a test section only is shown in Fig. 11. The opening crack and closed crack were modeled with an interface element with an X shape, and the Li and Maekawa model (Li *et al.* 1989) and the Coulomb friction model (Chen 1982) were applied to each interface. As splitting of the aggregate was observed in high-strength concrete, the aggregate dimension in an opening-crack model was set to 10 mm. On the other hand, for a closed crack with reference to the friction model applied to high-strength concrete in a previous paper (Shinohara 2007-2), the cohesion was set to 0, the expansion coefficient was set to 0.2, and the coefficient of friction

assumed values from 0.9 (F0.9) to infinity (F∞), which does not permit a shear slide. The concrete was modeled with an isoparametric plane-stress element that has an intermediate node. A trilinear bond-slip relation by the Hayashi model (Hayashi *et al.* 1985) based on an experiment on a member was applied to the bond behavior of the main reinforcement. The shear reinforcement was modeled with a two-node truss element, and the bond was not taken into consideration. As the vertical displacements of the nodes on the upper stub are changed uniformly to restrain rotation, an antisymmetric flexural is obtained as in the experiment. After introducing a predetermined axial load in 10 steps, the shear force was imparted by a compulsive displacement of 0.1 mm increments.

In the analysis, the strengths of high-strength concrete specimens having a low axial load and a high axial load were set to 98 N/mm^2 and 119 N/mm^2, respectively, that of a normal-strength concrete specimen was set to 40 N/mm^2 (see Table 1), and the strength of the cover concrete was reduced to 85%. A Drucker–Prager criterion (Chen 1982) having a 10-degree internal friction angle as a state of plane stress was adopted for the compressive failure of concrete, and linear softening behavior was assumed after maximum strength. The softening slope of the core concrete was set up, in consideration of the confining effect by shear reinforcement, more gently than that of the cover concrete (Fig. 12). Multidirectional crack models having a threshold value of 60 degrees were used for concretes other than the interface of the X shape, and the decrease in shear stiffness accompanying the increase in crack width was taken into consideration (Shinohara *et al*. 1999). The analytical models and mechanical properties of concrete are shown in Fig. 12. The reinforcement was modeled as perfect plasticity without strain hardening after yield strength.

Figure 13 shows the relation of the shear force and rotation angle obtained from the analysis, together with the envelope curve of the positive loading and the negative

Figure 12 Mechanical properties and analytical model

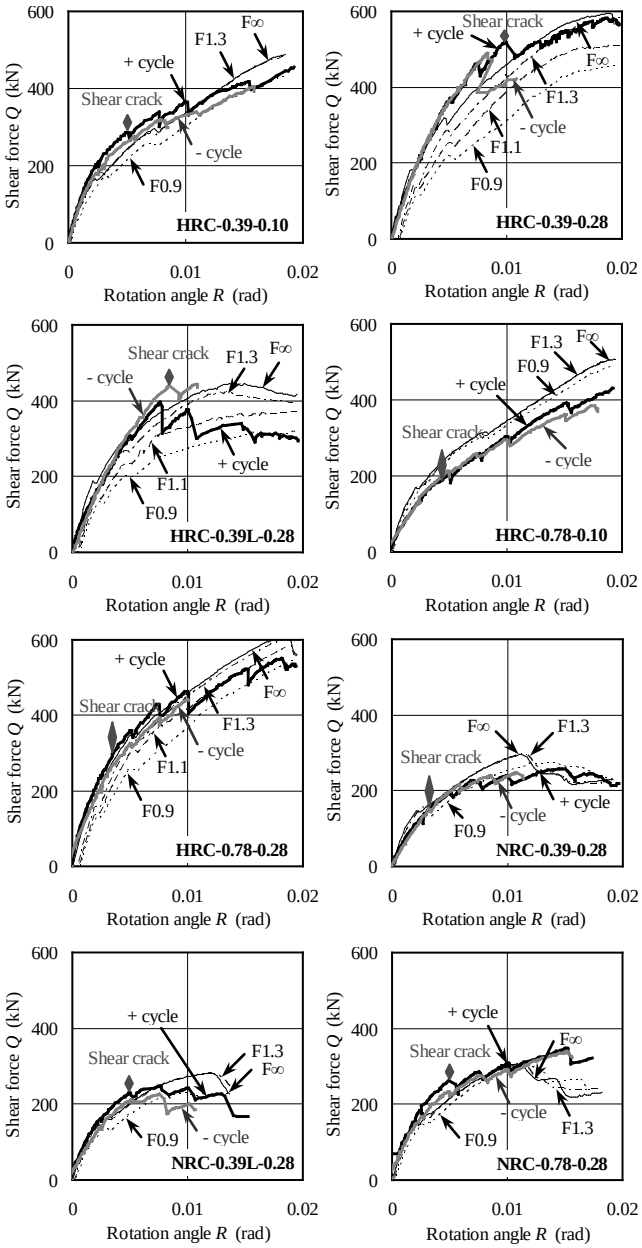

Figure 13 Comparison of Q-R curves obtained experimentally and analytically for different coefficient of friction

loading obtained from the experiment. The analysis of F∞ assumes a case of no shear slide in a closed crack. As shear reinforcement carries the majority of shear forces after shear cracking, and the interlocking effect of an aggregate decreases with an increase of an axial load, as shown in our previous paper (Shinohara *et al*. 2009), the same Li and Maekawa model was applied for all cases. In the experiment, a shear slide is produced in a closed-crack surface in reverse-direction loading after cracking (Figs. 8–10), and rigidity is reduced. On the other hand, in an analysis, as a crack interface is incorporated from the 1st stage, a shear slide grows in a friction interface during the axial-load introduction stage, the shear slide increases further in a subsequent shear loading progress, and rigidity is reduced. In the experiments, the envelope curve under positive and negative loading is almost the same until a shear crack occurs, and the analytical result of F∞, which does not permit the shear slide of a friction surface, exhibits behavior similar to the experimental result. As for a specimen with a high axial load and few shear reinforcements, the shear stiffness decreases after shear cracking in the experiment, and similarly, the effect of the coefficient of friction is remarkable also in the analysis. Especially, the shear stiffness of the HRC-0.39-0.28 and HRC-0.39L-0.28 specimens decreases greatly after shear cracking, and approaches the analysis result for coefficients of friction of 0.9 and 1.1, respectively. For high-strength concrete specimens having a small axial load and normal-strength concrete specimens, a distinct difference in the envelope curve under positive and negative loading was not seen in the experiment, even after shear cracking. Consequently, the effect of the coefficient of friction is negligible also in the analyses. The axial load introduced to these specimens is 500 kN to 600 kN, and is about one-third that of high-strength concrete columns having a ratio of axial load of 0.28. Moreover, although in the NRC-0.39L-0.28 specimen made of normal-strength concrete the shear-crack width exceeded 1 mm after the yield of shear reinforcement, the shear slide of the crack surface increased, and the shear force decreased in a negative loading. From the above, the shear slide of the closed crack related to the solidity of a member is greatly influenced by the amount of axial load and the yield of shear reinforcement. In addition, if the axial load increases and the amount of shear reinforcements decreases, it can be seen that the effect of the crack surface configuration (coefficient of friction) becomes remarkable.

In the case of the HRC-0.39L-0.28 specimen in which a shear crack occurs under negative loading and a large shear slide is produced under positive loading, the deformations after introducing the axial load, at a rotation angle of R = 1/300, R = 1/150, and R = 1/100 are expanded 30 times, as is shown in Fig. 14. In the case of a coefficient of friction of F∞, the shear slide was not produced in the friction surface, but the opening of an opening crack increased with the shear loading, and, in particular, it increased rapidly between R = 1/150 and R = 1/100 when the shear reinforcement yielded. If the coefficient of friction is reduced, the shear slide in a closed crack and the axial contraction increase, and the crack width of an opening crack decreases, that is, the phenomenon seen in the experiment reappears in the analysis.

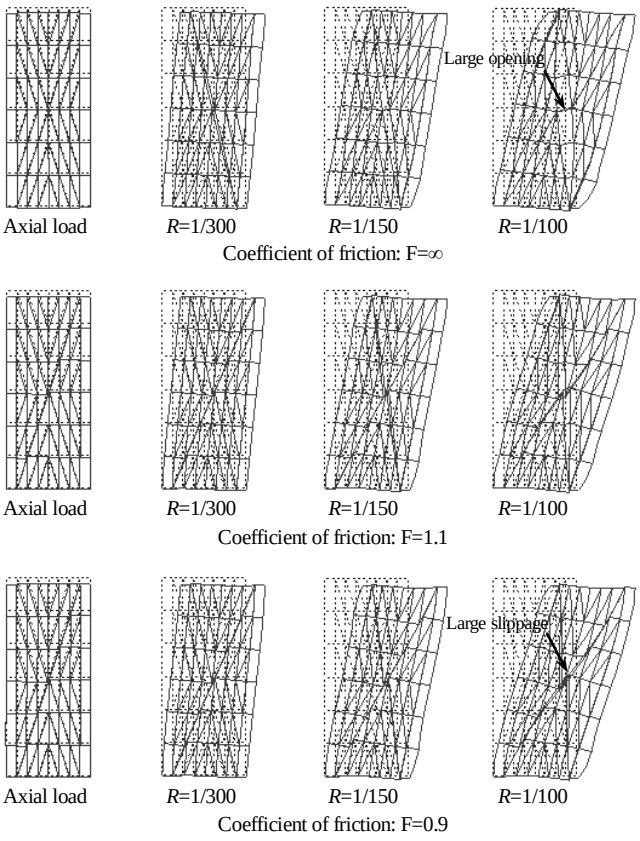

Figure 14 Comparison of transformation for HRC-0.39L-0.28 with different coefficient of friction

6. CONCLUSIONS

A flexure-shear experiment was conducted and the effect of the crack surface configuration, axial load, and shear reinforcement on the hysteresis characteristics of high-strength RC columns was studied. Furthermore, FEM analysis in consideration of shear friction was conducted, and the coefficient of friction of a smooth crack surface was examined. The main conclusions are as follows:

1) The asymmetry of the hysteresis characteristics of a high-strength concrete column originates in an increasing slide in a smooth crack surface closed by a reverse loading.
2) If the shear force currently carried in the concrete can be transmitted by shear reinforcement after shear cracking, an opening crack will have little influence on the hysteresis characteristics.
3) Although shear slide in a closed crack increases with an increase in axial load and with a decrease in the roughness of a crack surface, it can be controlled by proving a large amount of shear reinforcements.
4) The strain of shear reinforcement increases with the increase in crack width and/or a shear slide. Thus, the

shear reinforcement functions to control not only the shear-crack width but also shear slide.

5) In the case of a specimen that has a high axial load and a small amount of shear reinforcements, the shear slide of a closed crack is greatly dependent on the coefficient of friction, and the coefficient of friction of the crack surface of high-strength concrete is 0.9 to 1.1 according to the analytical results.

Abstract: Seismic performance capacity of a real in service building structure may differ from what it was expected in its design stage because of damage accumulation from long term withstanding to service loads, previous earthquakes or degeneration in material properties caused by serious environment. In view that for most commonly used material models cumulated damage in a structure can only be measured by residual strain, a two step pushover analysis procedure has been proposed herein. First response analysis of the structure to a cyclic loading of certain intensity was performed, and then a static pushover analysis was carried out in consequence with residual strain taken into account, which represents the damage accumulation in structures caused by previous loading history. A number of numerical examples are presented. It is shown that structures constructed in different time or designed according to different standard may suffer from cumulated damage in an obvious different manner. It seems that buildings designed following old version standard are more sensitive to cumulated damage.

1. INTRODUCTION

Recent earthquakes have shown that research in earthquake engineering has to be focused on the assessment of vulnerability of existing constructions. It is not only for their lacking appropriate seismic resisting characteristics but also for their capacity degeneration due to long term withstanding to service loads, serious environment or previous earthquakes (Rizzano and Tolone 2009, Ou and Wu 1993 and 1994). In fact, older buildings, designed and constructed before 1990's, without considering earthquake provisions, constitute a significant hazard in 2008 Sichuan earthquake (Wang 2008).

The structure's ability to survive an earthquake may be measured in terms of the expected state of damage of the structure after the earthquake. There are several ways to define the damage state of the structure. Empirical and theoretical approaches have been applied to yield various estimates of structural damage. The empirical damage models are based on statistics of observed structural damage following earthquakes and thus may be subjective. They provide useful qualitative information on the overall seismic performance of structural system. However, the empirical evaluation does not lend itself well to rationally prediction the strength reserve and response characteristics of a structure with a specified degree of damage. The analytical damage models may involve various degrees of complexity as they account for the characteristics of the structure and its seismic response. They can be generally divided into two classes: (1) strength-based damage indices; and (2) response-based damage indices. Strength-based damage indices are simple and do not require response analysis. However, it must be calibrated against observed damage using a large database. If field observations of damaged structures due to seismic loads are not available, the damage index may be calibrated based on damage prediction using nonlinear dynamic analysis.

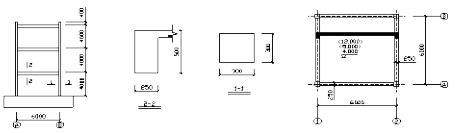
The seismic performance of structures is commonly related to the capacity to undergo inelastic deformations, defined as the ratio of peak inelastic response to the corresponding yield response or ductility. Experimental studies show that failure of brittle systems is caused by excessive deformation while failure of ideal ductile systems is initiated by repeated inelastic deformations. The problem is that for existing building damages are usually already undertaken in someway and to a certain extent. Seismic performance capacity of a real in service building structure must take this into account. Ghobarah et al. (1999), after an extensive reviewing and evaluating the available response-based damage models, proposed a new approach for damage assessment of structures. The approach is to perform pushover analysis for the structure twice; once before subjecting the structure to the earthquake and once after subjecting the structure to the ground motion. Before performing the second pushover analysis, the structure is returned to the unloaded static state. It is believed that the difference in initial stiffness before and after subjecting the structure to an earthquake shows damage accumulation. In view that for most commonly used material models cumulated damage in a structure can only be measured by

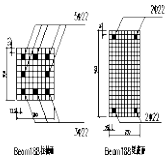
residual strain, the full dynamic response analysis can be replaced by a cyclic loading procedure for computational efficiency.

In this context, the two-step pushover analysis procedure has been proposed. First response analysis of the structure to a cyclic loading of certain intensity was performed, and then a static pushover analysis was carried out in consequence with residual strain taken into account, which represents the damage accumulation in structures caused by previous loading history. A number of numerical examples are presented. It is shown that structures constructed in different time or designed according to different standard may suffer from cumulated damage in an obvious different manner. It seems that buildings designed following old version standard are more sensitive to cumulated damage.

2. STRUCTURAL DETAILS OF THE BUILDING AND FE MODELING

As examples, the damage analysis is performed for a simple low-rise three story concrete frame building with different reinforcement, named as Frame A, B and C, as shown in Figure 1. Frame A is designed according to GB50011-2010, the current code, Frame B according to earlier code GBJ11-89, while Frame C without any reinforcement, which may represent a serious rusty in steel





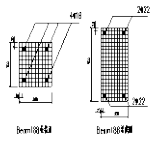


Figure 1 Dimensions of the Three-Story Frame Building

reinforcement. Section dimensions for the columns and beams and the reinforcement are also shown in Figure 1

Cyclic loading

Figure 3 Loading Pattern in Two-Step Pushover Analysis

A finite element model for the frame has been established by using ANSYS package, in which concrete beams and columns were modeled by elements with fiber-like section discretization, as shown in Figure 2. The elasto-plastic material model with bilinear isotropic hardening is adopted.

The loading program is designed as that: before pushover analysis, two cyclic loading with specified intensity was applied to the structure first, as shown in Figure 3. The intensity of the cyclic loading depends on target design base shear. The design base shear for the frame at different earthquake intensity is list in Table 1.

Table 1 Design Base Shear (kN)

Modal No.	Frame A	Frame B	Frame C
Frequent, intensity Ⅷ	71	70	68
Rare, intensity Ⅶ	196	189	174
Rare, intensity Ⅷ	389	372	344

3. NUMERICAL RESULTS

3.1 Results of Modal Analysis

The first six vibration modes were computed and modal frequencies are listed in Table 2. There are slight differences in modal frequencies for the three frames because of difference in reinforcement.

Table 2 Modal Frequencies (Hz)

Modal No.	Frame A	Frame B	Frame C
1	1.24	1.19	1.08
2	1.24	1.19	1.08
3	1.75	1.69	1.55
4	3.71	3.54	3.24
5	3.71	3.54	3.24
6	5.27	5.04	4.63

3.2 Pushover Analysis

First, a conventional pushover analysis was conducted using an inverted triangular load. The base shear-displacement curves at top floor are shown in Figure 4. It can seen that initial slops of the base shear-top deflection of the three frames are almost the same while ultimate loading capacities are 616kN, 397kN and 179kN for Frame A, B and C, respectively.

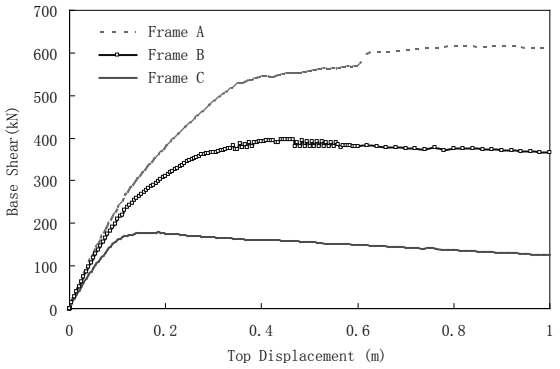

Figure 4 Base shear-displacement curves

3.3 Pushover Analysis to Frames with cumulated damage

Then, the two-step pushover analysis was carried out. In this analysis, response analysis of the structure to a cyclic loading with base shear intensity of three levels listed in Table 1 was performed first. And then, a static pushover analysis was conducted in consequence with residual strain taken into account, which represents the damage accumulation in structures caused by previous cyclic loading.

Numerical results are given in Figure 5, 6 and 7 for Frame A, B and C, respectively. It can be seen that structures with damage accumulation will exhibit an obvious initial slop decrease in response curves. Structure designed following old version standard that is Frame B, seems more sensitive to cumulated damage. For Frame C, the structure without any reinforcement or a structure with its steel reinforcement in serious rusty, it may even crash in the first cyclic loading step of high intensity.

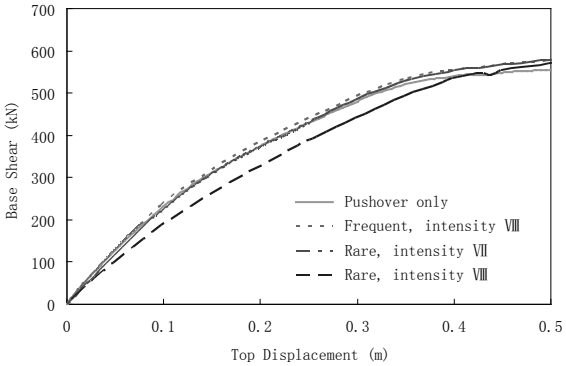

Figure 5 Pushover analyses with different level of damage accumulation for Frame A

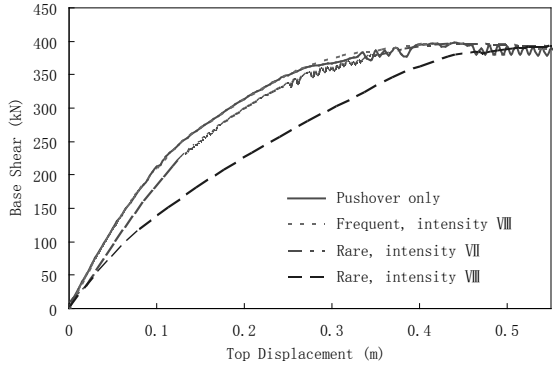

Figure 6 Pushover analyses with different level of damage accumulation for Frame B

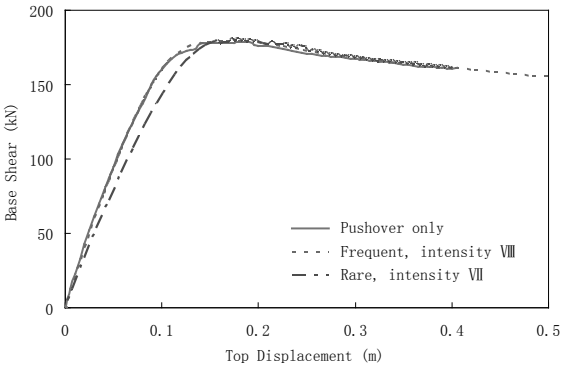

Figure 7 Pushover analyses with different level of damage accumulation for Frame C

4. CONCLUSIONS

A simplified numerical approach to cumulated damage effects on seismic performance of existing RC frame structures has been proposed. It is a two-step pushover analysis procedure. Response analysis of the structure to a cyclic loading of certain intensity was first performed to produce designed damage in the structure, and then a static pushover analysis was carried out in consequence with residual strain taken into account. Numerical examples show that structures constructed in different time or designed

according to different standard may suffer from cumulated damage in an obvious different manner. It seems that buildings designed following old version standard are more sensitive to cumulated damage.

Abstract: Vertical post-tensioning has been proposed as a cost effective technique to improve concrete shear wall performance by improving shear resistance and minimizing residual deformations following large earthquakes. Monotonic loading response of finite element models for precast concrete reinforced walls are compared to published test data, showing good agreement.

1. INTRODUCTION

Reinforced concrete walls are effective lateral systems for seismic design in buildings. However concrete walls have potential problems for severe cracking and residual deformations from extreme earthquakes that are difficult and costly to repair. Vertical post-tensioning has been proposed as a cost effective technique to improve concrete shear wall performance by improving shear resistance and minimizing residual deformations following large earthquakes.

While the basic principles of vertical post-tensioning are straightforward, details of the shear wall response, including the interaction of flexure and shear and self-centering characteristics are not well understood.

We have analyzed conventional wall and post-tensioned concrete wall to evaluate these ultimate flexural moments and residual drift angles. And we have verified our modeling method and analyses[1].

This paper examines the behavior of post-tensioned precast concrete walls through detailed finite element modeling. Monotonic loading response of finite element models for precast concrete reinforced walls is compared to published test data.

2. FE ANALYSIS

2.1 Specimen in published test data

Figures 1 and 2 show the specimen in published data[2]. The specimen consists of precast concrete wall and foundation. The wall has a total height of 3,658mm, total length of 2,438mm and a thickness of 158.8mm. Four #6 bars and two 13mm unbounded tendons are located in the center of the wall. The concrete at the wall toe are confined by hoop of #3 and reinforced by wire mesh.

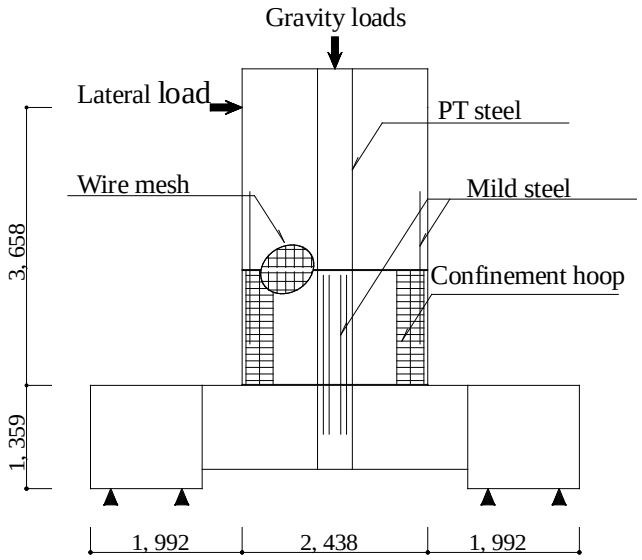

Figure 1 Specimen (unit : mm)

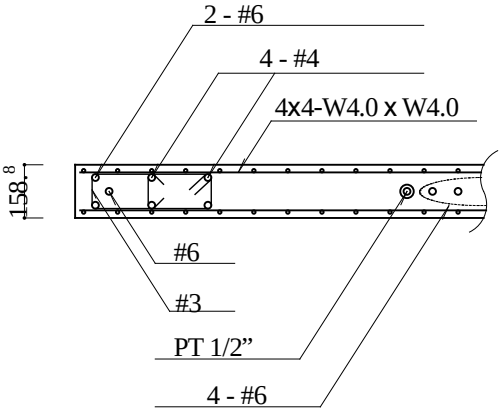

Figure 2 Section of wall (unit : mm)

Table 1 Property of material

	Steel grade		Measured area(mm^2)	Perimeter(mm)	Measured yeild strength(N/mm^2)
#3	ASTM A706 STEEL	Grade60	71	30	517
#4			129	40	517
#6			284	60	445
PT 1/2"	ASTM A 416-06	Grade270	96.1		1675
WIRE MESH	4x4-W4.0xW4.0	Grade60	254mm^2/m		420

Concrete Strength 33N/mm^2

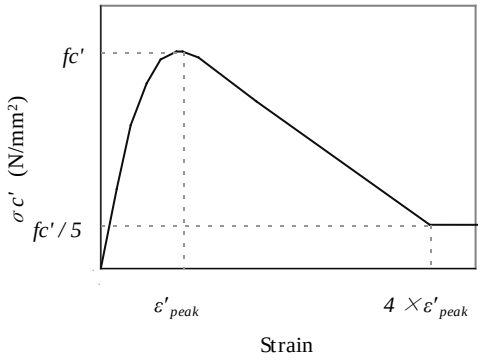

Figure 3 Compressive stress – stress history (concrete)

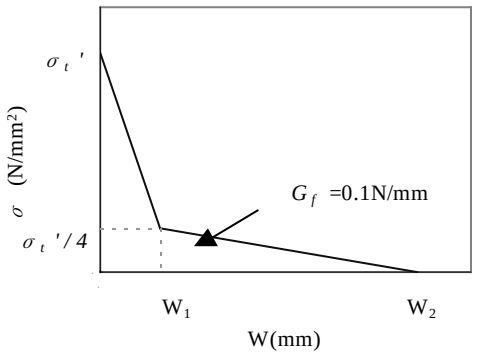

Figure 4 Tensile stress – crack width history

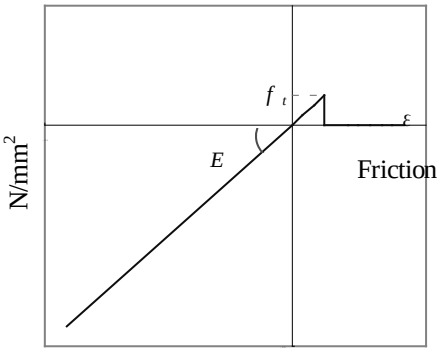

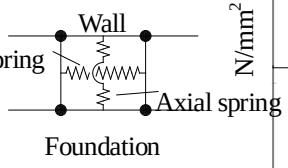

Figure 5 Axial stress – strain history at the concrete joint

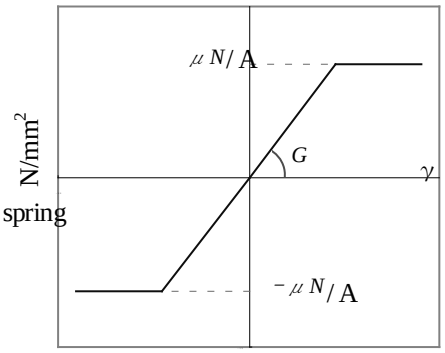

Figure 6 Friction – slip history at the concrete joint

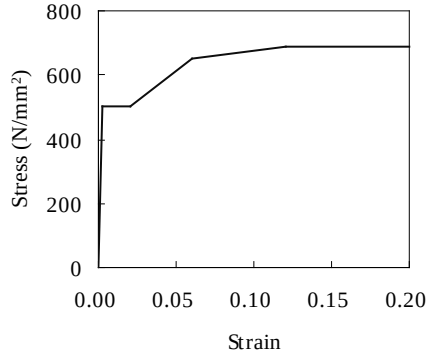

Figure 7 Stress – strain history (bar)

Table 1 shows the property of the materials. All bars except PT steel tendons are mild steel and concrete strength was 33N/mm^2.

A downward axial load of about 325kN was applied at the centerline of the wall. The average initial stress in the tendons was 1,024N/mm^2. A reversed-cyclic lateral displacement history was used during the test, with three fully repeated cycles at each displacement increment.

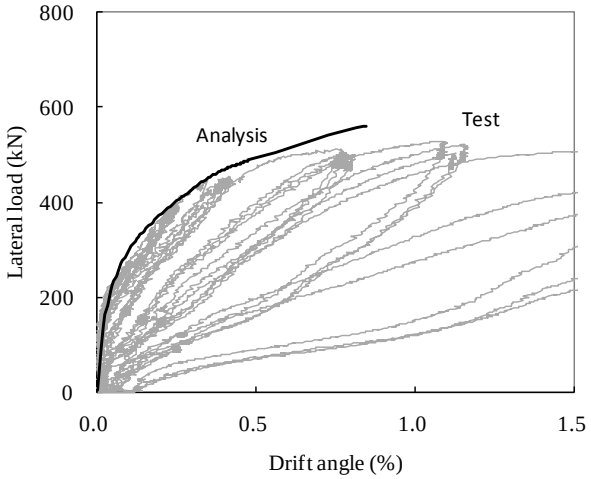
2.2 Modeling

To simulate the behavior of the specimen, a nonlinear finite element analysis applying monotonic loading is conducted under plane stress conditions. The four-node iso-parametric shell elements were used for the concrete, and the bar elements included hoops for reinforcements were layered on the shell elements as truss considered bond slip. Wire mesh was embedded. PT steel was unbounded and modeled as bi-linear. Bond between mild steels and concrete was considered just as the published paper[1].

Concrete was modeled as shown in Figures 3 and 4 considered strain softening. The joint between foundation and wall was modeled as shown in Figure 5 and 6, where the friction coefficient is 0.4; however they have enough stiffness and strength just as proven in the test result. Strain hardening was considered for mild steels located in the center of the wall as shown in Figure 7.

2.3 Solution

At first, the post tension force was given and axial load was applied at the top of the center of the wall. Next, the lateral load was applied at the wall. By applying the Newton method, the number of load steps required to minimize the work done by the unbalanced forces was determined. The number of iterations in each loading step was placed less than 50.



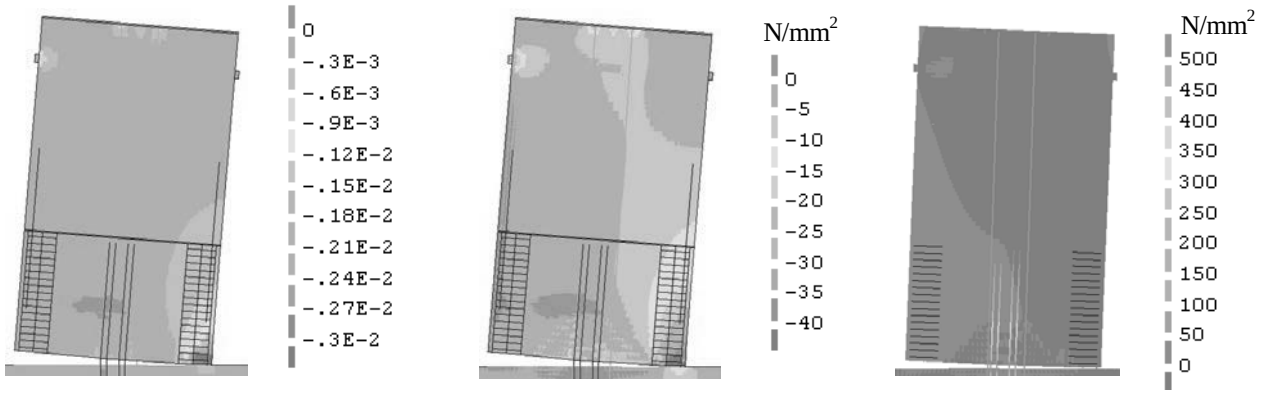


Figure 8 Hysteresis curve

3. ANALYSIS RESULT

3.1 Hysteresis curve

Figure 8 shows hysteresis curve. The grey line represents the test result and the black line represents the analysis result. The analysis was stopped because of large unbalance energy.

According to the test result, the residual drift angle is eliminated to under 0.2% due to post tension tendons, even though peak drift angle is over 1%. Stiffness and lateral load in the test and analysis are almost suited up to 0.5% drift angle. Maximum lateral load in the analysis 561kN was larger than in the test result 527kN. Good agreement was shown between the test result and analysis result up to 0.85% drift angle.

(a) Concrete strain (b) Concrete stress (c) Longitudinal bar stress

Figure 9 Stress and strain distribution at the final step

3.2 Concrete compressive strain and stress

Figure 9(a) shows concrete compressive strain distribution. Large compressive strain is observed at the bottom right of the wall. Hoops are effectively located at the toe of the wall.

Figure 9(b) shows concrete compressive stress distribution. Large compressive stress is observed at the bottom right of the wall as well as the concrete compressive strain distribution. In addition, large compressive stress is concentrated and developed at the local area. Concrete compressive strut is diagonally formed which resist lateral load. This analysis is useful to observe concrete stress distribution.

3.3 Longitudinal bar stress

Figure 9(c) shows longitudinal bar stress. Four mild steels #6 located in the center of the wall are yield but two PT steels are not. PT steel stress distribution is constant because they are unbounded. This result is as well as the test result.

Bonded mild steels are effective to absorb energy during large earthquake. PT steels are effective to eliminate residual drift angle, because they are almost elastic. It is important to examine the amount of PT steels and PT force, not to be yield.

3.4 Hoop and wire mesh stress

Figure 10(a) shows hoop stress distribution. The stress is developed to be yield at the bottom right corner of the wall. Hoops are partially effective to confined concrete at the toe of the wall, therefore they should be located as this specimen, because strain softening is improved by its' confined effect.

Figure 10(b) shows wire mesh stress distribution. The stress is developed to be yield at the bottom right corner of the wall as well as the hoop. It is easy to be yield, because the diameter of the wire mesh is smaller than that of the hoop. The wire mesh is not so expected to resist such a lateral load, but it is partially effective.

3.5 Displacement distribution

Figure 10(c) shows displacement distribution. The gap between the foundation and wall is developed, because this specimen consists of precast concrete having concrete joint there. The gap is easily opened and developed, so it was grouted by non-shrinkage mortar and longitudinal bars are located around the center of the wall. Damage is concentrated at the gap, so there is little damage on the wall except for the bottom right corner.

4. CONCLUSION

We have verified our modeling and analyses in the published paper[1)], and studied on the behavior of the post-tensioned precast concrete wall applied lateral force using finite element analysis. Hysteresis curve in the analysis was suited to that in the test up to about 0.85% drift angle, hoops and wire mesh at the toe of the wall were effective. Ultimate flexural moment can be estimated by our model and analysis.

Abstract: This paper addresses the seismic performance of core-walls with L-shaped cross sections based on an experiment and numerical analysis on three reinforced concrete specimens with 1/4.5 scale. The specimens had large amount of vertical reinforcement in wall panels and boundary columns, and the concrete compressive strength of 80 MPa so that the core-walls behaved as a major seismic resisting component in tall buildings. Test variables included section configurations and loading directions. Axial load was varied up to 12MN or 31% of axial load capacity as a linear function of the lateral load intensity. The lateral load-drift relations were recorded with local deformation and damage focusing on the yield of reinforcement and crushing of concrete. Damage of boundary columns was severe and indicated the importance of good confinement at the end of wall sections. A simple fiber model simulated the lateral load - drift angle relations by considering pullout of longitudinal reinforcement. It was concluded that the pullout of longitudinal reinforcement and local crushing of concrete had a significant influence on the behavior of core-walls.

This paper was reprinted from the 3rd International FIB Congress PaperID #613[1] after making minor changes.

1 INTRODUCTION

Maffei and Yuen[2] addressed the advantage of core-wall buildings in their article as follows. "*In recent years, a new type of tall buildings is being constructed. They use reinforced concrete core-walls without supplemental moment resisting frames in the seismic force resisting system. RC core-walls offer advantages of open and flexible architecture. By eliminating the need for moment resisting frames, smaller framing members or flat slabs can be used for the building floors, and the framing depth of floors can be reduced. In a core-wall building, resistance to seismic forces is provided by a reinforced concrete core that surrounds the elevator banks. A core-wall building eventually realizes lower costs and faster construction.*"

Adebar et al.[3] summarized previous tests on concrete structural walls with height-to-length ratios greater than 2.0. The cross section of those specimens were mainly rectangular, flanged, and barbell. Total vertical reinforcement, as ratio of gross area of wall cross section, was 2.62 and the axial compression level was 20% at maximum. In Japan, a large seismic demand requires larger core-walls with heavy vertical reinforcement and higher concrete strength. Since late 1990's, behaviors of large scale core-walls have been studied extensively in Japan [4] and [5]. Konishi et al.[6] reported that the confinement of concrete at the corner or the end of the section increased the deformation capability. They simulated the load-displacement relation with good accuracy with a fiber model adapting the plane-sections-remain-plane assumption. Maruta[7] proposed a method to determine the amount of shear reinforcement at the boundary column region to confine the crushed concrete based on Konishi's work. However, Nakachi[8] reported that the plane-sections-remain-plane assumption cannot be applied to a core-wall after the formation of flexure-shear cracks.

Recently, additional experiments have been conducted on core-walls with different types of cross sections in some Japanese research institutes. In Kyoto University, a seismic behavior of core-walls was studied using three 1/4.5 scaled specimens with L-shape cross sections. The specimens had well confined boundary columns, a large amount of vertical reinforcement, and high strength concrete of 80 MPa. The vertical load up to 12MN or 31% of axial load capacity was applied to simulate the variation of axial load conditions of tall buildings. The damage process was recorded and the load-displacement relation was simulated with a fiber model.

2 TEST SETUPS

Figure 1 shows configuration and reinforcement arrangement of three specimens (L00A, L45A and L45B). The cross section of L45A and L00A were equilateral and that of L45B was inequilateral. The 1/4.5 scaled core-walls with L-shaped cross sections represented three lowest stories

of a prototype 40-story reinforced concrete office building. All wall panels had same thickness of 200mm and height of 2480mm. In this study, a square area of 200mm by 200mm at either end of the wall section was treated as a boundary column. The boundary columns were confined with large amount of longitudinal and shear reinforcement as shown in Table 1. Two types of test variables are section configuration and loading direction as shown in Table 2. It is noted that high strength concrete with the compressive strength of 80 MPa was used as shown in Table 3.

Table 1 Types of reinforcement

Member (Section size)	Reinforcement		Steel ratio (%)
Column (200x200mm)	Longitudina	16-D13	5.07
	Transverse	4-D6@80	0.79
Wall (200 mm	Vertical	3-D13@63	3.02
	Horizontal	2-D10@80	0.89

Figure 1 Configuration and reinforcement arrangement (Unit: mm)

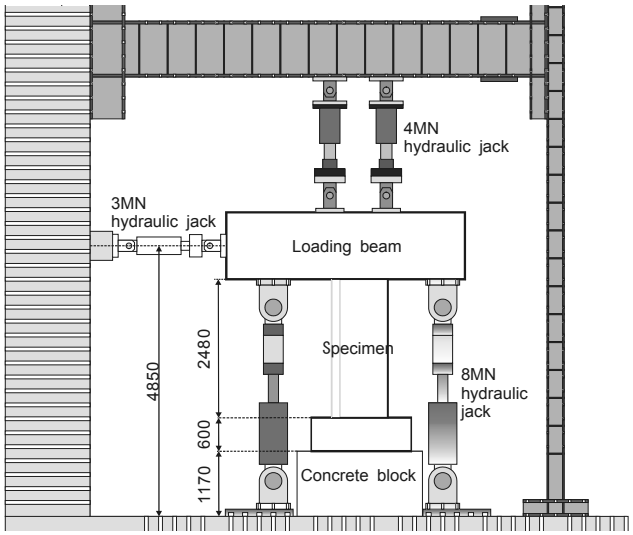

Figure 2 Loading system (Unit: mm)

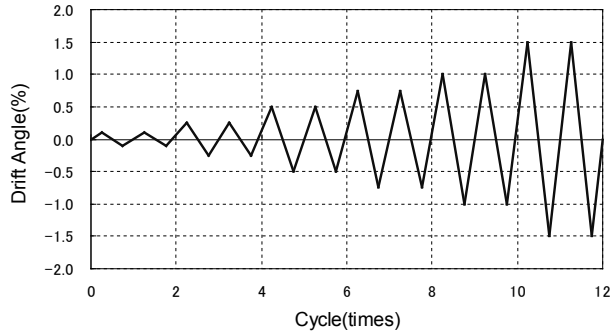

Figure 3 Loading protocol

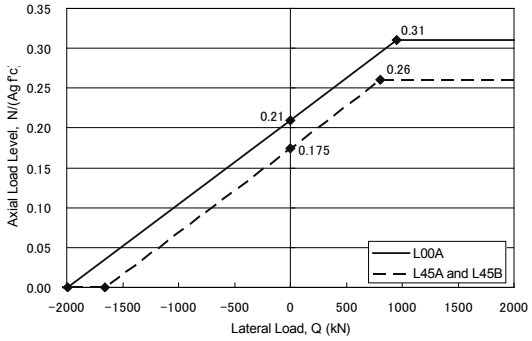

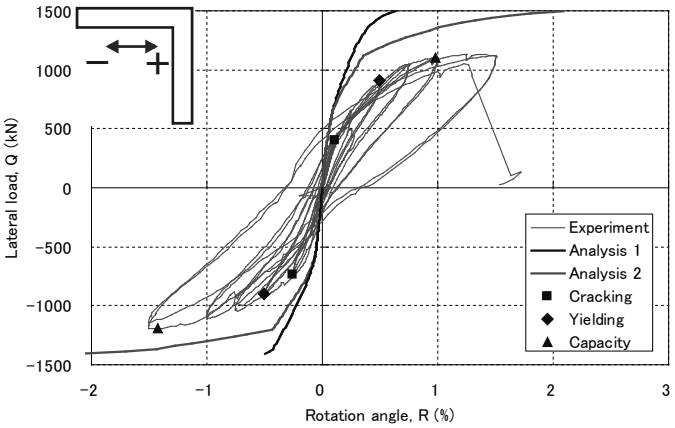

Figure 4 Loading path on the axial load level - lateral load relation space

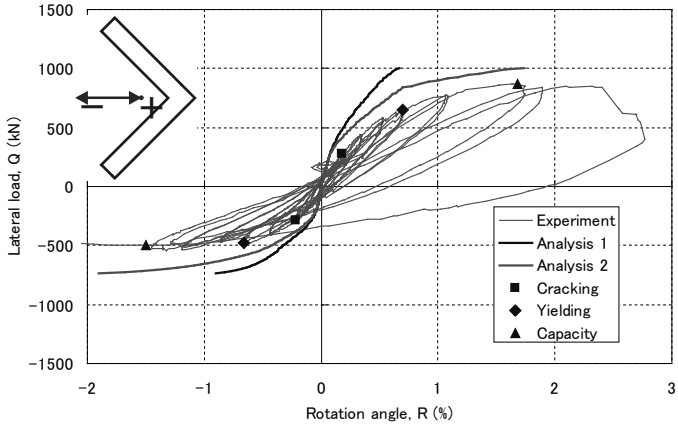
Figure 2 shows the loading system. In addition to 3MN hydraulic jack for the lateral load, four hydraulic jacks were used to control the vertical load. Additional three 1 MN hydraulic jacks, which are behind the loading beam and not shown in the figure, were used to prevent the out-of-plane movement of the loading beam. Loading protocol of lateral displacement is shown in Figure 3. The drift is defined as the horizontal displacement of the centroid of the section at 2130 mm above the upper surface of the stub where 2130 mm is the height of the sixth floor level of the prototype building. The drift angle was computed by dividing the drift by 2130 mm. Four vertical hydraulic jacks were adjusted so that the height of contraflexure point remained a constant value of 4260 mm above the upper surface of the stub. In addition, the long term vertical load, N, was set $0.21A_gf'_c$ for L00A and 0.175 $A_gf'_c$ for L45A and L45B where A_g is the gross section area of the core-wall. The vertical load was varied as the linear function of the lateral load as shown in Figure 4. Loading direction was either parallel to or 45 degrees angle to the wall panel as shown in Figure 1(c) and (d).

3 TEST RESULTS

Figure 5 shows the lateral load (Q) – drift angle (R) relations and damage at the ultimate loading stage. L00A had the initial flexural cracks at drift angle (R hereafter), R=+0.1%. Longitudinal reinforcement in Columns B and C (Naming of boundary columns is shown in Figure 1) yielded in compression at R=+0.25% and that in Column A yielded in tension at R=+0.5%. Concrete in compression region showed no damage until R=+1.0%, at which the peak load was reached. After the peak, the damage of concrete in compression region progressed rapidly. The final failure occurred at the base of the wall between Columns B and C when the concrete failed in shear suddenly as shown in Figure 5 (b). In negative loading, the damage progress was similar to that in positive loading until R=-0.5%. However, the crushing of concrete at Column A occurred at R=-0.5%. The concrete crushing took place much earlier than that in positive loading because a large amount of tensile reinforcement carried large tensile force and compressive strength of concrete was not sufficient to balance it.



L45A had the initial flexural cracks at R=+0.16%. Longitudinal reinforcement in Column B yielded under compression at R=+0.34%, and the concrete at the base of Column B started to crush at R=+0.5%. The peak load was reached at R=+1.5% but the deformation progressed without losing too much load carrying capacity until R=+2.5%. The final failure occurred at R=+2.5% when the concrete at Column B crushed under compression. In the negative loading, the initial flexural cracks were found at R=-0.34% at Column B, the reinforcement in Columns A and C yielded in compression and that in Column B yielded in tension at R=-0.5%. The crushing of concrete at Columns A and C happened at R=-1.5%. The damage under negative direction was less severe than that under positive direction at the same drift ratio because the axial load is lower on the negative side. When the loading was reversed at R=+2.5% to the negative direction, the shear sliding failure occurred near the base of the wall.

(b) Failure mode of L00A

(c) Q-R relation of L45A

(d) Failure mode of L45A

(e)Q-R relation of L45B

(f) Failure mode of L45B

Figure 5　Lateral load – drift angle relations and failure modes

L45B showed a similar damage progress to L45A until the positive peak load. The peak load was reached at R=+1.0%. The load carrying capacity degraded gradually till the concrete completely crushed at R=+1.5%. In the negative loading, the shorter side suffered severer damage than the longer side.

Figure 6 shows strain distributions of the vertical reinforcement along the section, which is 60mm above the wall base, of L45A. X-axis represents the distance of strain gages from the corner as shown in a small diagram in the figure. For drift angle less than R=+0.34%, the strain distribution was nearly linear. However, when the drift angle exceeded R=+0.5%, the strain of compression region progressed rapidly and the strain distribution was not linear anymore as can be seen in Figure 6(a). In negative loading in Figure 6(b), the strain distribution was nearly linear until the end of the loading. Two other specimens showed similar strain distributions. This shows that the plane-sections-remain-plane assumption is not valid after the concrete started to crush.

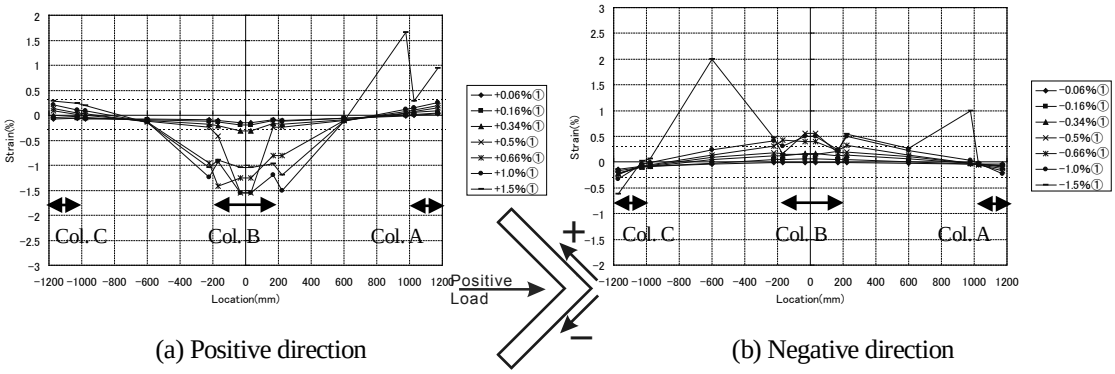

Figure 7 shows the strain distribution of longitudinal bars along the axis of Columns A and C of L45A. After R=1.0%, the strains became greater than 0.5% at the columns base. The figure indicates the effect of pullout of longitudinal reinforcement from the stub and columns on the drift of the core-wall as follows. Defining that $\varepsilon_r(x)$ is the strain of reinforcement and $\varepsilon_c(x)$ is the strain of concrete along the reinforcement at gage height, x, the elongation of reinforcement, δ_r, and that of concrete, δ_c, are expressed as Eqs. (1) and (2), respectively. Then, the pullout of reinforcement, $\delta_{pullout}$, can be obtained as Eq. (3). Assuming the total pullout appears at the interface between the stub and columns, the drift angle due to pullout of reinforcement, $R_{pullout}$, can be computed based on the distance between the reinforcement and the neutral axis, d_n, where d_n was obtained from the section analysis. In numerical computation, Figure 7 was used for $\varepsilon_r(x)$ and a section analysis was used for $\varepsilon_c(x)$.

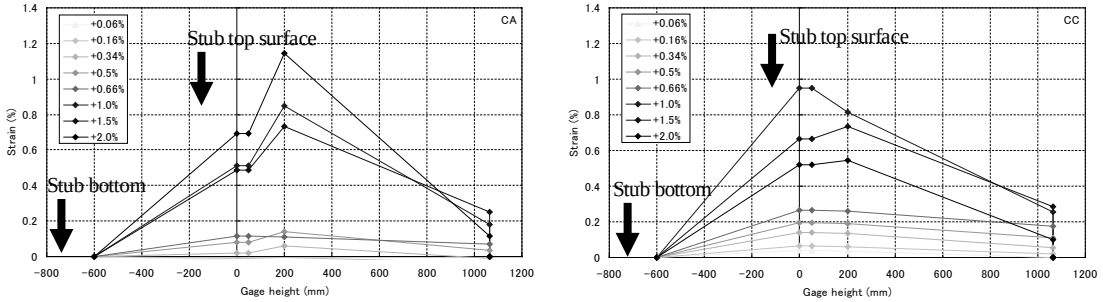
$$\delta_r = \int_{x=-600}^{x=+2480} \varepsilon_r(x)dx \tag{1}$$

$$\delta_c = \int_{x=-600}^{x=+2480} \varepsilon_c(x)dx \tag{2}$$



$$\delta_{pullout} = \delta_r - \delta_c \tag{3}$$

$$R_{pullout} = \frac{\delta_{pullout}}{d_n} \tag{4}$$

(a) Positive direction (b) Negative direction

Figure 6 Distributions of vertical strain at 60 mm above the stub surface in L45A

(a) Column A (b) Column C

Figure 7 Strain distributions of longitudinal reinforcement under positive loading in L45A

The drift angle due to pullout of reinforcement, $R_{pullout}$, was computed separately using strains of Columns A and C. The results are shown in terms of total drift angel, R, in Figure 8. The figure also have a solid line (Model A) representing $R_{pullout}$, using the proposed model in Ref. 9). It can be seen that a large amount of drift is attributed to the pullout of reinforcement from the stub and column. It should be noted that the longitudinal reinforcement of columns were welded to anchor plates at the base of the stub and the rotation due to the pullout of reinforcement was not attributed to incomplete anchorage.

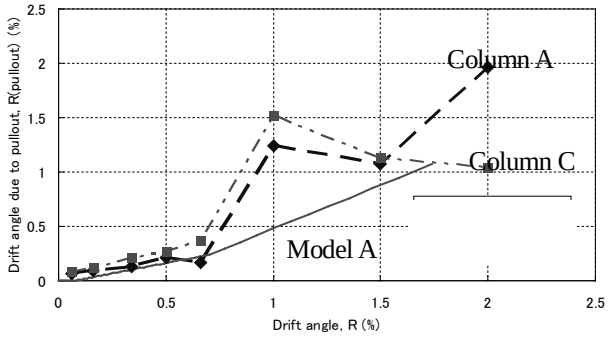


Figure 8 $R_{pullout}$ and R relation in L45A

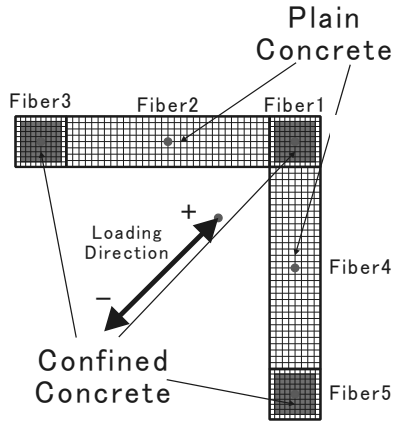

Figure 9 Fiber model mesh in a numerical simulation

4 NUMERICAL SIMULATION

The lateral load – drift angle relation of a core-wall was simulated using a fiber model. The specimen was divided into eight layers vertically and each layer was subdivided into 704 fibers as shown in Figure 9. Fibers were categorized into three material groups; plain concrete, confined concrete and longitudinal steel. Hoshikuma's model[10] was used for plain concrete, and Sun and Sakino's model[11] was used for confined concrete, and the elastic-perfectly plastic model was used for longitudinal steel, respectively. The numerical results are compared with the experimental results in Figure 5. Analysis 1 is a fiber model without considering pullout and Analysis 2 is a combination of a fiber model and pullout expressed in Eq. (4).

Figures 5(a), (c) and (e) show that the pullout of longitudinal reinforcement had a significant influence to predict the drift of the core walls by comparing Analyses 1 and 2. Analysis 2 simulates the experimental results relatively well for both L45A and L45B although the precision is not so good for L00A. The larger stiffness and maximum lateral load of L45B compared to L45A due to larger section size was simulated by Analysis 2. However, the stiffness of Analysis 2 is still smaller than the experimental results. Especially the large drift increment after the yielding of the longitudinal reinforcement in three specimens was not explained by the current model. It is considered that the effect of concrete crushing should be included to further increase the precision in displacement. The predicted lateral load capacities in the positive direction for both Analyses 1 and 2 are higher than the experimental results by 27% for L00A, 14% for L45A and 13% for L45B. This may be attributed to the immature concrete crushing due to buckling of the wall panel. However, it is not conclusive at this moment and the further study is under way.

5 CONCLUSIONS

Three reinforced concrete model specimens of an L-shaped core-wall were constructed with 1/4.5 scale and statically loaded to study the effect of loading direction and the section configuration on the seismic behavior of core-walls.

- Three specimens showed large deformation capability until the peak load. The peak load was reached at drift angle of 1.0% in positive direction when the vertical load was about 30% of the axial load capacity. The failure was caused by the crushing of concrete at the compression zone. The failed region in L45A and L45B covered a relatively larger area than predicted by a section analysis and that of L00A covered the whole flange section. It is recommended to provide good confinement to a relatively larger region of concrete to secure higher ductility.
- The deformation followed the 'plane sections remain plane' assumption until the drift ratio of +0.34%. After +0.5%, the deformation of concrete under compression progressed faster than the deformation of other region and the assumption was not valid any more.
- A simple fiber model simulated the lateral load - drift angle relation if the pullout of reinforcement was properly modeled.

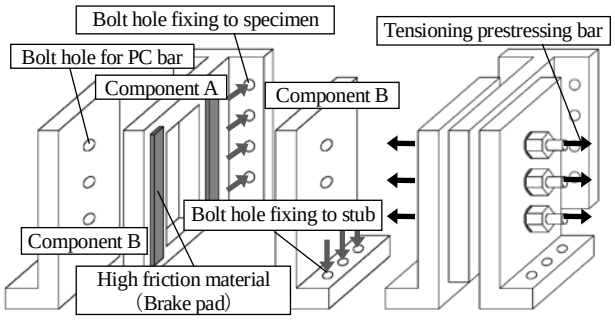
Abstract: Structural damage due to earthquakes can be reduced in prestressed concrete (PC) buildings by their self-centering characteristics, comparing to reinforced concrete (RC) buildings. However, seismic energy dissipation of PC buildings is much lower than that of RC buildings. Therefore, this paper proposes a new energy dissipation device to be attached to PC members to improve their energy dissipation capacity. A friction damper was developed and its performance was verified in preliminary tests. Repeated loads were applied to the damper to measure its frictional forces. As a result, friction increased with a higher compression on the damper, which also indicated that the frictional coefficient was approximately 0.27. A typical PC beam specimen was prepared to quantitatively evaluate the contributions of the developed damper to the seismic performance of specimen. Cyclic loading tests of the specimen were carried out with and without the damper. As a result, 1) the energy dissipation of the specimen increased significantly when the damper was attached to it. 2) Although residual deformations also increased in this case, they could be canceled by releasing frictional forces of the damper. 3) The damper contributions were asymmetric in each loading direction, which was clarified theoretically.

1. INTRODUCTION



Structural damage due to earthquakes can be reduced in prestressed concrete (PC) buildings by their self-centering characteristics, comparing to reinforced concrete (RC) buildings. However, seismic energy dissipation of PC buildings is much lower than that of RC buildings.

A method to improve the energy dissipation capacity of PC buildings using a friction damper was proposed in the past study (Morgen and Kurama 2004). It is effective to improve the seismic performance of PC buildings using this kind of damper because the damper performance can be controlled by compression applied to it. In this study, it was applied to the upper and lower surfaces of beam members. However, it seems more convenient to be attached only to the lower surface for practical application.

Therefore, this paper proposes a new energy dissipation device for PC members to improve their energy dissipation capacity. Several structural tests were conducted to evaluate the performance of the proposed device and to verify its contributions to the seismic performance of a PC beam.

2. FRICTION DAMPER

A friction damper was designed and manufactured, as shown in Figure 1. The damper consisted of the A and B components in the figure. Brake pads were welded to the A component. Compressive forces were acted between A and B by tensioning prestressing bars. Frictional forces were generated when relative displacements were caused between A and B.

(a) (b)

Figure 1 Friction Damper: (a) Components, and (b) Introducing Prestressing Force

Repeated loads were applied to the damper to measure its frictional forces under tension forces, T_0 of 300 to 1800 kN every 300 kN using the compression testing machine, as shown in Figure 2. As a result, friction increased with a higher compression on the damper, as shown in Figure 3. These results also indicated that the frictional coefficient was approximately 0.27.

3. DAMPER APPLICATION

3.1 PC Beam Specimen

An unbonded PC beam specimen was prepared to apply the friction damper developed as above. Figure 4 illustrates the details of specimen. Steel jacketing was applied to the specimen to reduce damage because it was repeatedly subjected to cyclic loads under several levels of damper forces, as mentioned below. Table 1 summarizes the specimen including material properties. The damper was attached to the end of beam by high tension bolts, as shown in Figure 5.

Table 1 Structural Details of Specimen

	Tensile strength	3.5 N/mm^2

3.2 Loading Program and Measurement

The schematic representation of experimental set-up is shown in Figure 6. The specimen was vertically placed and fixed at the upper and lower stubs to the loading frames. Reversed cyclic loads were applied to the specimen using the horizontal jack under no axial load. Lateral loading program is shown in Table 2. Tension force applied to the damper, T_0 was varied during the test.

3.3 Behavior of PC Beam without Damper

Figure 8 gives the relationship between lateral force and drift ratio of the specimen without the damper (T_0=0 in Table 2). The initial stiffness degraded at the circle in the figure during the cycle to R=1/200, then initial yielding of a prestressing bar was observed at the triangle during the cycle to R=1/33. The specimen exhibited stable hysteresis loops up to the final cycle to R=1/20.

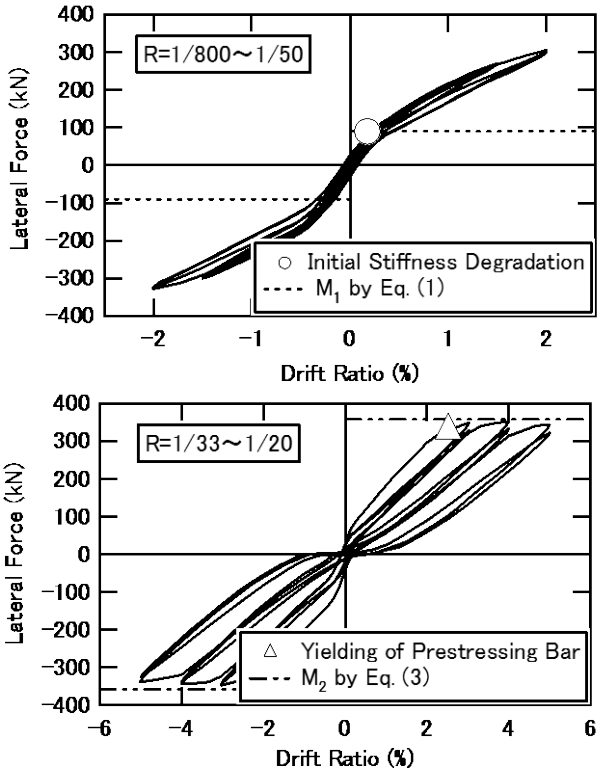

Figure 8 Lateral Force and Drift Ratio Relationship of Specimen without Damper

The circle in Figure 8 represents an initial separation between the beam end and stub. Therefore, the strength, M_1 can be evaluated by Eq. (1).

$$M_1 = \frac{\Sigma P_N}{A_e} Z_e \tag{1}$$

where, ΣP_N: prestressing force, A_e: equivalent cross-sectional area, Z_e: equivalent section modulus.

On the other hand, the triangle in Figure 8 means the flexural yielding of specimen. The flexural strength, M_2 was evaluated as follows:

1. Calculating an initial strain of each component (ε_{pc0}, ε_{c0} in Figure 9) of the beam after tensioning prestressing bars.
2. Assuming strain distributions at yielding of the prestressing bar (ε_y in Figure 9) based on Navier's hypothesis, as shown in Figure 9.
3. Determining strains (ε_{pcp}, ε_c, ε_s in Figure 9) and forces (N_y, N_{pcp}, N_c, N_s in Figure 9) of all components assuming a distance from the compressive edge to the axis with concrete strain of ε_{c0}, x_r.
4. Evaluating x_r and M_2 from Eqs. (2) and (3), respectively.

$$N_y + N_{pcp} + N_c + N_s = 0 \tag{2}$$

$$M_2 = N_y L_1 + N_{pcp} L_2 + N_c L_3 + N_s L_4 \tag{3}$$

where, N_y: yield strength of prestressing bars on the tensile side, N_{pcp}: axial force of prestressing bars on the compressive side, N_c: compressive force of concrete, N_s: compressive force of steel jacket, L_1, L_2, L_3, and L_4: refer to Figure 9.

The lateral strengths converted from M_1 and M_2 are also indicated in Figure 8, which had good agreements with the test results.

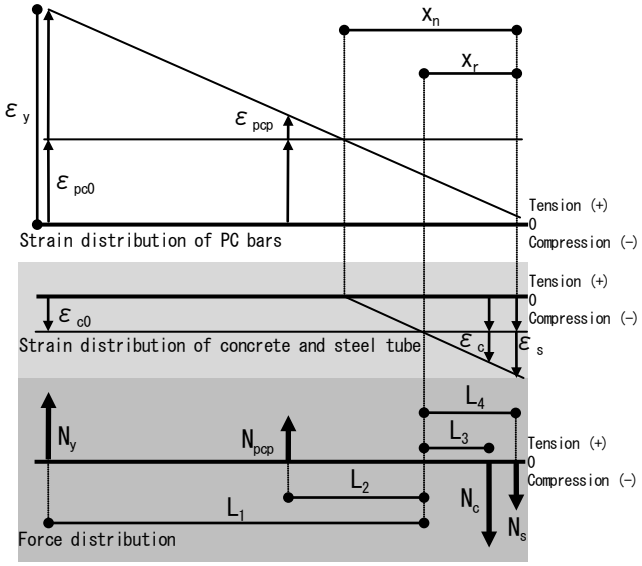

Figure 9 Strain Distributions at Flexural Yielding

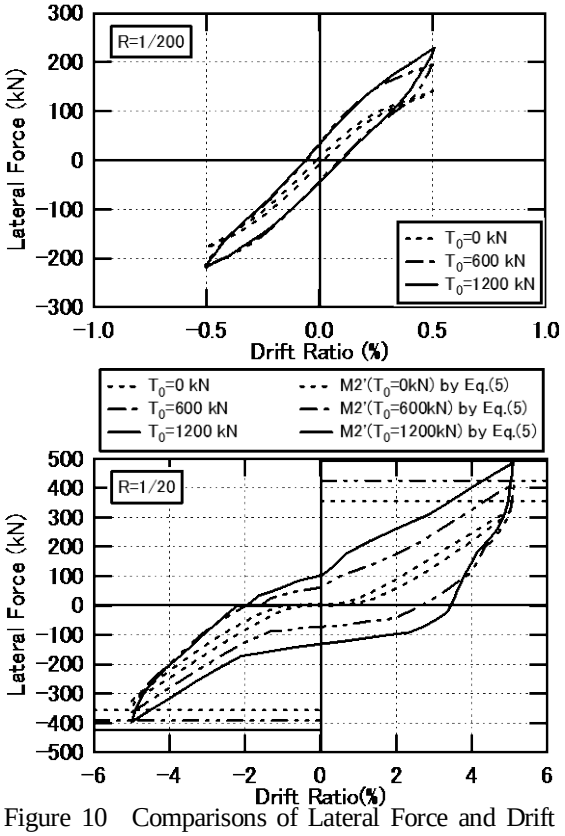
3.4 Contributions of Damper to the Seismic Performance of PC Beam

Figure 10 compares the relationships between lateral force and drift ratio observed during the cycles to R=1/200 and 1/20 among the cases of T_0=0 (the second cycle in Table 2), 600, 1200 kN. Applying the damper to the beam specimen, the maximum strength, hysteresis loop, and residual drift increased, and the incremental ratios were higher with higher T_0 values. However, the damper contributions were asymmetric in the positive and negative loading. Figure 11 shows the equivalent damping factors (h_{eq} defined in Figure 12) throughout the test. The values were evaluated as an average observed in both the loading directions because of the asymmetric damper contribution, and plotted in the figure. In the case of T_0=0, h_{eq} of the



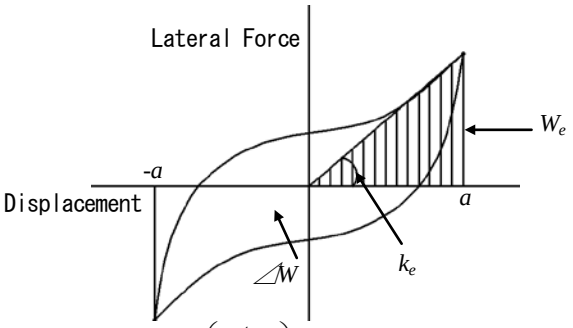


Figure 10 Comparisons of Lateral Force and Drift Ratio Relationships of Specimen with/without Damper

$$h_{eq} = \frac{1}{4\pi}\left(\frac{\Delta W}{W_e}\right)$$

ΔW= area of hysteresis loop

W_e= equivalent potential energy

$$= \frac{1}{2} k_e a^2$$

Figure 12 Equivalent Damping Factor

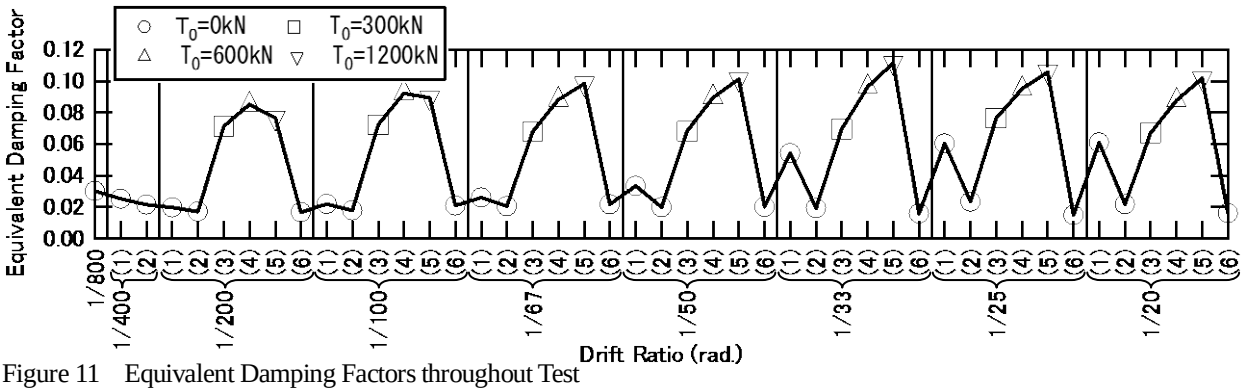

Figure 11 Equivalent Damping Factors throughout Test

second cycles decreased compared to those of the first cycles. However, little differences were observed between the second and sixth cycles, which means that the beam specimen did not degrade after the second cycle. On the other hand, h_{eq} of the specimen with the damper was generally higher in the case of higher T_0 values.

The damper contributions to the strength of specimen were asymmetric in the positive and negative loading, as mentioned above. It seemed to be caused as follows.

Figure 13 gives the distributions of curvatures along the member length, which were evaluated from outputs of vertical transducers in Figure 7. The specimen approximately exhibited a locking behavior, and hence the damper behaved as shown in Figure 14. Therefore, the damper contributions were different in the positive and negative directions because of different distances between the axis of rotation and the center of damper. The maximum strengths of the specimen with the damper were evaluated by Eqs. (4) and (5) considering a damper term in Eqs. (2) and (3), respectively, and plotted in Figure 10. Good agreements were observed between the experimental and calculated values.

$$N_y + N_{pcp} + N_c + N_s + N_d \cos\theta = 0 \qquad (4)$$

$$M_2' = N_y L_1 + N_{pcp} L_2 + N_c L_3 + N_s L_4 + N_d L_d \qquad (5)$$

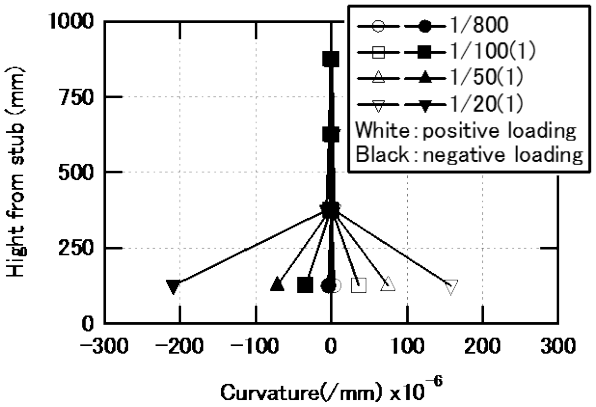

Figure 13 Distributions of Curvatures along Length

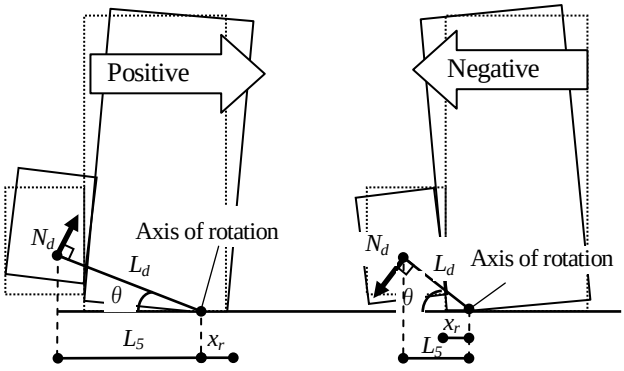

Figure 14 Behavior of Specimen with Damper

where, N_d: frictional force of damper, θ and L_d: refer to Figure 14.

Finally, larger residual displacements were focused when the damper was attached to the specimen. Figure 15 shows the behavior when releasing friction of the damper after the fifth cycle to R=1/20 (T_0=1200). It was found that the residual displacement under T_0=1200 was restored to that without the damper observed after the second cycle. This means that the residual displacement can be restored to that of PC members without the damper by releasing tension forces of the prestressing bars in Figure 1, even if large residual displacements were caused under severe seismic loads.

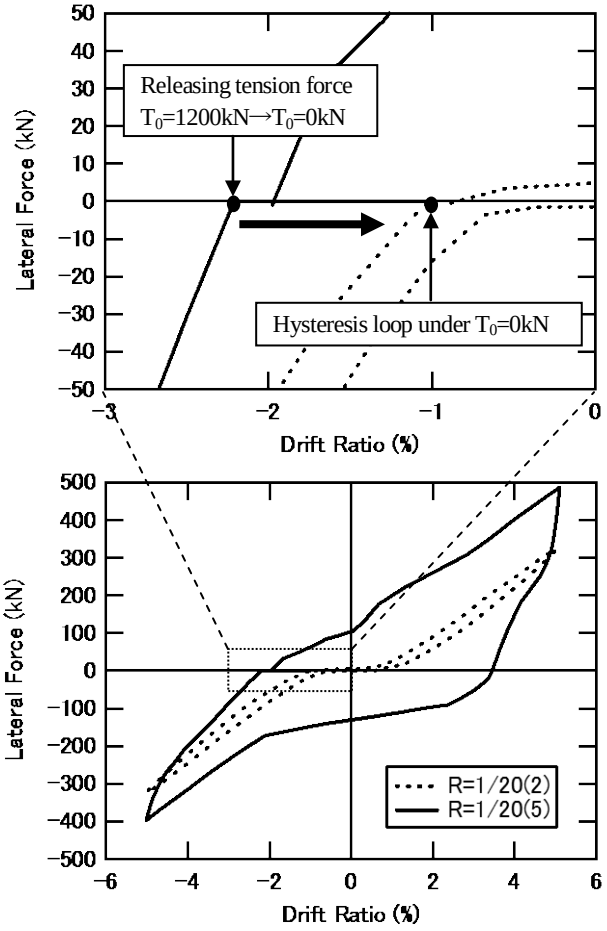

Figure 15 Behavior when Releasing Friction of Damper

4. CONCLUSIONS

A friction damper was developed to improve the seismic performance of PC buildings. Major findings of this study are as follows:

1. Performance evaluation test of the damper was conducted using the compression testing machine. The frictional coefficient was approximately 0.27.
2. The damper was applied to an unbounded PC beam specimen. It increased the overall strength and energy dissipation capacity. However, asymmetric contributions

were observed in each loading direction.

3. The asymmetric contributions were caused by different axes of rotation in both the loading direction. Therefore, the damper contributions could be evaluated by determining the distance between the axis of rotation and the center of damper.

4. The damper also increased residual deformations after unloading, however, which could be canceled by releasing compression acting on the damper.

Abstract: The cyclic and pseudo-dynamic performance of a new infill panel system made of precast, high-performance fiber reinforced concrete to retrofit existing steel moment-resisting frames has recently been investigated. The infill system is used to protect a structural system under an extreme seismic event and secondarily provide protection to non-structural components. The panels are bolted to each other and into existing steel moment-frames with pre-tensioned, slip-critical connections to add stiffness, strength, and energy dissipation to the structure. The effectiveness of the proposed seismic retrofit system has been evaluated with component testing as well as state-of-the-art hybrid simulation of a 2-story steel moment resisting frame designed in the United States in the 1980s and tested at the Network for Earthquake Engineering Simulation facility at Berkeley. Infill panel performance from cyclic testing and from hybrid simulation are presented and compared. It was found that the SC-HPFRC panels performed similarly in the component and hybrid simulation experiments with the exception of the degree of multiple cracking. In both cases the primary mode of panel failure was flexural and the SC-HPFRC was robust against spalling and bearing loads. Damage of the infill panels in the hybrid experiment was well distributed as designed.

1 INTRODUCTION

Ductile, fiber-reinforced cement-based materials are being investigated for many structural-scale applications. These materials exhibit fine, multiple cracking in direct tension, reaching strains of 0.5 to 3 percent and generally exhibit little to no spalling in compression. The materials are often referred to as high performance fiber-reinforced concrete (HPFRC) or high performance, fiber-reinforced, cement-based composites (HPFRCC) if they contain no coarse aggregate. The term high performance is used when the fiber volume fraction is relatively low (2% or less) and the tensile properties are either high strength (e.g. increase in tensile strength after first cracking) or high ductility (e.g. >3% strain while maintaining full tensile carrying capacity).

An infill panel system using a self-compacting HPFRC (SC-HPFRC, Liao *et al.,* 2006) has been proposed to retrofit fracture-critical steel frames for seismic loading (Olsen & Billington, 2009) (Figure 1). The infill panels are precast, and intended to be both easily installed and rapidly replaced after an earthquake, if damaged. Three series of testing have been carried out to investigate the performance of the infill panels to cyclic

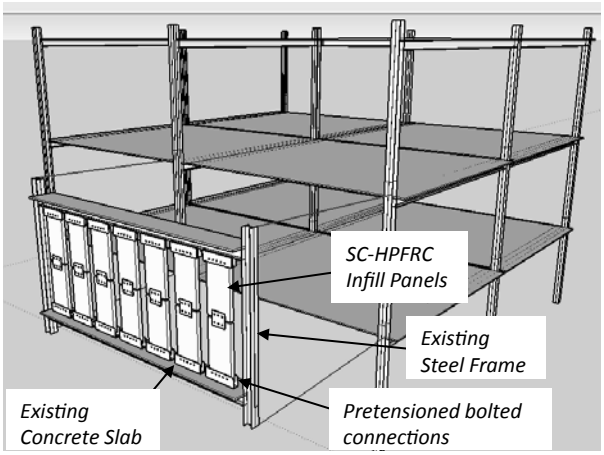

Figure 1 Ductile fiber-reinforced concrete infill panel system proposed for seismic retrofitting of steel frame structures.

loading and the performance of a retrofitted steel frame to simulated earthquake loading using hybrid simulation. In the first test series, seven single panel specimens were tested with a fixed base and loaded laterally at the top, where the point of inflection would be for a double panel system under lateral load in a frame (i.e. half of one of the seven double-height panels shown in Figure 1). The results of this test series are summarized in Olsen & Billington (2011). In the second test series, four double-height panel sets were tested under quasi-static cyclic lateral load within a 4-pinned steel frame (Hanson, 2008). In the third test series, a single-bay, two-story steel frame with 5 sets of double height infill panels in each story was tested using hybrid simulation (see Lignos *et al.,* 2011). Two phases of simulated earthquake loading were conducted in order to evaluate the seismic performance of the retrofitted test frame.

This paper focuses on the response of the SC-HPFRC infill panels to cyclic loading in the 2nd test series and Phase I of the 3rd (i.e. hybrid simulation) test series.

2 DOUBLE-HEIGHT PANEL EXPERIMENTS

Four full-story double panel components were designed and tested under quasi-static cyclic loading. A proposed center connection between top and bottom panels, the top panel-to-frame connection and the double panel interaction including out-of-plane response were of particular interest to evaluate during this series of tests. A brief overview of the panel designs and experimental results are presented here with details given in Hanson & Billington (2011).

The experiments consisted of a set of double panels connected to steel beam sections at the top and bottom and fixed in a four-pin testing frame. Lateral load was applied at the center of the top of the testing frame. The panel set up was approximately 2/3-scale. The double panel experiments included the SC-HPFRC panels, the connections of these to each other and to the top and bottom representative steel frame members, and the representative steel frame members' connections to the test frame (Figure 2). It is noted that the boundary condition at the top was fixed rather than allowed to rotate as would be the case in an actual moment-resisting frame where beams typically deform in double curvature.

The details of the three primary connections of the double panel system are shown in Figures 2 and 3. They are: a top connection where the top panel is connected to the upper floor beam, the center connection where the top and bottom panels are joined, and the bottom connection where the bottom panel connects to the base beam (test frame).

Four different panel designs were investigated (one per test for a total of four tests). Only one design, for Test 3, is discussed in detail here. The design for Test 3 was referred to as "P-bar with Interior bar" in Hanson (2008) and the reinforcement layout and geometry are

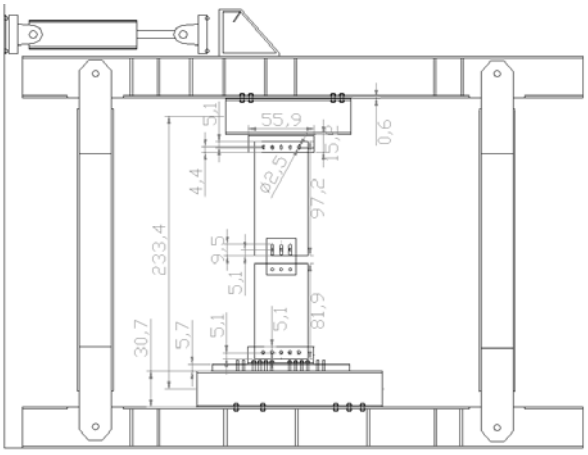

Figure 2 Double-height panel test set-up in a four-pin frame (dimensions in cm).

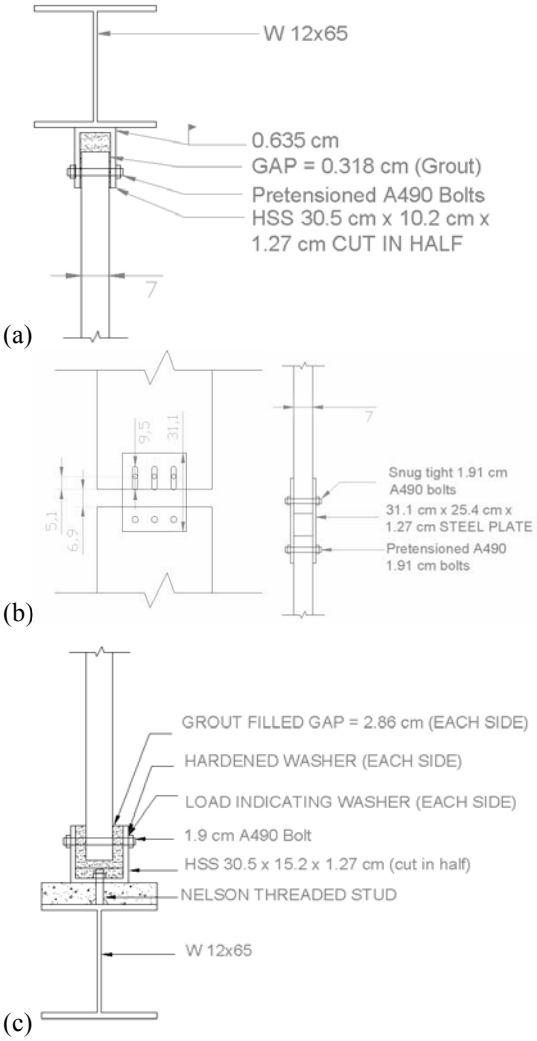

Figure 3 Details of the (a) top connection, (b) center connection, and (c) bottom connection (used for tests 2, 3 and 4). Dimensions in cm.

shown in Figure 4. The perimeter and U-shaped bars were US No. 3 (diameter 9.5mm) bars and the mesh reinforcement was a 10-gauge welded wire fabric with a

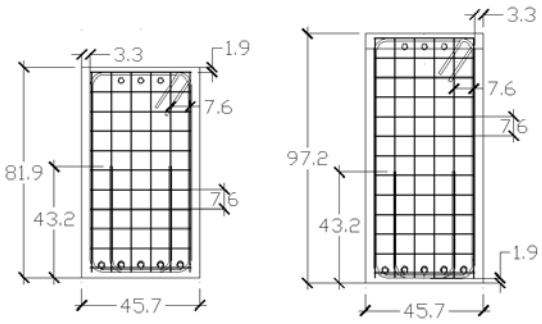

Figure 4 Panel design for Test 3 from Hanson & Billington (2011). Dimensions in cm.

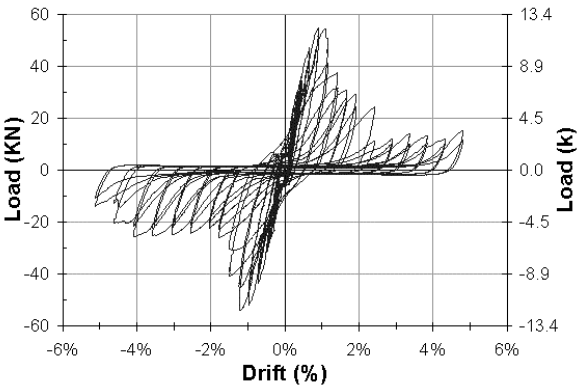
diameter of 2.6mm. The proportions of the SC-HPFRC mixture by weight were; Type III Portland cement (1), Class C Fly ash (2.2), Silica sand #16 (2.2), Crushed limestone with 12mm maximum sized aggregate (1.2), water (0.8), high range water reducing admixture (0.005), viscosity modifying agent (0.038), and high strength steel fibers (0.315).

The panels were tested under quasi-static cyclic displacement control. Three reverse cycles at drift levels of positive/negative, 0.25%, 0.375%, 0.5%, and 0.75% were followed by two reverse cycles at drift levels of positive/negative 1%, 1.25%, 1.5%, 1.75%, 2%, 2.5%, 3%, 3.5%, 4%, 4.5%, and 5%. The story drift represented the drift of the scale model frame, calculated as the displacement at the top of the test frame divided by the centerline story height (234 cm).

2.1 Hysteretic Response of Double Panel System

The load vs. drift response of Test 3 is shown in Figure 5. Drift was measured as the displacement of the testing frame divided by the center-to-center distance of the W-sections to which the panel retrofit system was attached (i.e. the "story drift"). At peak load in the positive direction damage localized in a flexure-shear crack slightly below the top of the interior bar. The crack widened, the welded wire mesh reinforcement fractured, fiber pullout in the SC-HPFRC was observed, and the interior bar pulled out. Multiple cracking was observed along the length of the bars near the failure zone in tension. In compression, the SC-HPFRC spalled along the tensile cracking lines from the opposite direction of loading and the material was no longer confining the reinforcement, which then buckled. A large section of the perimeter bar was exposed, essentially unbonded. Due to this large unbonded segment, the steel was able to continue to deform, as the SC-HPFRC carried compression in the center portion (Figure 6a). This reduced "moment arm" is apparent in the residual capacity of the panel system observed in the hysteretic response (Figure 5), which was 25% of the peak capacity in the positive direction and 45% of the peak capacity in the negative direction.



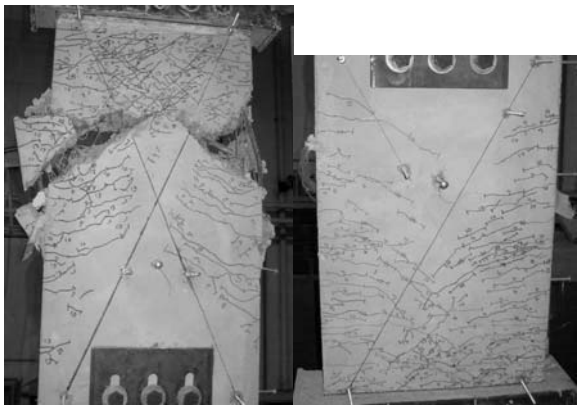


Figure 5 Hysteretic response of Test 3.

(a) Top panel (b) Bottom panel

Figure 6 Final appearance of Test 3 panels after testing

2.2 Representative Cracking Response

The cracking pattern up to failure is illustrated in Figure 7. Considerable distributed cracking was observed particularly in the bottom 2/3 of the panels (where "bottom" refers to the fixed end). As the cracking moved towards the center connection it remained well distributed, and as expected, flexure-shear cracks began to form. Some cracking was observed in both

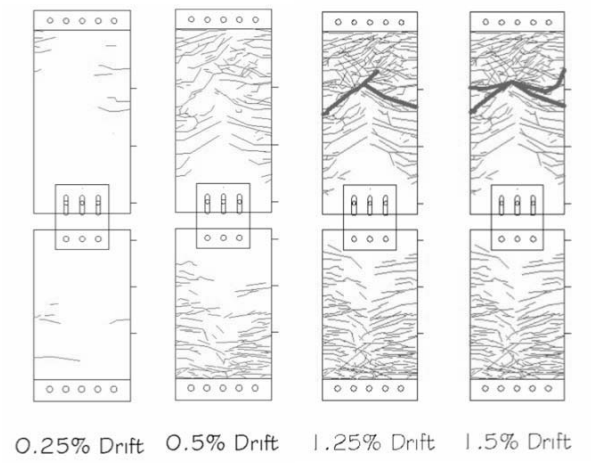

Figure 7 Crack progression up to failure

panels towards the center connection, with cracking stopping about 3" above the bolt line in the center connection in the top panel, and going all the way up to the bolt line of the center connection in the bottom panel. In both cases cracking was stopping roughly equidistant to the point of inflection of the double panel system.

3 INFILLED FRAME EXPERIMENTS: HYBRID SIMULATION

Large-scale hybrid (pseudo-dynamic) testing of the infill panels installed in a two-story steel frame has recently been completed as the third of three test series on the retrofit system. The testing included a physical subassembly of a one bay two-story sub-frame with five sets of SC-HPFRC panels per story, and a numerical subassembly to represent the remainder of the moment resisting frame and modeled in the Open System for Earthquake Engineering Simulation (OpenSees, 2009) platform. A schematic representation of the hybrid model is shown in Figure 8 (Lignos and Billington, 2010). This moment resisting frame was part of the lateral system of a 2-story office building designed in California in 1980s. The building did not meet the retrofit objectives based on ASCE41/07. This prototype building had a period of 0.75sec in the longitudinal direction of interest. The hybrid model of the moment resisting frame was scaled based on similitude laws that are summarized in Moncarz and Krawinkler (1981). The exterior columns of the test subassembly shown in Figure 8 were W10x45 and the first and second floor beams were W14x26 and W10x30, respectively.

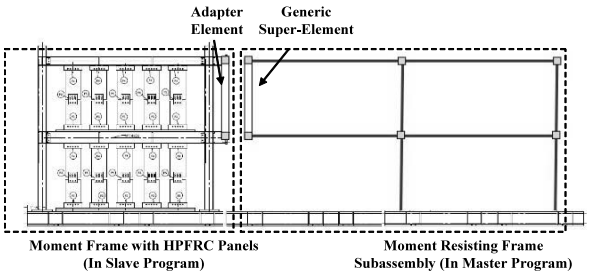

Figure 8 Hybrid simulation set up with physical model (left) and numerical model (right).

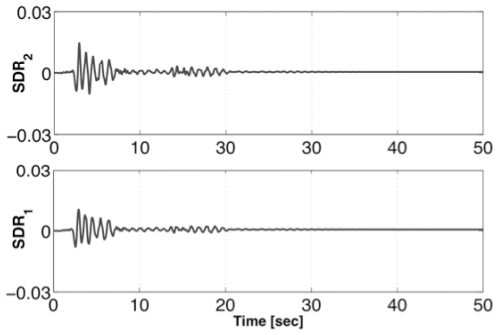
Two horizontal translational degrees of freedom at each one of the floor levels of the experimental subassembly were controlled during the hybrid test. Two phases of testing were performed with the loading for Phase 1 described in Table 1. A detailed description of the hybrid simulation testing and seismic response of the hybrid model is given in Lignos *et al.* (2011). This section focuses on the infill panel response from the Phase I testing and is compared with the quasi-static cyclic loading response presented in Section 2.

A picture of the physical subassembly is shown in Figure 9. Connection details of the panels were the same as those shown in Figure 3. Although the prototype frame was designed based on pre-Northridge seismic provisions, the four steel moment connections in the physical subassembly were designed as standard welded, unreinforced flange-bolted web connections per FEMA-350 (2000) provisions to avoid any control instability of actuators during testing due to beam-column joint fracture. Fracture was simulated in the numerical portion of the hybrid model though recognizing the possibility of having fracture(s) at design level earthquake events.

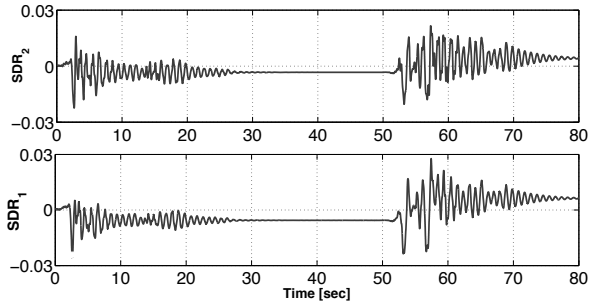
Figure 9 Physical test set-up prior to Phase 1 testing

Table 1. Hybrid Testing Experimental Program



Phase I			
Level of Intensity	**Notation**	**Gr. Motion Intensity**	**Earthquake Record**
Service Level	SLE	30%	Petrolia (Cape Mendocino, 1992)
Design Level	DLE-I	70%	Petrolia (Cape Mendocino, 1992)
Design Level	DLE-II	100%	Canoga Park (Northridge, 1994)

During hybrid testing the two horizontal translational degrees of freedom were the control quantities and the physical subassembly was connected with a link that was designed to behave elastically. Two 975-kN dynamic actuators imposed the computed displacements and also measured the force and displacement quantities from the physical subassembly.



The 2-dimensional test frame was modeled in OpenSees with elastic beam-column elements that had concentrated plasticity springs at their ends. The hysteretic response of these springs was bilinear. The springs simulated component deterioration based on the modified Ibarra-Krawinkler model (Lignos and Krawinkler, 2009, 2011). Deterioration parameters of the components were determined from relationships for deterioration modeling that were derived from a recently developed database of steel components for deterioration modeling (Lignos and Krawinkler, 2007, 2009, 2011).

3.1 Global Response of Hybrid Model (Phase 1)

The hybrid model reached a peak story drift ratio of 1.9% and a residual story drift ratio of less than 0.5% after the first design level earthquake loading (DLE-I, 70% Petrolia, Table 1). The maximum story drift ratio was 3% in the first story when subjected to the second design level earthquake (DLE-II, Table 1, unscaled Canoga Park) (Figure 10), which corresponds to a lateral displacement of 67mm. The maximum story drift ratios in the infilled frame were reduced by roughly 10% and 25% in the first and second stories, respectively, relative to the expected peak drift ratios in the bare frame (Lignos *et al.,* 2011). The residual story drift ratios after the completion of DLE-II were about 0.6% for both stories of the test frame, which corresponds to a roughly 50% reduction of residual drift ratios compared to the bare frame.

3.2 Infill Panel Response to Phase I Hybrid Testing

The damage to the panels after the DLE-I and DLE-II ground motions is shown schematically in Figure 11. Details of typically observed cracking and damage are shown in Figure 12. Flexural cracking was observed but to less of an extent than appeared in the component testing, i.e. the second test series (Section 2). The less cracking in the hybrid simulation experiment is attributed primarily to the boundary conditions of the test frame relative to that of the four-pin frame, which provided a fixed end condition to the component tests. Additional reasons for differences in cracking response are the differing loading protocols (earthquake vs. symmetric loading protocol), with fewer large cycles in the hybrid simulation relative to multiple symmetric cycles in the component tests, as well as the ductility of the SC-HPFRC material. The SC-HPFRC material in the hybrid simulation experiment was older and had an average compressive strength of 7400psi. The material in the component tests had an average compressive strength of 5860 ksi. Assuming a correspondingly larger tensile strength in the hybrid simulation experiment panels, it could be expected to see less multiple cracking due to

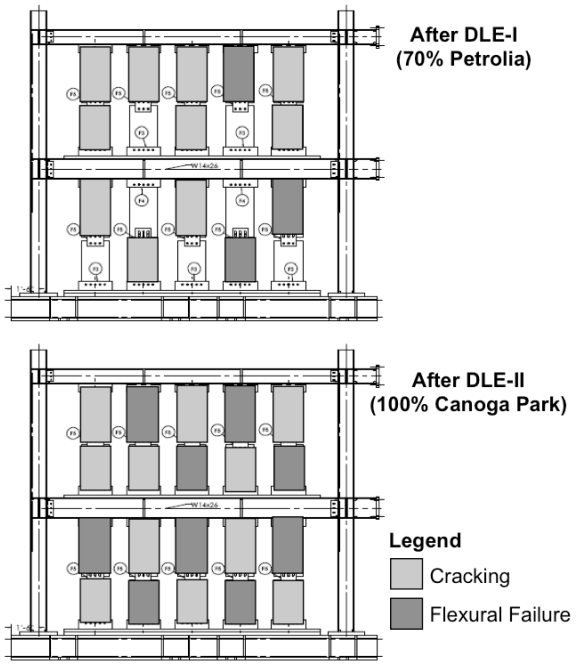

Figure 11 Schematic of cracking and damage in panels after the DLE loadings in Phase I testing.

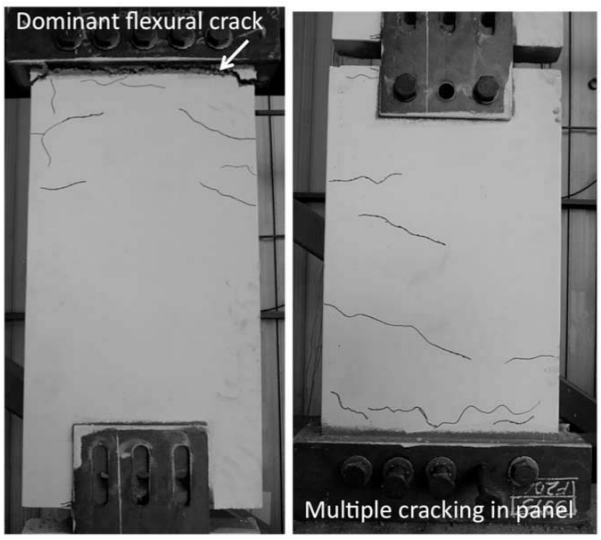

Figure 12 Tyipcal cracking and damage in panels observed in Phase I testing.

more rapid crack localization with higher forces required to open cracks.

For the panels that failed in flexure, the damage was localized at the base of the panel (top of the top panels or bottom of the bottom panels) where a dominant crack had formed and the reinforcement was observed to have fractured. After such failures, the panels were able to rock in a rigid body motion.

In addition to flexural cracking, some minor cracking was observed near the center connection where there appeared to be bearing of the bolts at this connection on the panel holes (Figure 13). It was later determined that the pre-tensioning force used in the center connection was considerably less than intended and the connection was therefore not acting as a pre-tensioned, slip-critical connection. Despite this fabrication error, the ductile nature of the material proved to be robust and allow for bearing without failure. In Phase II testing (Lignos *et al.,* 2011), adequate pre-tensioning was applied and no center connection slippage was observed.

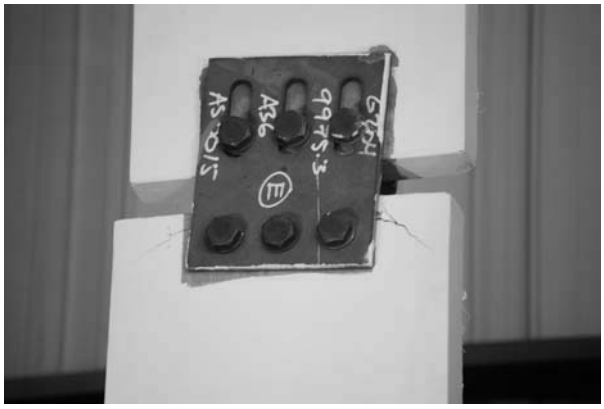

Figure 13 Cracking at center connection due to bearing (panels are 457mm wide).

Panel deformations are investigated in detail for the SLE loading here. Figure 14 shows the panel displacement time histories for displacements due to flexural deformation, as determined from the strain gage data of the top and bottom panels in the top right corner of the hybrid simulation experiment. The strain gages did not capture deformation beyond ~5 sec. most likely because they were not located exactly where cracking occurred. Shear deformations were also measured on the back face of the same panels during testing. The flexural displacement was estimated by assuming a linear shape for the curvature along the panel height with a localized curvature at the base of the panel. During the SLE loading, the peak displacement due to flexure and shear were determined to be 5mm and 0.2mm, respectively for the top panel and 12mm and 0mm, respectively for the bottom panel. The peak second story deformation at this point was in the negative direction and was measured to be 33mm during the SLE loading (compared with 17.2mm from pure panel deformations). The difference is assumed to be primarily due to panel rotation (rigid body) due to frame beam rotations. There is also a small contribution to displacement from the oversized holes and it is possible that curvature was underestimated from the data from the strain gages, which were not at the exact location of yielding of the reinforcing bar.

Figure 15 shows the estimated panel forces during the DLE-I loading after subtracting the 2nd story shear forces of the steel columns from the total 2nd story shear force history during DLE-I and equally distributing the remaining story shear force to the five sets of panels. For this estimate, it is assumed that each panel set carries the same amount of shear as individual force measurements during the test were not feasible. From Figure 15 it can be seen that the peak story shear in one panel set is roughly 45kN. Under the SLE loading the forces were slightly lower. At these peaks, the panel deformations computed from the instrumentation as described above corresponded to a relative panel deformation (from channel connection to channel connection) of ~1%. In the component tests (e.g. the test presented in Section 2), these levels of shear (lateral) force in the panels were

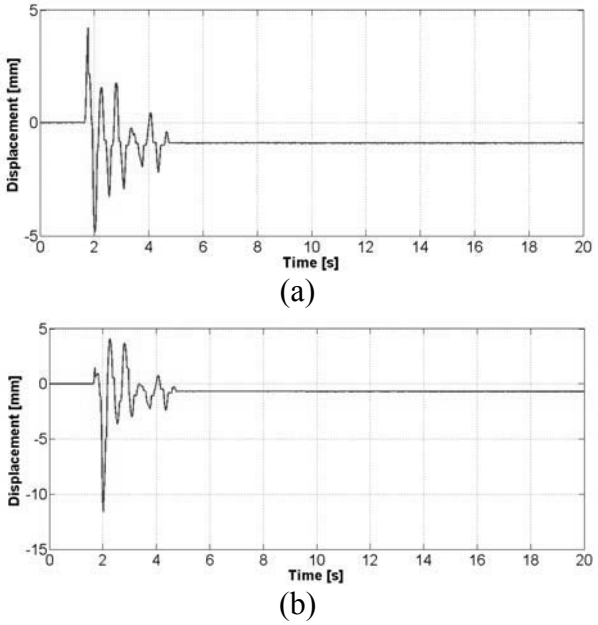

Figure 14 Displacement histories due to flexural deformations for SLE (a) Top Panel (b) Bottom Panel

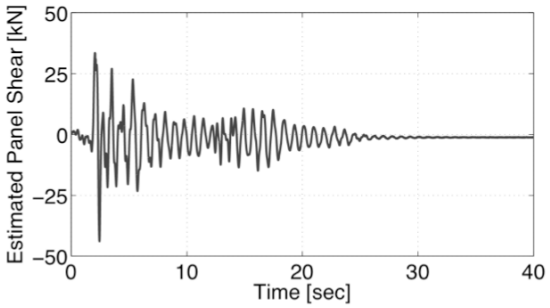

Figure 15 Estimated shear force in each panel set on the second story during the DLE-I loading.

reached at approximately the same amount of relative panel deformation (note Figure 5 shows story deformation, not relative panel deformation), indicating that the hysteretic response of the panels was similar in both sets of experiments (cyclic static and hybrid simulation tests). It is noted that the panels in the two sets of experiments were of slightly different design. The impacts of these variations are currently under investigation.

4 CONCLUSIONS

The experimental response of Self-Compacting, High Performance Fiber Reinforced Concrete (SC-HPFRC) infill panels retrofitting steel frames in two different experimental configurations has been presented. In the first configuration, a double-height panel system tested with fixed-end conditions in a four-pin frame under quasi-static cyclic loading was presented. In the second, the experimental response of SC-HPFRC infill panels in a two-story, single-bay frame with five sets of panels per story subjected to seismic loading through a hybrid simulation set up has been presented. The main conclusions from comparing the experimental responses of these two testing configurations are:

1. Infill panels in the hybrid simulation experiments behaved similarly to component panel tests with the exception of the degree of multiple cracking. Less cracking in the panels from the hybrid testing is attributed to the fewer load cycles, the boundary conditions in the frame that are able to rotate, and slightly higher SC-HPFRC strength.
2. Damage to the panels in the hybrid simulation experiments was well-distributed among panels as intended.
3. The SC-HPFRC material proved to be exceptionally robust in the base of center connection slippage, where bearing was well controlled by the tough SC-HPFRC material.
4. Panel deformation for the set of panels studied here was found to be primarily flexural based on instrumentation data. All cracking and deformation appeared to be flexural based on observation.

The data from the hybrid simulation experiments is currently being analyzed in greater detail.

5 ACKNOWLEDGEMENTS

Financial support provided by the National Science Foundation (CMS-0530383), the Blume Center for Earthquake Engineering and the School of Engineering at Stanford University, and the National Consortium for Graduate Degrees for Minorities in Engineering and Science (GEM). In addition the considerable support for the double-height panel testing, by faculty and staff in structural engineering at The University of Michigan at Ann Arbor as well as for the hybrid simulation testing by the staff at NEES@Berkeley is gratefully acknowledged. Generous donations from the Herrick Steel Corporation and Mid-State Precast as well as the University of Michigan, Williams Form Engineering, and Sika Corporation are also gratefully acknowledged. Abstract: A great earthquake of magnitude 8.8 struck on the Pacific coast of Chile, at 3:34a.m. local time on February 27, 2010, and the earthquake and Tsunami caused widespread damage in Chile. The group of Japanese and Peruvian researchers conducted disaster investigation especially for buildings from 26 April to 3 May, 2010.

1. INTRODUCTION

A great earthquake of Mw8.8 occurred at 3:34 A.M. on February 27, 2010 local time with the Pacific coast of Chile as the hypocenter. This earthquake collapsed or destroyed more than 810,000 buildings etc., resulting in more than 1.8 million victims including 432 deaths (as of March 27). When the earthquake occurred, in Peru, which a neighboring country of Chile, the Japan-Peru international joint research project, "Project for Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru" (JST-JICA Science and Technology Research Partnership for Sustainable Development Project, representative researcher: Fumio Yamazaki, professor at Chiba University, 2009-2014) was under way. Given that Peru and Chile are closely related to each other in terms of the seismotectonic and natural/social environments, and hence the findings obtained from the study on the great earthquake of Chile are expected to be mostly applied to Peru, with considerable ripple effects on other Latin-American countries, it was decided to perform investigation and information gathering on the damage caused by the earthquake and Tsunami that hit Chile, jointly with the counterpart from Peru. In addition, it was also decided that the second investigation team (team leader: Susumu Kawano) would be dispatched from the Architectural Institute of Japan to the site around the same period to perform a joint investigation.

The investigation was performed from April 26 to May 3, approximately two months after the earthquake. Given the JICA Study Team (March 13 to 23) and a joint study team comprised of four societies (Japan Association for Earthquake Engineering, Japan Society of Civil Engineers, Japanese Geotechnical Society, and Architectural Institute of Japan) (March 27 to April 8) already dispatched from Japan and the limited investigation days, this investigation was devoted chiefly to performing on-the-spot inspection of disaster-stricken buildings, acquisition of design documents, hearing with relevant parties, and so on, with the objective of elaborately investigating reinforced concrete buildings. While our activities included the investigation of buildings equipped with a base isolation or seismic control structures, we would like to report in this paper our investigation results on the damage to reinforced concrete structures.

2. OUTLINE OF INVESTIGATION

The investigation was performed chiefly in principal cities (Santiago, Concepcion, and Viña del Mar) of Chile and the surroundings. Figure 1 was the investigation points and the locations of faults. Table 1 shows the list of the investigated buildings. The results of our detailed investigation on the underlined buildings of those listed in the table are as follows:

3. RESULTS OF BUILDING DAMAGE

2.1 Damaged buildings in Santiago City

a) B4. Sol Oriente 1 and 2

It is an apartment complex constructed of box-frame-type reinforced concrete in 2007 with 18 stories above ground (2 stories underground) (Photo 1). The building was damaged particularly on the first basement level of the underground self parking lot (Photos 2, 3). The structural features and the summary of damage are follows:

- Multi-story shear wall structure connected by flat slabs.
- Flexural tension failure occurred in three structure planes out of five 4-span ones on the first basement. An end main reinforcement ruptured.

The height of the north side multi-story shear wall on the basement is shorter by 1200 mm than on higher floors. In addition, only the northern end of the north side multi-story shear wall lacks an orthogonal wall (Figures 2, 3). Accordingly, the flexural strength of the north side multi-story shear wall is low on the first basement, likely resulting in the flexural tension failure in the south direction on the north side multi-story shear wall.

2.1 Damaged buildings in Concepcion City

Concepcion City is a city located approximately 105 km away from the hypocenter with a population of approximately 900 thousand. The earthquake brought eight buildings into serious damage, of which one was completely collapsed. We could obtain entry permits to and design documents of several buildings thanks to the cooperation of the Urban Development Bureau and the Police Bureau of Concepcion City.

a) B11. LINCOYAN 440 (Torre Livertad)

It is an RC wall flat slab structure constructed in 1973. The building has 17 stories above ground and one basement (with no underground car park), of which the three lower floors are occupied by commercial tenants and the fourth and above floors are used for housing (Photo 4). The machine room on the first basement was hardly damaged. The non-structural brick wall collapsed more seriously on upper floors. The walls on the first and second floors failed in flexural tension with the wall-end main reinforcement fractured or buckled (Photo 5). While the building was damaged particularly on the walls in the northeast and southwest directions, little damage was observed on the walls in the orthogonal direction. The damage concentrated on the wall footing is likely attributable to the lack of flexural strength of the T section web resulting from the respective bending deformation of two multi-story shear walls arranged in parallel due to the limited floor slab area in the staircase (Figures 4, 5, 6).

b) B13. Alto Rio

It is a reinforced concrete apartment complex constructed in 2008 with 15 stories above ground and two stories underground (parking lot). The building completely fell down from the base on the first floor (Photo 6, 7). Photo 7 shows the appearance of all the reinforcing bars on the first floor having been pulled out or cut down from the wall pillars and load-bearing walls on the first floor during the overturning of the building. Conversely, little damage was observed on the underground end plane walls. As shown in the plan view of Figure 7, the walls on the first floor and the basements (parking lot) are smaller than those on the second and above floors in both length and volume. This fact may have resulted in the damage particularly on the wall footing on the basements.

c) B14. SALAS 1343

It is an apartment complex constructed in 2007 with 13 stories above ground and an underground car park provided beside the building. It consists of two buildings arranged in L shape and connected with an expansion joint (Photo 8, Figure 8). It is constructed with a middle corridor in planar shape with more wall volume in the ridge direction. While the south side building was seriously damaged, the north side building was slightly damaged. The south side building seems to have suffered torsional vibration caused by stiffness eccentricity resulting from the many walls in the surrounding of elevators and staircases.

2.3 Damaged buildings in Viña del Mar City

Viña del Mar City is a city with a population of approximately 300 thousand. The 1985 Chile Earthquake (magnitude 7.8, 150 deaths) damaged many high-rise RC buildings within the city.

a) B21. Building Festival

It is an apartment complex (wall-type flat slab structure) with 14 stories above ground and one basement. It was severely damaged (Photo 9). The building had undergone seismic retrofitting such as the placement of additional concrete for walls and beams and the additional installation of walls in response to the earthquake in 1985, but suffered damage in the recent earthquake such as flexural tension failure and separation of concrete- added walls in the wall footing (Photo 10, Figure 9).

4. SUMMARY

The characteristics of the damaged buildings are as summarized below:

- Many of the damaged buildings are flat slab structures with no beam or frame column on the wall.
- The standard size of wall reinforcement is D10@250.
- At the wall end, confinement steel (or supplementary cross ties) is installed as well as bending reinforcement.
- The wall pillars, which are provided in place of pillars, are arranged longitudinally in the span direction for reasons of the layout of the parking lot. This fact may result in lower flexural strength and stiffness in the ridge direction.
- The length of a multi-story shear wall may be reduced in the underground parking lot space for the sake of vehicular traffic.
- A parking lot in the underground of the building may be

constructed in a shape protruded in one direction. In this case, the parking lot is enclosed only by the three-side retaining walls immediately below the building, with the other side of wall set back in the ridge direction.

- Some walls or wall pillars in the span direction are not connected to orthogonal walls. Such walls include a wall extending in the span direction on the side without a retaining wall and a piloti-type wall pillar (ground parking lot). They were damaged probably due to the low flexural strength when the tensile load was exerted to the side with no orthogonal wall.
- The buildings have a relatively large number of stories and a high slenderness ratio. As a result, the walls of such buildings mostly underwent flexural tension failure. In addition, lack of enough strength to bear the story shear force on the compression side may result in collapse of the building.

Most of the severely damaged or collapsed buildings were high-rise constructions with 13 or more stories and damage concentrated on the footing of the multi-story shear wall observed as a common characteristic. Conversely, most buildings in cities appeared to be sound and few buildings suffered intermediate damage, e.g. slight or medium damage. This may be a characteristic of damage to box frame constructions without plastic deformability. The damage can be considered generally minor, in view of the great magnitude of the recent earthquake at 8.8. While elaborate analysis is still required as to the extent of the seismic force applied to the buildings, given the fact that the damage remained so modest after the great earthquake, the Chilean Seismic Code seems to have functioned extremely well. One of the factors behind the major lack of damage to buildings in the recent earthquake was the positive introduction of the load-bearing wall.

The Chilean Seismic Code includes a provision likely encouraging the positive introduction of the load-bearing wall such as a strict restriction of deformation and reduction of the design seismic force according to the load ratio of the load-bearing wall. In Japan, the height of wall-type rigid-frame structures is limited to 15 stories. Given the modest damage to buildings in the recent Chile Earthquake and the continuous usability of post-earthquake buildings, Japan may also need to recognize anew the benefits of box frame constructions.

From the research perspective, a design method needs to be established to prevent such brittle failure after flexural yielding as observed in the recent seismic damage. Structural testing on flexural failure of load-bearing walls is not common in Japan and future research and development is awaited.

Acknowledgements:

This damage investigation was performed as a part of the international joint research project "Project for Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru" (JST-JICA Science and Technology Research Partnership for Sustainable Development Project, representative researcher: Fumio Yamazaki, professor at Chiba University, 2009-2014) and an earthquake disaster investigation of the Architectural Institute of Japan. In conducting this investigation, we obtained cooperation from many people including Professor Boroschek and Mr. Tomas of the University of Chile; Professor Cruz of the Pontifical Catholic University; an ex-trainee, Mr. Raul; and the JICA Chile Office. We wish to express our gratitude to them.

Abstract: Seismic fragility analysis is performed for RC frame building structures that are designed in line with the current Chinese seismic design code for buildings, considering the uncertainty of structural performance and earthquake ground motions. Site soil type, number of stories, and seismic fortification intensity are taken as the main variables of design parameter of reference structures. The global seismic damage index and the maximum inter-story drift ratio, which have close relationship with seismic damage of structural and non-structural components, are employed as the damage identifiers. Four damage levels, i.e. fully operational, operational, repairable, and collapse prevention, are considered in this study. For each frame structure, the probability exceeding each damage level under the earthquakes with each specified PGA is obtained by conducting nonlinear time history analysis with the aid of OpenSees. The fragility curves of each damage level are obtained by regression analysis using nonlinear least-squares method. The seismic fragility analysis results indicate that the required seismic performance objectives could be realized for RC frames structures designed by using the current Chinese seismic design code.

1. INTRODUCTION

Reliable earthquake risk evaluation requires a good analysis of seismic vulnerability of structures through appropriate seismic damage indicators. Seismic fragility is a measure of how vulnerable a building is to the damage under a given severity of earthquake. Generally, seismic fragility can be formulated by fragility curves or damage probability matrices. Fragility curves describe the conditional probability of attainment or exceedance of a certain damage state for a given intensity of ground excitation. The conditional probability is defined as

$$P_{ik} = P[D \geq d_i \mid Y = y_k] \tag{1}$$

where P_{ik} is the conditional probability of attainment or exceedance of the damage state d_i for a given intensity of ground excitation y_k; D is the variable that reflects the damage; and Y is the variable that reflects the intensity of ground excitation.

Different types of approaches have been proposed by the researchers to build fragility relationships, which could be classified into four categories (Rossetto and Elnashai 2003): (1) Empirical Method. This method, as the most practical way, is based on the statistical analysis on post-earthquake survey data of damage (Orsini 1999); (2) Judgmental Method. This method depends on expert experience and opinion; (3) Analytical Method. This method utilizes numerical analysis to simulate the behavior of structures under earthquakes. A variety of analysis procedures have been followed, ranging from elastic analysis (Mosalam et al. 1997), adaptive pushover analysis (Rossetto and Elnashai 2005), to nonlinear time history analysis (Seyedi et al. 2010). (4) Hybrid Method. This method is formed by the combination of more than one of the former three methods. The comprehensive review on the four types of approaches could be found in the literature (Rossetto and Elnashai 2003).

There is very limited information available about the seismic vulnerability of building structures designed according to the current seismic design code. In this study the seismic fragility analysis is conducted on RC frame building structures designed in accordance with current Chinese seismic design code by means of analytical method. The fragility curves corresponding to four damage levels quantified by the global seismic damage index and the maximum inter-story drift ratio are generated on the basis of regression analysis on the results of a large number of nonlinear time history analyses of numerical models. The global damage index proposed by the authors, different from those in the literature, takes the contribution of the individual structural member into account. The appropriateness of the current Chinese seismic design code is verified by the results of this work.

2. SEISMIC DAMAGE LEVELS

2.1 Seismic Damage Index

One of the best known and most widely used seismic

damage models for structural members is the Park-Ang model (Park and Ang 1985). A modification as follows is proposed by the authors for the Park-Ang damage model, eliminating its non-convergence problem at upper and lower limits:

$$D = (1-\beta)\cdot\frac{\delta_m - \delta_c}{\delta_u - \delta_c} + \beta\cdot\frac{\int dE}{F_y(\delta_u - \delta_y)} \tag{2}$$

where D is the damage index of the structural member; δ_c, δ_y, and δ_u, are the deformations at cracking, yielding, and ultimate limit state under monotonic loading, respectively; δ_m is the maximum deformation experienced during the loading history; F_y is the yielding strength; β is the combination coefficient; and $\int dE$ is the total dissipated energy during the loading history. The bigger one of the two ends is taken as the damage index of the structural member.

The damage index of a story in a building is derived based on the weighted average of damage scores of all the relevant members as follows:

$$D_i = \sum_{j=1}^{n} \lambda_j D_j^{(i)} \tag{3}$$

$$\lambda_j = \frac{D_j^{(i)}}{\sum_{k=1}^{n} D_k^{(i)}} \tag{4}$$

where D_i is the damage index of the ith story; $D_j^{(i)}$ is the damage index of the jth member at the ith story; and λ_j is the importance factor of the jth member. The global damage index of the entire building structure is taken as the maximum of the damage index of all stories, expressed as

$$D_G = \{D_1, \quad D_2, \cdots, D_i, \cdots, D_N\}_{\max} \tag{5}$$

2.2 Limit Values of Damage Parameters

Four damage levels, i.e. fully operational, operational, repairable, and collapse prevention, are considered. The global seismic damage index and the maximum inter-story drift ratio, which correlate well with seismic damage of structural and non-structural components respectively, are used as the damage indicators in this study. The seismic performance objectives for ordinary buildings, expressed as the coupling of expected damage levels with expected levels of earthquake ground motions, and the limit values of the two damage parameters corresponding to the attainment of each damage level are given in Table1. The return periods of the four intensity levels of earthquakes are 50, 475, 975, and 2475 years respectively, and the corresponding exceeding probability in 50 years are 63.2%, 10%, 5%, and 2%.

Table 1 Seismic Performance Objectives and Limit Values of Damage Parameters

Earthquake design level	Damage level	Global damage index	Maximum Inter-story drift ratio
Frequent earthquake	Fully operational	0.05	1/550
Occasional earthquake	Operational	0.20	1/250
Rare earthquake	Repairable	0.40	1/100
Extremely rare earthquake	Collapse prevention	0.80	1/50

3. ANALYTICAL MODEL

Site soil type, number of stories, and seismic fortification intensity are considered as the main variables of design parameter of reference building structures in this study. Three numbers of stories, 3, 6, 10, representing low-rise, mid-rise, and high-rise building respectively, are taken. Two seismic fortification intensities, intensity 7 and 8, are selected since most of the areas in China belong to the zone of intensity 7 and 8. In Chinese seismic design code there are four categories of site soil condition ranging from stiff to soft soil, i.e. Class I, II, III, and IV, each of which is further classified into three design groups according to the characteristic period of the earthquake. The design group reflects the influence of the epicentral distance. All the 12 types of site soil are taken into account here. Therefore, in total 72 frame structures are designed in accordance with Chinese seismic design code. The typical plan layout of reference building structures is shown in Figure 1. The material strengths are chosen as follows: standard yielding strength of steel reinforcement is 335 MPa, and standard concrete cubic compressive strength is 30 MPa.

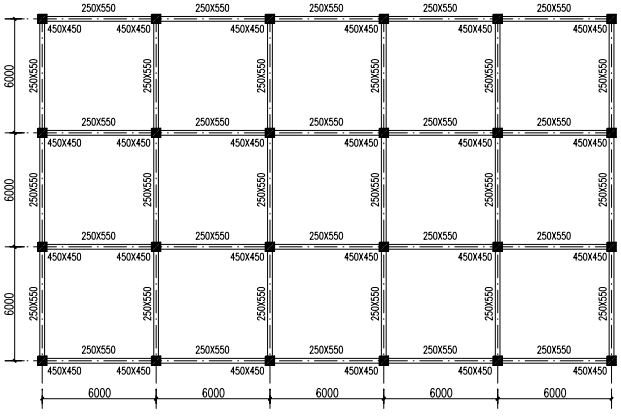

Figure 1 Typical Structural Plan Layout (unit: mm)

The analytical model is constructed with the aid of the program OpenSees. The flexibility-based fiber model is applied. The modified Kent-Park model for confined and unconfined concrete, proposed by Scott et al. (1982), is

employed for the core concrete and cover concrete respectively. The constitutive model proposed by Filippou et al. (1983) is employed for steel reinforcement. The rigid zone at the member joint is considered in line with the Chinese design code for RC tall buildings.

4. UNCERTENTY MODELING

According to Eq.(1), the seismic fragility assessment results are mainly affected by the uncertainty existing in the demand of earthquake response and the capacity of the structural system. The demand and capacity depend significantly on the earthquake ground motions and the properties of the structure. It has been found that one of the main sources of uncertainty of an RC structure is the inherent variability of material strengths (Ji et al. 2009).

4.1 Variability of Material Strength

In this study the compressive strength of concrete and yielding strength of steel reinforcement are chosen as the principal random variables. As the randomness of compressive strength of concrete is concerned, normal distribution is assumed for convenience according to the statistical survey of the test results in different areas in China. The coefficient of variance is taken as 14%. Similarly, normal distribution is assumed for steel reinforcement, and the coefficient of variance is taken as 5%.

To reduce the computation efforts effectively, the advanced sampling method, Latin Hypercube Sampling proposed by Mckay et al. (1979), is utilized for the combination of the properties of two constituent materials. The distribution of sampling material strength is shown in Figure 2. The abscissa represents the compressive strength of concrete, and the ordinate represents the yielding strength of steel reinforcement.

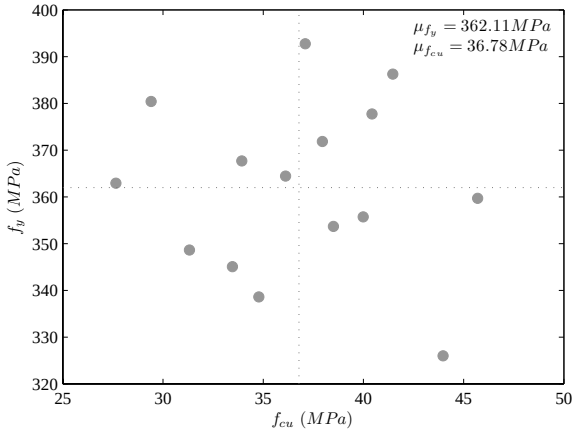

Figure 2 Material Strength of Sample

4.2 Earthquake Ground Motions

The main source of uncertainty exists in the seismic demand due to the uncertainty of earthquake ground motions resulted by the complexity of source mechanism, path attenuation, and site effects. In this study the natural earthquake ground motion records are carefully selected in line with the design acceleration spectra specified in Chinese seismic design code. There are 641 pairs of natural earthquake ground motions collected by the authors' laboratory. All the ground motions are classified into 12 groups in accordance with Chinese seismic design code. In each group 10 pairs of ground motions whose elastic acceleration spectra agree best with the design spectra specified in the code are picked out from the database. In total 120 pairs of ground motions are used as the input motions in the time history analysis. The comparison between the mean acceleration spectrum of the selected ground motions and design spectrum for four groups is shown in Figure 3, which shows good agreement.

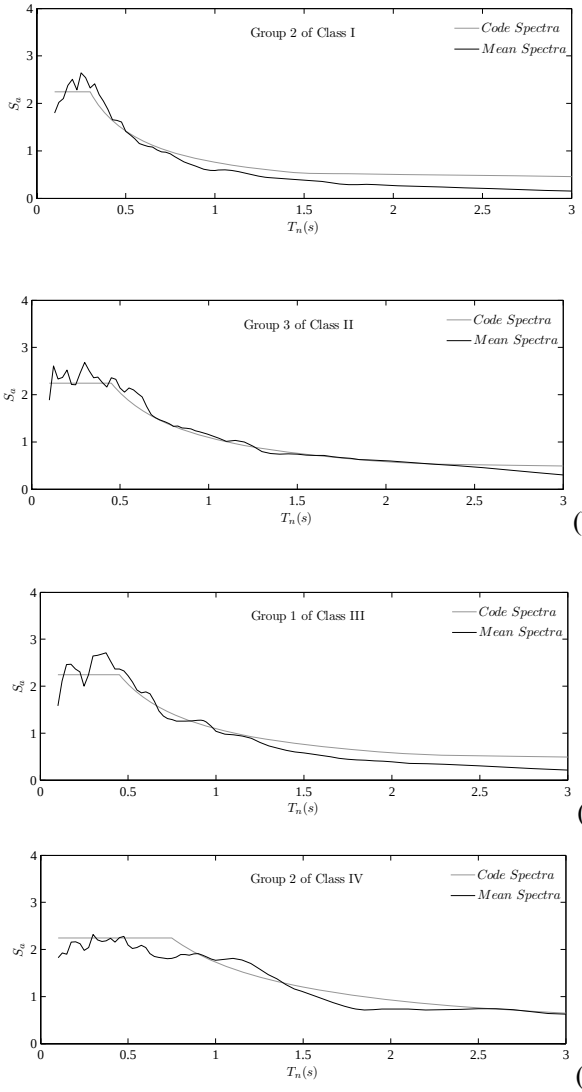

Figure 3 Comparison of Acceleration Spectrum: (a) Design Group 2 of Class I, (b) Design Group 3 of Class II, (c) Design Group 1 of Class III, and (d) Design Group 2 of Class IV

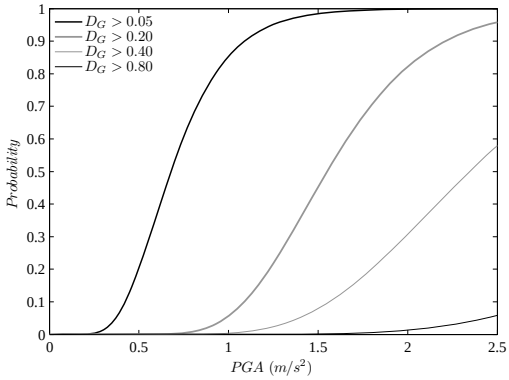
For each frame structure, one group with 10 pairs of selected ground motions covering the uncertainty aspects, which is in line with the design group of site soil for determining the strength and steel reinforcement of the structure, is used as the input motions.

There are several commonly used intensity measures

for seismic fragility assessment, such as peak ground acceleration (PGA), spectral acceleration, and spectral displacement. In this study PGA is taken as the only parameter of intensity measure. The accelerations of input motions are scaled according to the required PGA. Five discrete PGA values, 0.5m/s^2, 1.0m/s^2, 1.5m/s^2, 2.0m/s^2, and 2.5m/s^2, are set for the structure designed with the fortification intensity of 7. Six discrete PGA values, 0.5m/s^2, 1.0m/s^2, 1.5m/s^2, 2.0m/s^2, 3.0m/s^2, and 4.0m/s^2, are set for that of intensity 8.

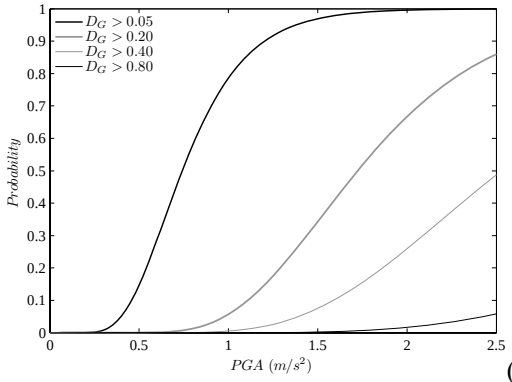
5. FRAGILITY CURVES

5.1 Derivation of Fragility Curves



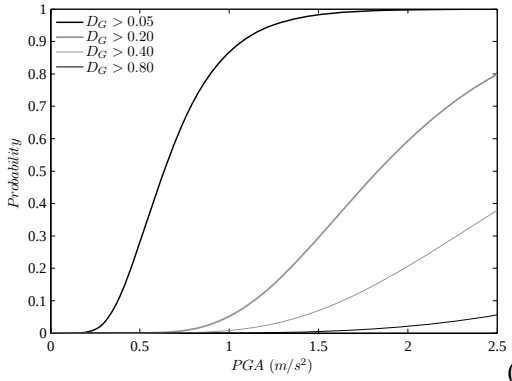
In total there are 59400 numerical simulations of time history analysis for 72 reference building structures. A MATLAB code is written to control the execution of analysis including modification of the input data, running OpenSees, and post-processing the simulation results. The probability of exceeding the limit of global damage index and maximum inter-story drift ratio specified for each damage level under a given intensity of ground excitation is obtained by using Eq.(1). Lognormal distribution as follows is assumed for regression of the fragility relationship according to the work (Sucuoglu et al. 1998):

$$P_i = \Phi\left[\frac{\ln Y - \lambda}{\zeta}\right] \tag{6}$$



where Φ is the standard normal accumulative distribution function; Y is the intensity measure of ground motions, and here it is PGA; and λ and ζ are function parameters, indicating the mean and standard deviation of $\ln Y$. Nonlinear curve-fitting techniques are used to optimize the two function parameters. Accordingly, the fragility curves are derived.

5.2 Parameter Analysis



The derived fragility curves of frame structures with same fortification intensity and different stories are shown in Figures 4~7. The variation of exceeding probability with number of stories is not distinct. Generally, the slope of curve gets steeper for slighter damage level.

5.3 Verification of Seismic Performance Objectives

Based on the fragility curves derived above, the average probability of exceeding each damage level at each specified earthquake design level is obtained to verify the seismic performance objectives listed in Table 1. The results are shown in Tables 2 and 3. In general the exceeding probability of maximum inter-story drift ratio is a little larger than that of global damage index. All the exceeding probabilities are less than 10%. The multiple seismic performance objectives could be realized with high reliability for the buildings structures designed in line with the current Chinese seismic design code.

Table 2 Average Exceeding Probability of Global Damage Index (unit: %)

Design earthquake level	Fully operational	Operational	Repairable	Collapse prevention
Frequent earthquake	5.17	0	0	0
Occasional earthquake	90.17	4.88	0.50	0.04
Rare earthquake	97.78	28.51	4.63	0.26
Extremely rare earthquake	99.94	83.98	37.73	3.84

Table 3 Average Exceeding Probability of Maximum Inter-story Drift Ratio (unit: %)

Design earthquake level	Fully operational	Operational	Repairable	Collapse prevention
Frequent earthquake	8.46	0.01	0	0
Occasional earthquake	84.86	9.42	1.21	0.01
Rare earthquake	94.72	33.47	7.19	0.15
Extremely rare earthquake	99.51	79.60	38.87	5.55

6. CONCLUSIONS

The seismic fragility relationships of RC frame building structures designed in accordance with current Chinese seismic design code are derived from the results of a large number of nonlinear time history analysis, which take the uncertainty of structural performance and earthquake ground motions into account. The main variables of design parameter of frame structure include site soil type, number of stories, and seismic fortification intensity. Fragility curves are obtained for four damage levels, i.e. fully operational, operational, repairable, and collapse prevention, using global seismic damage index and maximum inter-story drift ratio as damage identifiers. The reliability of multiple seismic performance objectives predefined for ordinary buildings are checked in terms of exceeding probability. The results indicate that the performance objectives of the structures designed according to Chinese seismic design code could be implemented appropriately.

STUDY ON INFLUENCES OF CONSTRUCTION JOINTS AND MULTI-LAYERED LONGITUDINAL BARS ON RESTORING FORCE CHARACTERISTICS IN R/C CANTILEVER BEAMS

Koshiro Nishimura

Assistant Professor, Dept. of Architecture and Building Engineering, Tokyo Institute of Technology, Japan
nishimura.k.ac@m.titech.ac.jp

Abstract: It is important to estimate stiffness of R/C beams accurate enough. However, studies on influence of multi-layered longitudinal bars and construction joints are limited. It is necessary to make clear those influences in view of the development in the design methods in these days. In this study, the influences of the construction joints and multi-layered longitudinal bars upon flexural strength, stiffness, cracks and damages were examine. R/C cantilever specimens were subjected to cyclic lateral loads. Parameters in this experiment were arrangement of longitudinal bars, place of the construction joints, and condition of joint surfaces. As results, the construction joint degraded initial cracking strengths, but there were no remarkable difference in yield strength and stiffness between with and without the joints. And then, stiffness up to flexural yielding was considered based on the test results.

1. INTRODUCTION

It is important to estimate stiffness of R/C beams accurate enough. However, studies on influence of multi-layered longitudinal bars and construction joints are limited. Moreover, strengths and stiffness in R/C members are often calculated as there are no construction joints in seismic design. It is necessary to make clear those influences in view of the development in the design methods in these days.

In this study, the influences of the construction joints and multi-layered longitudinal bars upon flexural strength, stiffness, cracks and damages were examine. R/C cantilever specimens were subjected to cyclic lateral loads. Parameters in this experiment were arrangement of longitudinal bars, place of the construction joints, and condition of joint surfaces.

2. EXPERIMENTAL PROGRAM

2.1 Specimens

Eight cantilever beam specimens were prepared for the tests. Three of them had construction joints on beam sections, which had four D10 of longitudinal bars in single layer on each top and bottom side. The other five specimens had no construction joints. Parameters for those five specimens were diameter, which were D6 and D10, respectively, and numbers of layer for longitudinal bars, which were single layer, double layer, and single with center layers. Figure 1 shows detail of specimens. The longitudinal bars were welded on steel anchor plates at the top and bottom. Table 1 and Table 2 show the parameters of specimens and material properties for concrete, and properties for deformed bar, respectively. Deformed bars D4 were used for transverse bars, which the beams were designed not to fail in shear. And Figure 2 shows condition for construction joints. The construction joint in B-D10-4, named normal joint, were roughen by wire brush next day to concrete placing in order to remove laitance on the surface. The smooth joints were formed by lumber board.

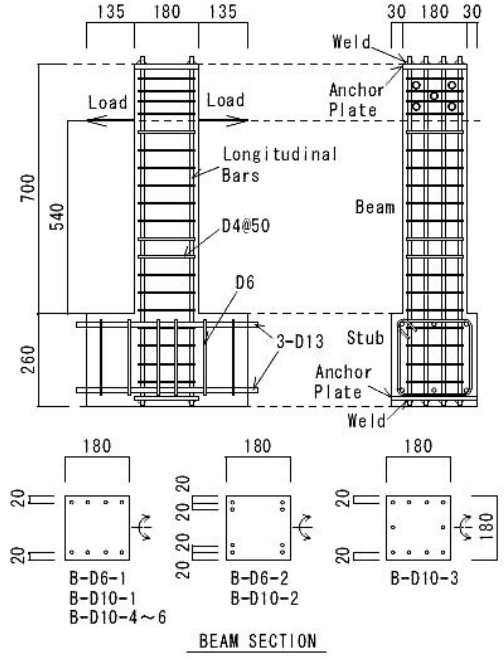

Figure 1 Details of Specimens

Table 1 List of Specimens and Material Properties for Concrete

Name of Specimens	Longitudinal Bars (p_g: total area of bars/section area)	Construction Joint	Concrete		
			Compressive Strength [N/mm^2]	Splitting Tensile Strength [N/mm^2]	1/3 Secant Modulus [N/mm^2]

2.2 Loading Setup and Measurement System

The cantilever beam specimens were subjected to cyclic loading as shown in Figure 3. Two hydraulic jacks attached to the specimen applied only tension load in this test. Steel plates were attached on the top of specimens in order to make bending moment distribution linear in shear span of 540 mm. The Figure 3 also shows measurement setup that lateral displacements and rotation on top and bottom of the beams were measured. Deformations in this study were defined as shown in a right figure of Figure 3. A rotation of beam, R_X, are given by dividing δ_X by initial shear span of 540 mm, and a rotation θ_X are given by subtracting rotation on bottom from that on top those were measured as shown in the left figure of Figure 3.

3. TEST RESULTS AND CONSIDERATION

3.1 Outline of Test Results

Figure 4 shows a test result of specimen B-D10-1. As shown in this figure, the beam yielded in flexural. Axial deformation grew tensile side after yielding and was almost constant under unloading. Therefore the axial deformation accumulated to tensile side. As Shown in the P_X-R_X curve, good loops were observed because longitudinal bars contributed to energy dissipation. Those were caused by no restraint in axial direction and easier bond condition than anti- symmetric bending or hooked anchorage of longitudinal bars at the end. These tendencies were observed in all the specimens in this study.

3.2 Influence of Multi-Layered Longitudinal Bars

In Figure 5, the test result of beams with double layered longitudinal were compared with that of single layered one, where left one shows results for D6 of longitudinal bars and right one shows results for D10. Three tendencies were observed in this figure; double layered one had almost the same yield strength as single layered one in initial loading direction, double layered one had lower yield strength than single layered one in the opposite direction, and

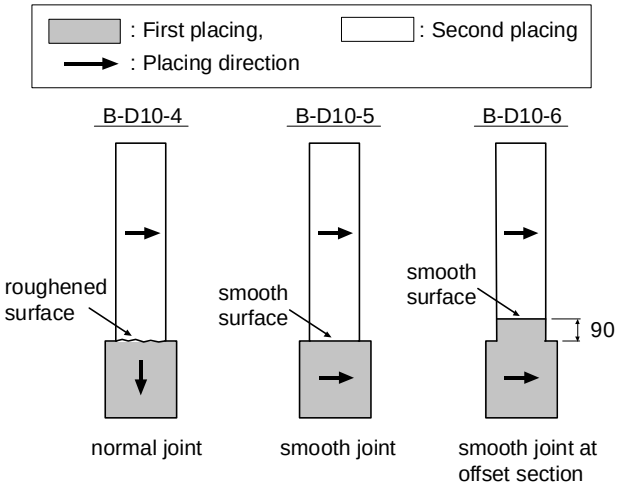

Figure 2 Construction Joints

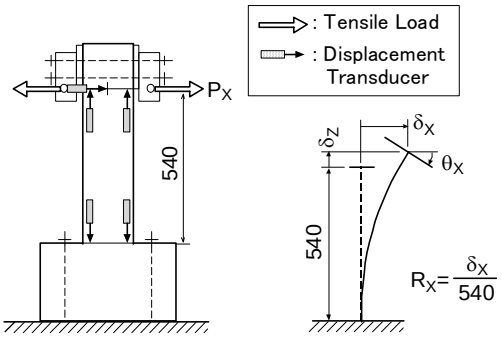

Figure 3 Loading Setup and Deformations

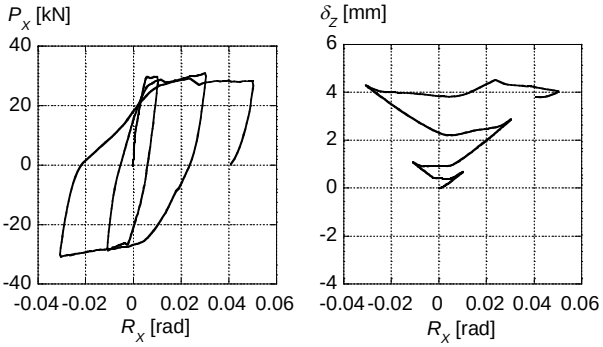

Figure 4 Test Result of Specimen B-D10-1

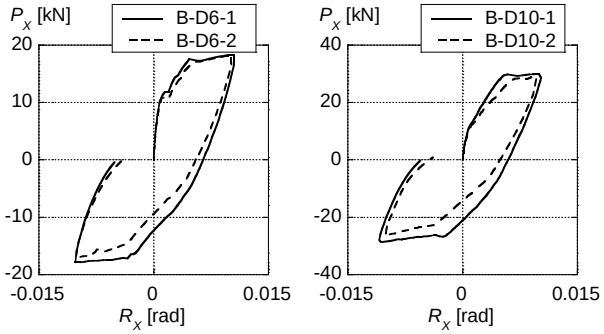
displacement for yielding in double layered one was larger than that in single layered one. The second tendency must be due to stress in longitudinal bars in interior layer of compressive side in the double layered beam, which was tensile stress under initial loading and compressive stress under the opposite side loading. It was considered that the third tendency depended on yielding in longitudinal bars in interior layer of tensile side in the double layered beams. In this test, rigidities must be obviously degraded after yielding in the longitudinal bars in interior layer of tensile side. Figure 6 shows photos of the specimens after the cyclic loading test. As shown in this figure, cracks in the double layered beam were more dispersed than those in single layered beam.



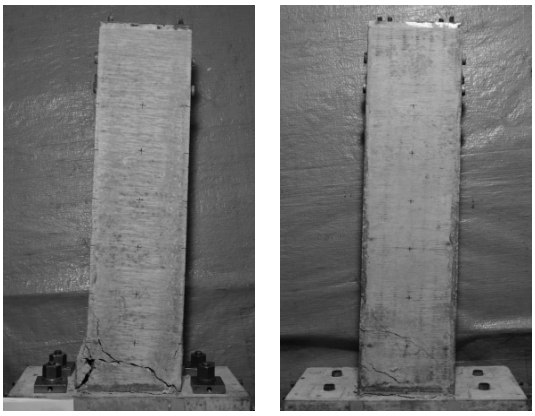


Figure 5 Comparison between Beams with Single and Double Layered longitudinal bars

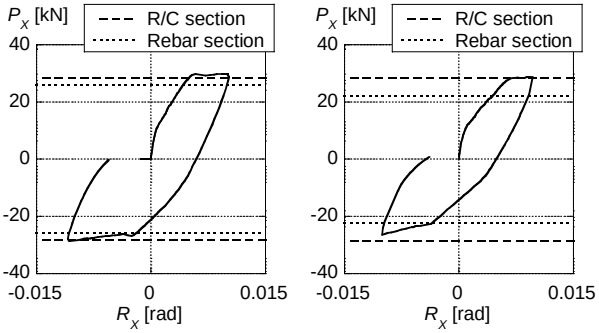
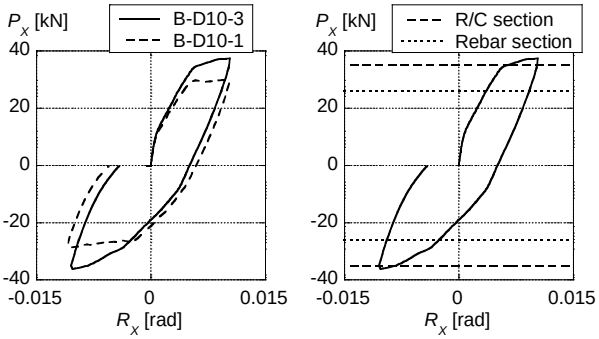


B-D10-1 B-D10-2

Figure 6 Photos of specimens after the tests



Two Calculations for yield strengths are shown in Figure 7 those are R/C section and longitudinal bars section without concrete. The yield bending moment were calculated with assumptions of rigid-perfectly plastic body in materials, which yield strengths of concrete and deformed bars were compressive strength in Table 1 and yield strength in Table 2, respectively. As shown in Figure 7, the yield strength under initial loading showed good agreement with R/C section strength of calculation, however, in the opposite direction, the strength of test results agreed with longitudinal bars section strength. This is because, as mentioned above, concrete resisted very low stress due to axial tensile deformation.

Figure 8 shows strength and deformation for yielding in B-D10-3. As shown in a left figure, longitudinal bars at the center of beam depth were contributed to yield strength and yield deformation was almost the same as B-D10-1. The yield deformation seemed to depend on yielding in longitudinal bars of exterior layer of tensile side. As shown in a right figure of Figure 8, the yield strength under initial loading showed good agreement with calculated R/C section strength, however there was no clear yielding up to -0.01 rad in the opposite direction.

B-D10-1 B-D10-2

Figure 7 Yield Strength for B-D10-1 and B-D10-2

B-D10-3

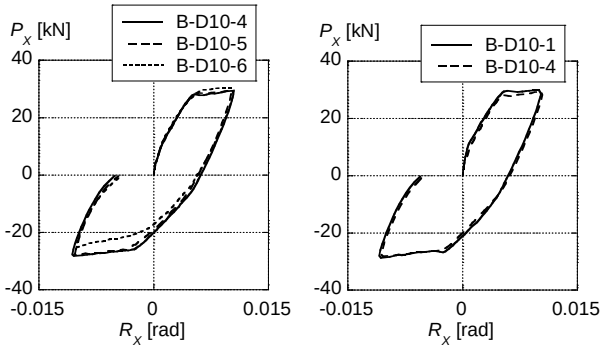
Figure 8 Strength and Deformation for Yielding in B-D10-3

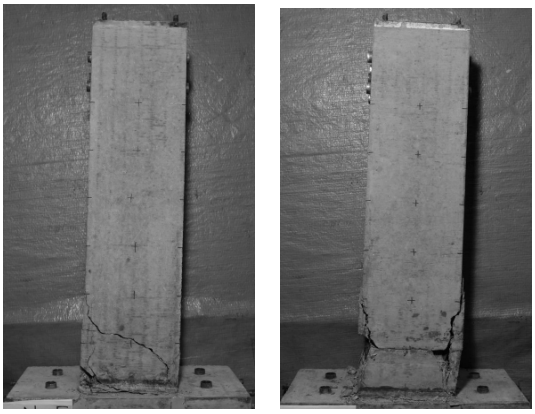
3.3 Influence of Construction Joints

A left figure in Figure 9 shows difference due to condition in construction joist. B-D10-4, B-D10-5, and B-D10-6 had normal joint at the end of beam, smooth joint at the end of beam and at the section of 90 mm apart from the end, respectively. Figure 10 shows photos of the specimens after the tests those had normal joint and smooth joint apart from the end of beam, respectively. As shown in a left figure in Figure 9, B-D10-4 and B-D10-5 had almost the same curves. B-D10-6, which had offset jointed section, had a little larger yield strength than the other two specimens in initial loading direction, and obvious lower strength in the opposite side loading because of damages at the offset construction joint, as shown in Figure 10.

In a right figure of Figure 9, the test result of B-D10-4, which had normal joint, is compared with that of B-D10-1 that had no construction joint. These two curves were almost the same. In the detail, B-D10-1 showed a little larger yield strength than B-D10-4 that could be seen in comparison between B-D-10-4 and B-D10-6. It can be said from these

comparison that the specimens without joint at the end of beam showed larger yield strength than the specimens with construction joint at the end of beam. It can be considered this difference is due to tensile stress in concrete at the end section of the beam. As shown in Figure 11, it was observed that bending crack in the beam without joint grew toward inside of stub as against bending crack with joint grew along the joint. Therefore, tensile resistance in concrete at the end of beam without the joint must be larger than that with the joint.





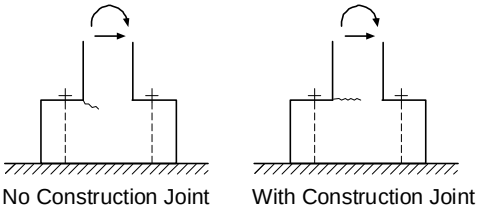


Figure 9 Difference due to Condition in Construction Joint

B-D10-4 B-D10-6

Figure 10 Photos of specimens after the tests

No Construction Joint With Construction Joint

Figure 11 Cracking at the End of Beam

Figure 12 shows initial stiffness in detail. In this figure, initial P_X-R_X curves and R_X-θ_X curves of test results were compared with calculation. In calculation, contribution of longitudinal bars and shear deformation of concrete were considered, where poisson's ratio and coefficient concerning relationship between mean shear stress and shear deformation for concrete were assumed as 0.2 and 1.2, respectively. A clear span of beam is assumed as 540 mm, as shown in Figure 1. In Figure 12, solid lines are results for specimens without construction joint, and broken lines are for specimens with construction joints. Those curves were normalized by dividing test results by bending strength and deformation at initial cracking, which the bending strength for initial cracking was calculated as following equation (Architectural Institute of Japan, 1999).

$$M_c = 0.56\sqrt{f_C}Z_e + ND/6 \quad \text{(N mm)} \quad (1)$$

In above equation, f_C, Z_e, N, and D are compressive concrete strength, section modulus including contribution of longitudinal bars, axial load, and depth of the member, respectively. As shown in a left figure of Figure 12, loads in the specimens with construction joints were lower than that without joint. On the other hand, as shown in a right figure, normalized R_X-θ_X curves were almost the same. These means influence of construction joints could be seen in tensile resistance of concrete at the end of beams and the other effects like a deformation could be neglected in this test.

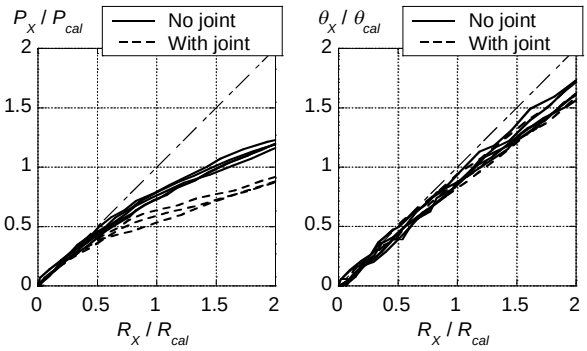

Figure 12 Initial Stiffness and Initial Rotation

3.4 Comparison with Tri-Linear Model

The restoring force characteristics of R/C members are often modeled in tri-linear curves, which two points of changing rigidities are initial cracking and yielding against bending, and third rigidity is very small or zero. Here, the test results are compared with the calculated tri-linear model.

The calculation for initial stiffness, bending moment of initial cracking, and yield strength were mentioned above. Therefore, the tri-linear model was completed if yield deformation can be estimated. In AIJ standard (Architectural Institute of Japan, 1999), the following equation is shown as degrading ratio of yield point secant stiffness, α_y.

$$\alpha_y = \left(0.043 + 1.64np_t + 0.043a/D + 0.33\eta_0\right)\left(\frac{d}{D}\right)^2 \quad (2)$$

α_y is based on more than 200 experimental data, which parameters were with in p_t=0.4 to 2.8 %, a/D=2.0 to 5.0, and η_0=0 to 0.55. The yield point secant stiffness is given by multiplying α_y and initial bending stiffness of concrete section with no longitudinal bars and no shear deformation. In Eq.(2), n is a ratio for young's modulus of deformed bar to concrete; p_t is a ratio for area of tensile longitudinal bar to total section; a is a shear span; η_0 is a ratio for axial force to maximum force of concrete section; and d is effectiveness depth of member concerning tensile longitudinal bars. α_y is basically used to R/C section with single layered

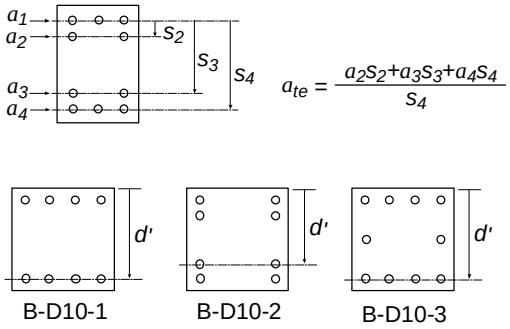

Figure 13 Equivalent Coefficient a_t and d in Eq.(2)

longitudinal bars, therefore some kind of modeling is needed for adopting to R/C section with multi-layered longitudinal bars. The multi-layered longitudinal bars were usually converted into single layer, but this method didn't adapt to the test result of B-D10-3 due to longitudinal bars at the center of depth. In this paper, p_{te} is assumed as the following equation, and is substituted for p_t in Eq.(2).

$$p_{te} = \frac{a_{te}}{A} = \left(\sum_{i}^{n} a_i s_i \right) \Big/ \left(A s_n \right) \tag{3}$$

In above equation, A is total section area, a_i is a sum of section areas of longitudinal bars in the same layer, s_i is a distance from an exterior layer in compressive side, and a subscript i is a number of order for the layer from the exterior layer so that subscript n means an exterior layer in tensile side. An example for a_{te} is shown in an upper figure of Figure 13. In this example, a_{te} is the same as sum of a_3 and a_4 if $a_2 = a_3$ and $s_2 + s_3 = s_4$. Regarding d in Eq.(2), d' shown in a lower figures of Figure 13 were adopted those were decided as a distance from compressive edge to a layer of longitudinal bars that was suggested to yield at the yield point of R/C beam. In the other word, a person who calculates α_y needs to judge d'. Figure 13 shows comparison between the test results and the tri-linear model. As shown in these figures, tri-linear models show good agreements with the test results. It is noticed that the methods of calculating yield deformation shown here need to examine with more experimental data including data of beams and columns with high strength material.

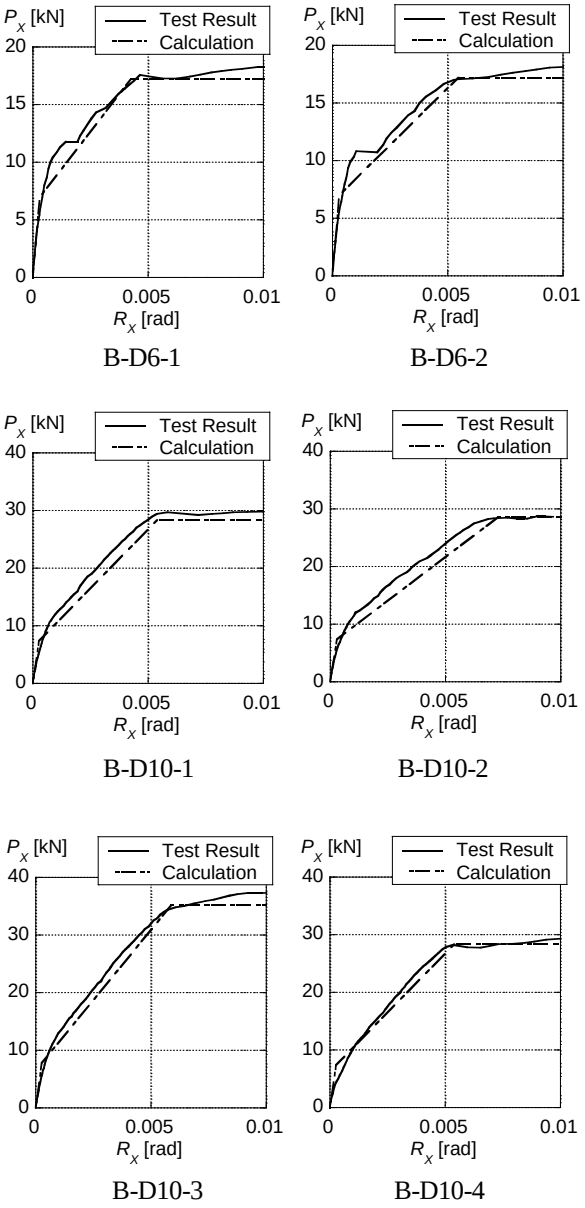

Figure 14 Comparison with Tri-Linear Models

4. CONCLUSIONS

In this study, eight cantilever beam specimens were prepared for cyclic loading tests, and the influences of the construction joints and multi-layered longitudinal bars upon flexural strength, stiffness, cracks and damages were examine. As results, the following conclusions could be found.

1. Though the construction joints at the end of the beam degraded initial stiffness, cracking strength, and yield strength because of lower resistance against tensile stress in concrete at the joints, there were no significant differences in load- displacement curves between beams with and without the joints.
2. The construction joint apart from the beam end, which is the same distance as a half beam depth, caused obvious loss of strength in cyclic loading.
3. The beams with double layered longitudinal bars showed larger yield deformation, and lower yield strength in the opposite directional loading against first loading, than the beams with single layered longitudinal bars.
4. A Tri-linear model written in AIJ standard (Architectural Institute of Japan, 1999) showed good agreement with the test results.

Abstract: Bonding action between concrete and rebar plays one of the most important roles for reinforced concrete structure. Investigation on the bonding action is, however, very difficult since strain gauges are usually used to measure the strain distribution of the rebar and they can disturb the bonding action itself. In this research, Neutron diffraction technique was applied to measure the strain distribution on a rebar in a concrete. Normal concrete does not have enough permeability because of hydrogen contained in the concrete. Therefore, concrete was dried absolutely to get high permeability. The pull-out test with the rebar with the diameter of 10mm embedded in the reinforced concrete specimen was conducted and the strain distribution was measured with the neutron diffraction technique. Results showed the accuracy of the measuring system with the Neutron and non-linearity of the bonding action.

1. INTRODUCTION

Bonding action between concrete and rebar plays one of the most important roles for reinforced concrete structure. If the bonding strength is not strong enough or the anchorage length of rebar is not enough, the rebar is pulled out before yielding under tensile stress. Its failure mechanism is called 'bonding failure'. If the bonding failure occurs, the structure cannot keep its unity. Therefore the bonding failure is classified as 'brittle failure'. Investigation on the bonding action is, however, very difficult since strain gauges are usually used to measure the strain distribution of the rebar and they can disturb the bonding action itself.

In this research, neutron diffraction technique, which does not need any sensor to paste on rebar, was applied to measure the strain distribution on a rebar in a concrete. Elastic Strain of rebar embedded in concrete can be measured from outside of the concrete by measuring diffraction angle of neutron. The engineering diffractometer for stress analysis, RESA-1 **(Suzuki et al. 2008)**, in the Japan Research Reactor No. 3 (JRR-3) at the Japan Atomic Energy Agency was utilized for the test. Normal concrete, however, does not have enough permeability because of hydrogen contained in the concrete. Therefore, concrete was dried absolutely to get high permeability. In this paper, a pull-out test was conducted under moment and shear forces with various tensile force levels. The same test with same tensile force levels were also conducted with a specimen of which rebar has strain gauges to measure strain. The comparison of test results from RESA and strain gauges is also discussed.

2. OUTLINE OF NEUTRON DIFFRACTION TECHNIQUE

The engineering diffractometer for stress analysis, RESA-1 is located in the Tokai Research Area of Japan Atomic Energy Agency. The outline of the RESA-1 is shown in Photo 1. Monochromatic neutron beam is obtained from the Japan Research Reactor No.3 (JRR-3), and irradiated to the specimen at the angle of θ. The diffracted neutron is detected by the detector. The diffracted angle becomes slightly different from θ according to the intermolecular distance. The number of neutrons diffracted at each angle is measured by the detector. The relationship between diffracted angle and number of neutrons follows Gaussian distribution as shown in Figure 2 if there is no error contained. The average strain of the specimen at hatched area in Figure 1 is calculated as Equation (1).

$$\varepsilon = -\frac{2\theta - 2\theta_0}{2} \frac{1}{\tan(2\theta_0/2)} \quad (1)$$

Where; θ is diffraction angle at the peak intensity, and θ_0 is the diffraction angle without stress (initial angle).

Since the measured strain, ε, is calculated according to the intermolecular distance, ε is elastic strain. Therefore, stress can be obtained by multiplying Young's modulus to ε.

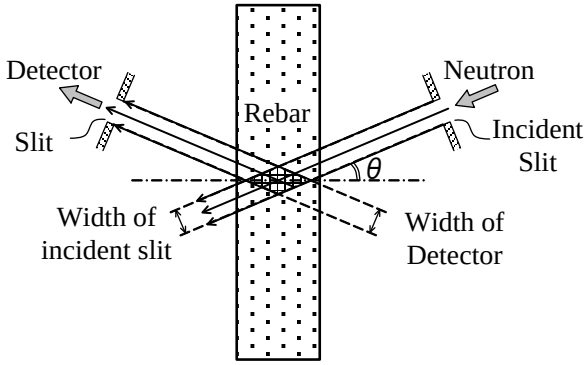

Figure 1 Outline of Measurement

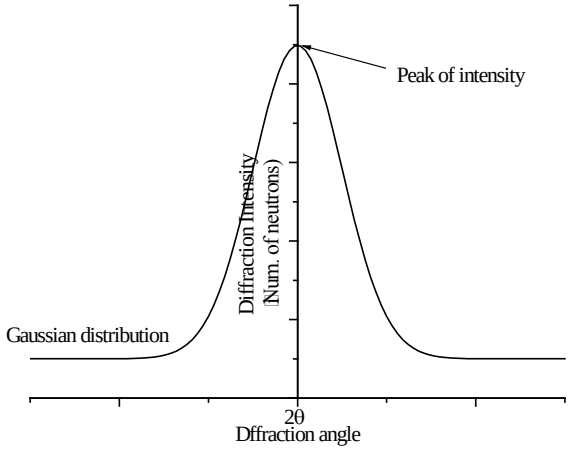

Figure 2 Diffraction Profile

2. OUTLINE OF LOADING SYSTEM

Applied loading system is shown in Figure 3. Tensile force was applied by the center hole jack, which was measured by the load cell. A steel spring was also used to maintain the applied force constant. The shear force and moment distributions in the specimen are shown in Figure 4. The loading system reproduces the shear and moment distributions as beam and column.

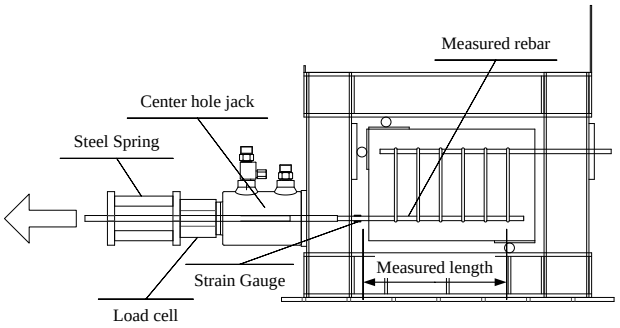

Figure 3 Loading System

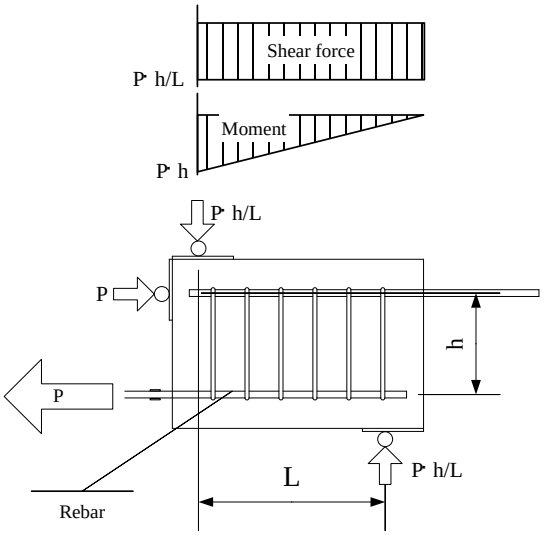

Figure 4 Shear force and moment distribution

2. OUTLINE OF SPECIMEN

2.1 Dimensions of Specimen

Dimensions of the specimen are shown in Figure 5. The rebar measured by RESA-1 is D10, deformed bar with the diameter of 10mm, which is embedded to the concrete with the length of 370mm. Specimen has D6 stirrups with the pitch of 50mm. The embedded length was decided so that the rebar yields at outside of the concrete and bonding failure does not occur. Two strain gauges were pasted to the

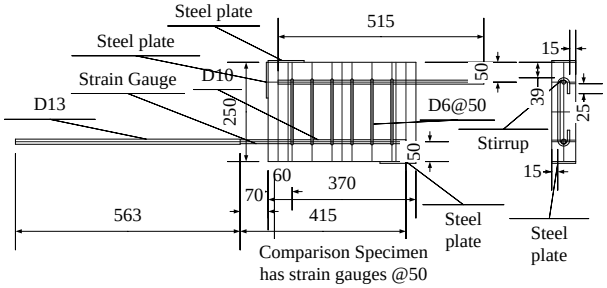

Figure 5 Dimensions of the Specimen

rebar outside of the concrete to measure the strain of the rebar. Two specimens were constructed. One of them had strain gauges inside of the concrete. The location of the gauges were 30mm, 80mm, 135mm, 185mm, 235mm and 285mm from the surface of the specimen as shown in Figure 5.

2.2 Material Properties

Design strength of concrete was 24 N/mm^2. Maximum size of rough aggregates was 20mm. Water-cement ratio was 59.4% and fine aggregate ratio was 47.7%. Material test was conducted at 42 days old. The average compression strength was 33.4N/mm^2 and tensile strength was 2.8N/mm^2. The specimens were moved into an absolute dry oven in Building Research Institute at 16 days old for 2 weeks with the temperature of 105 Celsius. Then the temperature in the oven was cooled down to 10 Celsius in 24 hours. The weight of the specimen reduced from 14306.4g to 13539.9g. From the concrete cylinder test, which was with the specimen in the oven, the compression strength was 26.9N/mm^2 and tensile strength was 2.0N/mm^2 at 31 days old.

Steel bar of D10 was also tested to find the yield strength and Young's modulus. The yield strength was 357N/mm^2 and Young's modulus was 184,826N/mm^2.

3. TEST RESULTS WITH RESA-1

3.1 Loading History

Tensile force was induced to the rebar with the loading system shown in Figure 3. The load levels of 20N/mm^2、145N/mm^2、270N/mm^2、145N/mm^2、270N/mm^2、20N/mm^2 were applied in order.

3.2 Outline of Measurement

The grid strain of Fe atom was measured by RESA-1. The wavelength of neutron beam was 2.0 A, and the diffraction angle 2θ was about 58.5 deg. The dimensions of the neutron beam was 5mm in width and 10mm in height. The neutron beam path is shown in Figure 6. The average strain in the hatched region in Figure 6 is measured by RESA-1.

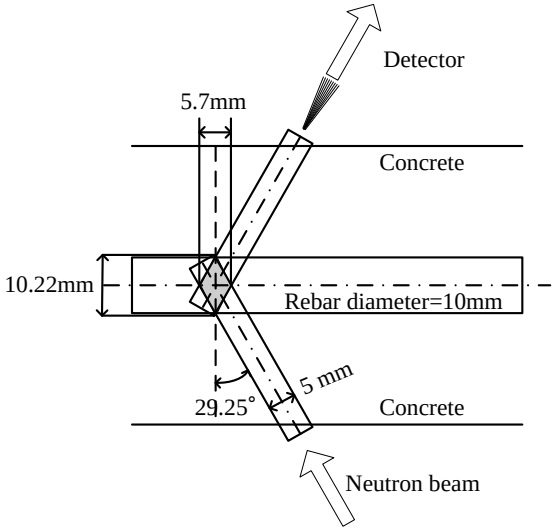

Figure 6 Neutron Beam Path

From the preliminary measurement, the neutron beam was irradiated for 30 minutes at each point to get better diffraction profile. Every 5mm to 10mm point was measured. The measured points were limited due to the time limitation of the RESA-1 machine time (96 hours in total).

3.3 Test Results

Figure 7 shows the Gaussian distribution approximation error at each force level along with the rebar. The errors at most of all points were less than 0.003, but the error becomes larger at every 50mm. It shows the location of the stirrups.

The strain at each point was calculated with Equation (1) from the measured diffraction angle profiles. The diffraction angle measured at 300mm from the surface at the second 22 N/mm^2 tensile force was applied as $2\theta_0$. The strain along with the rebar at each force level is shown in Figure 8. Note that the calculated strain is the absolute elastic strain. The strain distributions also show disturbed at every 50mm as Figure 7.

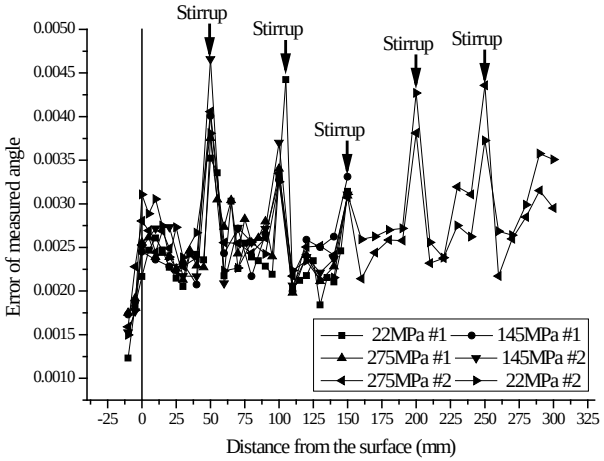

Figure 7 Gaussian Distribution Approximation Error

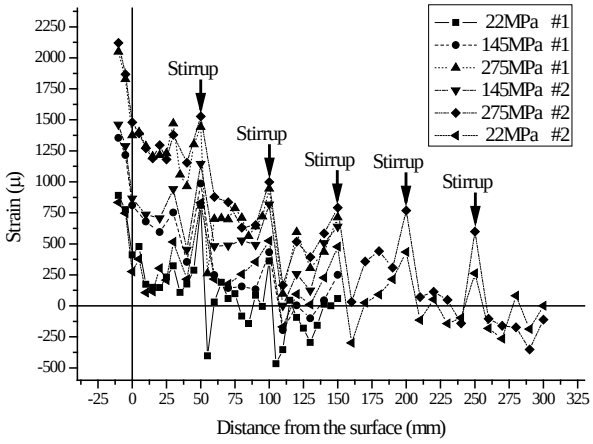

Figure 8 Strain Distributions Measured by RESA-1

The stress distributions along with the rebar at 275N/mm^2 tensile force are shown in Figure 9. The stress at

each point is calculated by multiplying the strain shown in Figure 8 by the Young's modulus of 2.24×10^5 N/mm^2.

The stress distributions at the first and second loadings were almost the same and the effect of unloading was not observed.

The stress distributions along with the rebar at 145 N/mm^2 and 22 N/mm^2 tensile forces are also shown in Figure 10 and Figure 11, respectively. Different from Figure 9, the slope of the stress distribution at the second loading is gentler than the first time. At the second loading of 145 N/mm^2 loading, the specimen suffered 275 N/mm^2 loading once, and the second time of 22 N/mm2 loadings suffered 275 N/mm^2 − 145N/mm^2 − 275N/mm^2 loadings. It can be said that the nonlinearity due to higher load causes the change of the slope.

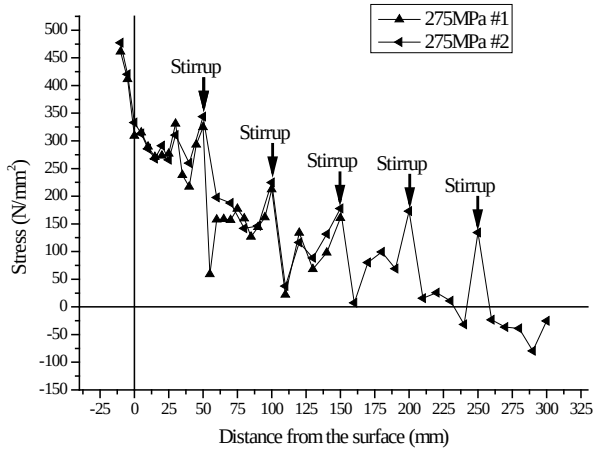

Figure 9 Stress Distribution Measured by RESA-1 (275N/mm^2)

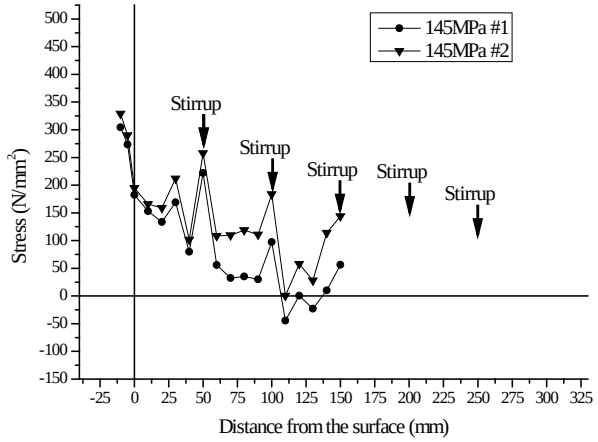

Figure 10 Stress Distribution Measured by RESA-1 (145N/mm^2)

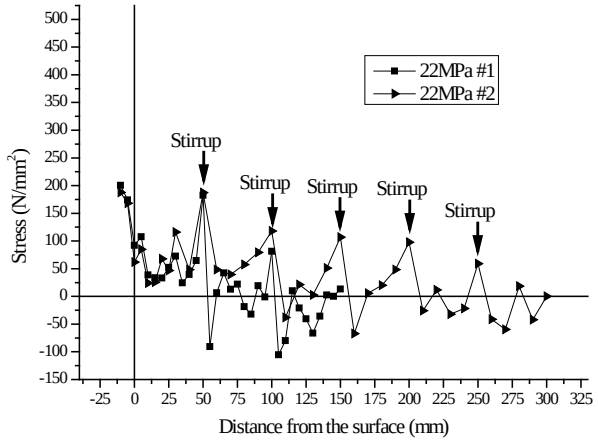

Figure 11 Stress Distribution Measured by RESA-1 (22N/mm^2)

In Figure 9 to 10, the stresses outside of the concrete (shown as the "minus" distance in the figures) must be the same as applied force, but they are not. One of the reason is that the stress along with the rebar was calculated based on the $2\theta_0$ of the diffraction angle measured at 300mm from the surface at the second 22N/mm^2. The result shows that $2\theta_0$ at each point can be different. In order to neglect the effect of $2\theta_0$, the relative stress distributions at each force level to the distribution at the second time of 22 N/mm^2 are calculated and shown in Figure 12. The stress distributions becomes clear. It can be said that the stress distribution at the second time of 145 N/mm^2 is almost constant until the stress distribution curve reaches that of 275 N/mm^2.

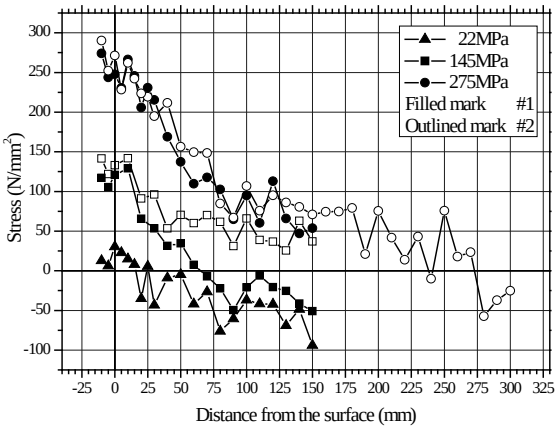

Figure 12 Stress Distribution Measured by RESA-1 (Relative to the Distribution at 22N/mm^2 #2)

3. TEST RESULTS WITH STRAIN GAUGES

The specimen with strain gauges was loaded with the loading history shown in Figure 13, which is the same as the loading history for RESA-1. The initial values of strain gauges were measured just before starting the loading. Therefore, the measured strain does not contain initial strain due to shrinkage. The cables of strain gauges were arranged perpendicular to the rebar to reduce the effect of the cable on the bonding action.

The relationships between the applied tensile force and strains measured by strain gauges are shown in Figure 14. The stress-strain relationship at the outside of the concrete is linear, since the applied force is less than the yield strength of the rebar. On the other hand, the stress-strain relationships at the inside of the concrete show nonlinearity. Unloading stiffness is, however, as

high as the initial stiffness.

Figure 15 shows the measured stress distributions at the tensile force levels that are close to the levels applied for the RESA-1 specimen. The stress distributions at 275 N/mm^2 at the first and second loadings are almost same. On the other hand, the stress distribution at the second 145 N/mm^2 level showed constant stress distribution from the surface of the specimen to the point where the stress meets the slope of 275 N/mm^2, though the stress distribution at the first 145 N/mm^2 level showed constant descending. The nonlinearity of the bonding action shown in Figure 14 can be one of the reasons. The internal tensile stress was measured at the second 22 N/mm^2 loading.

4. COMPARISON OF THE TEST RESULTS

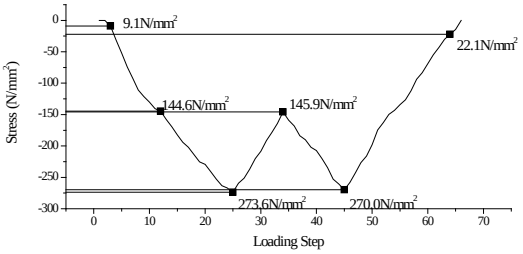

Figure 13 Loading History

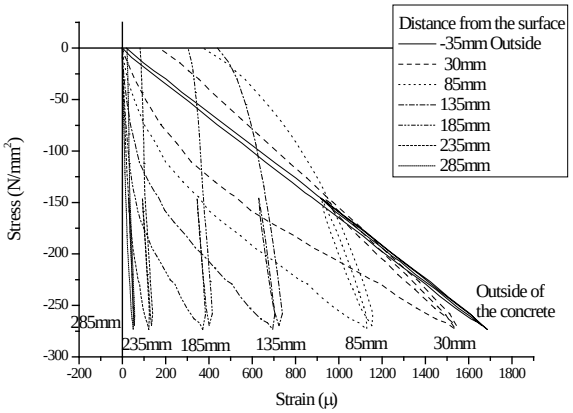

Figure 14 Relationships between Applied Tensile Force and Measured Strains by Strain Gauge

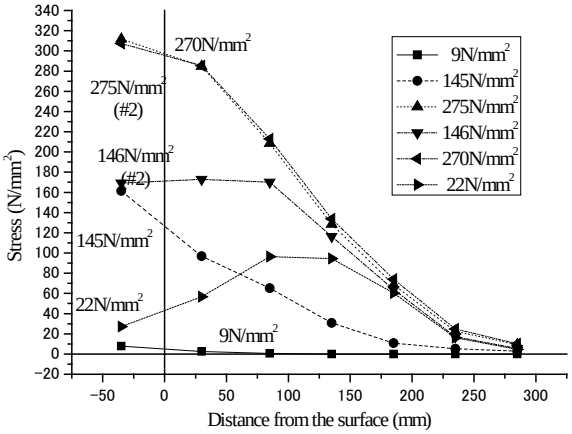

Figure 15 Stress Distribution Measured by Strain Gauges

Since strain measured by strain gauges cannot consider the initial strain due to shrinkage, and the same value of the diffraction angle is used for $2\theta_0$ for the whole rebar, direct comparison of the stress distributions measured by RESA-1 and strain gauges is not appropriate. Therefore, relative stress distributions to the final measurement at the second 22 N/mm^2 level are compared. The result is shown in Figure 16. The tendency of the stress distribution measured by RESA-1 and strain gauges coincide well each other.

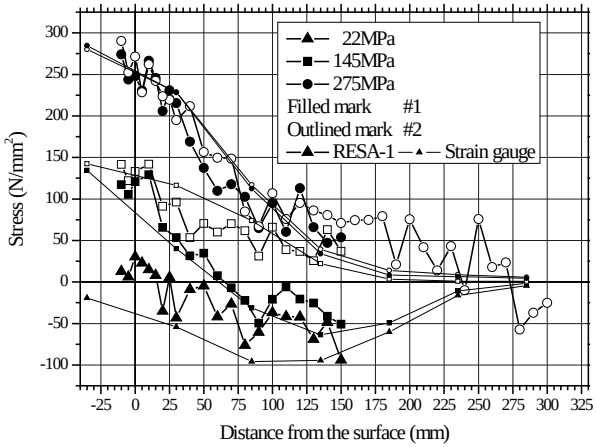

Figure 16 Comparison of Stress Distributions Measured by RESA-1 and Strain Gauges (Relative to the Distribution at 22N/mm^2 #2)

3. CONCLUSIONS

Results obtained from the research can be summarized as follows;

1. Neutron beam can go through dried concrete.
2. Stress distribution of rebar can be measured from outside of the concrete with neutron diffraction technique.
3. The stress distribution measured by carefully arranged strain gauges agreed well with the distribution measured by RESA-1
4. Bonding action shows nonlinearity if it experiences higher loading.

Abstract: The historic centre of Lima city was declared as World Heritage site in the year 1988 for its originality and high concentration of historic monuments constructed in the time of the Colonial period and at the beginning of the Republican era. The architecture of the buildings corresponds in general to typical Hispano-American baroque of the 17th and 18th centuries. Together with churches and palaces there are particular buildings constructed of traditional adobe-quincha materials. These buildings consist of a first floor made of adobe or sun-dried bricks and upper floors made of wooden frame or panels which support a mesh of cane to receive a finishing plaster of mud and gypsum. In this paper a preliminary study of the dynamic characteristics of these traditional buildings is presented. Microtremor measurements have been performed in one typical building to obtain its vibration characteristics. Although light weight of the upper stories could signify a better seismic behavior, deterioration and lack of repair and maintenance make critical the vulnerability of these buildings. This study is part of a more general SATREPS project on Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru supported by JST/JICA.

1. INTRODUCTION

The city of Lima, the capital of Peru, was founded by Spanish conquistador Francisco Pizarro on January 18, 1535 and given the name City of the Kings. Lima played a leading role in the history of the New World from 1542, when Carlos V establish the vice royalty of Peru, until the middle of the 18th century. In 1988, UNESCO declared the historic center of Lima a World Heritage Site for its originality and high concentration of historic monuments constructed in the time of Spanish presence and at the beginning of the Republican era. The architecture of the buildings corresponds in general to typical Hispano-American baroque of the 17th and 18th centuries. Since its foundation the city has suffered the action of many earthquakes that have severely affected historical buildings and reconstruction works have been done keeping the originality of the buildings. However due to the age of buildings studies for retrofitting or strengthening are necessary. In this study attention is focused on one type of traditional construction called adobe-quincha. A difference than churches and palaces this type of construction was widely used to construct residences or houses. At present this old big houses in some cases had been converted into slum dwellings. These buildings consist of a first floor made of adobe or sun-dried bricks and upper floors made of wooden frame or panels which support a mesh of cane to receive a finishing plaster of mud and gypsum. This system of wooden frame with cane and plaster is called as quincha. In this paper a preliminary study of the dynamic characteristics of these traditional buildings is presented. Apparently, from experiences of past earthquakes that strike Lima city, a second floor or upper floors made of light material provided better seismic behavior. However since the basic material is earth (earthen constructions) is obvious that appropriate maintenance and conservation task are necessary. Therefore, in this research, a preliminary evaluation of structural condition of these kinds of buildings is presented. As example a building that correspond to an old hotel is presented where ambient vibration measurements were performed to estimate the period of vibration. The building presents some partial collapse of interior walls and serious deterioration of the quincha walls. Although light weight of the upper stories could signify a better seismic behavior, deterioration and lack of repair and maintenance make critical the vulnerability of these buildings.

At present the adobe-quincha system is investigated in Peru as an alternative for low cost housing in towns and rural areas. In those zones buildings are mostly adobe masonry structures and due to the increasing need of housing in populated areas and the low cost of construction, two story adobe dwellings are often built in cities and small

towns in the interior regions where adobe is sometimes the only material available. However, two story adobe masonry structures have shown poor behavior during earthquakes, due, mainly, to the large weight of the walls. One alternative, to these two-story adobe buildings is to employ a lightweight second story. However the main problem became the connection and continuity between the first story made of adobe and the second story made of a lightweight material.

2. THE ADOBE QUINCHA SYSTEM

To explain the characteristics of the adobe quincha system the model employed by Miranda et al. (2000) are used. This model is shown in Figure 1.

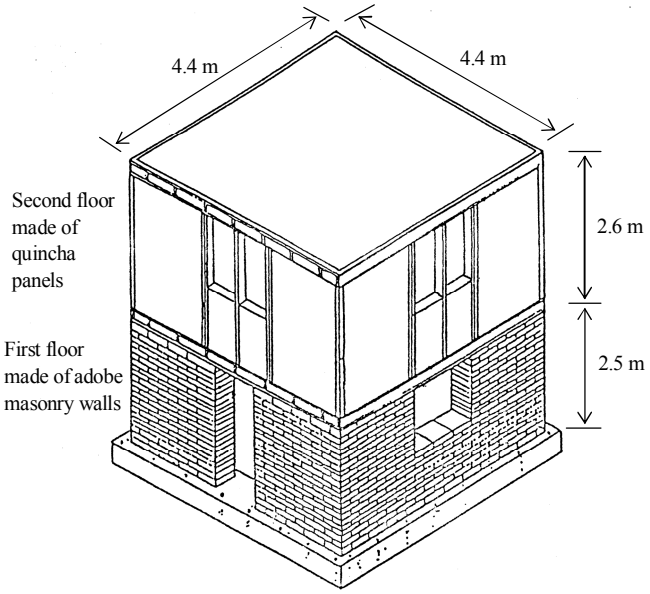

Figure 1 Prototype of the adobe-quincha system

The quincha system of construction consists, basically of wood panels with a kind of bamboo mesh and a plaster made of mud and gypsum. The construction of this full-scale model permitted to solve some constructive problems in relation to the inter-story floor and the connection between the adobe walls and the quincha panels of the second floor. As it is observed, the first floor is made of adobe masonry and the second floor consists of wood panels with finishing plaster of mud and gypsum. The thickness of the walls of the first floor is 40 cm, while the second floor walls are of 10 cm of thickness. In order to connect appropriately the first floor and the second floor, eucalyptus rods of 7.5 cm of diameter were fixed in the foundation to act as columns. These rod columns are embedded in the adobe wall and are located at the corners and distributed along the wall with 1.2 m of spacing. To permit the inclusion of the rod columns in the walls, the adobe masonry units have an especial shape as is shown in Figure 2. The adobe masonry units have a modular dimension of 40 × 40 cm and 10 cm of height with semicircular incisions of 10 cm of diameter in two opposite sides. Also there are adobe units which are half units to permit the appropriate fabric of the masonry. The incisions of the adobe masonry units permit to form the cylindrical space to allocate the eucalyptus rod columns.

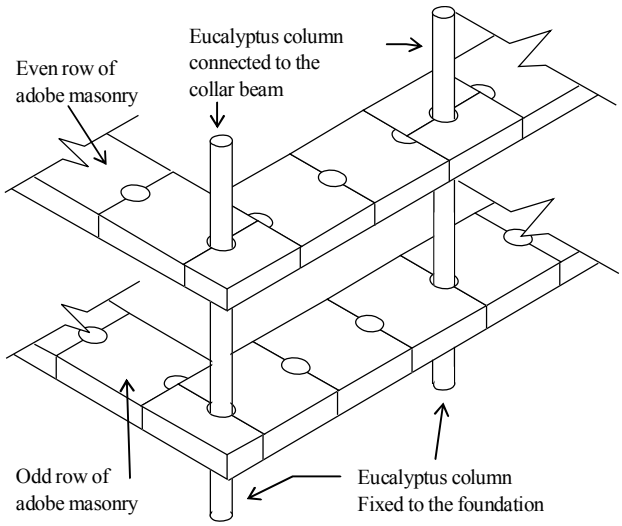

Figure 2 Detail of the adobe masonry and eucalyptus columns

These rod columns permit to fix the collar beam in the upper perimeter of the adobe walls. In this way the adobe masonry wall is confined and the collar beam on the top of the masonry wall permit an efficient connection with the quincha panels as is shown in Figure 3. These rods also contribute to take the tension stress produced by the lateral load during earthquakes. The inter-story floor is supported by the floor beams, which rest on the collar beam, transmitting the load to the walls of the first floor. Also these beams receive the load transmitted by the quincha panels. The quincha panels are fixed to the inter-story floor beams with nailed connections.

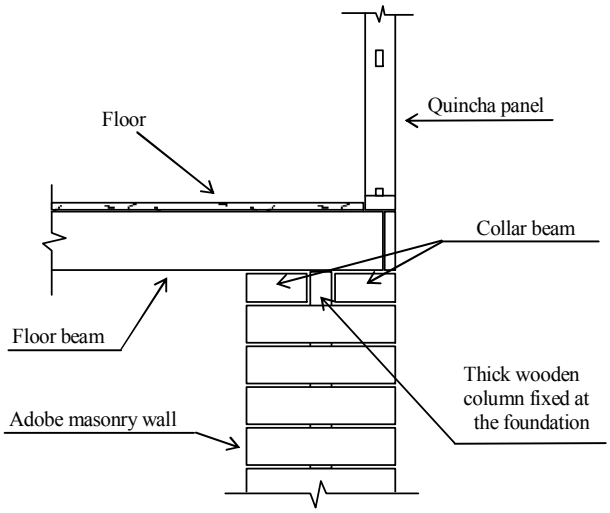

Figure 3 Detail of the connection between adobe wall and quincha panel

In the case of old traditional constructions that are

found in Lima Centre, the dimensions of the walls and inter-story heights are quite large. The adobe walls of the first floor have a thickness that varies from 60 cm. to 100 cm. The height of the first floor reaches sometimes 5 m. or more. The thickness of the upper floors ranges from 20 cm to 50 cm. In general the wooden frames were constructed in-situ and the connection between elements presents different patterns like insertions of beam ends into the columns, nailed joints, joints fixed with ties made of animal fur or leather, etc. The mesh of cane is made of very thin canes called "carrizo", and "caña brava". These canes are fixed to the wooden structure by means of cords or ropes made also of vegetal material. To fix the quincha system to the adobe walls the bottom part of the wooden frame is constraint by means of heavy materials like adobe itself or clay bricks as can be observed in Figure 4.

Figure 4 Typical quincha wall at Lima centre

3. VIBRATION CHARACTERISTICS

3.1 Pseudo dynamic test

A series of pseudo-dynamic tests were performed on prototype described in the previous section to verify the dynamic behavior of this system. The pseudo-dynamic test method uses on-line computers to monitor and control a test specimen closely resemble those that would occur if the test specimen were tested dynamically. Pseudo-dynamic tests combine analytical and experimental techniques. Experimental measurements are made of the restoring forces during the test. These measured forces are used by the computer, together with a set of mathematical equations which, ideally, describe the dynamic responses of the structure, to determine changes in the structural displacements that should be imposed on the specimen as a consequence of the given ground acceleration. The structural restoring forces are experimentally measured rather that computed from a mathematical model, and physical force actuators are used to cause the displacements of the test specimen to equal the computed structural displacements.

Two degree of freedom systems with lumped masses at floor level were adopted to model the specimens. The degrees of freedom were associated to the horizontal displacements at the center of each floor since perfect symmetry was assumed.

In order to obtain initial flexibility matrices of the specimens, a load was applied at one of the floor level while the other floor level was free. The fundamental period computed from these preliminary tests was 0.12 s.

Viscous damping was considered in the form of a matrix proportional to initial stiffness, with 2% of critical damping for the first mode and remained unchanged during the test.

The specimen was tested with a ground acceleration corresponding to the N08E component of the Lima earthquake of October 10, 1966, (IGP66-NE). A portion from 18.25 to 22.25 seconds, which contains the peak acceleration of 293.6 Gal, was selected for this test program. The record was scaled to have maximum ground acceleration of 100, 200, 400 and 600 Gal. The specimen was tested with these earthquake motions. The average duration of each test was 6 hours.

Time history responses for story displacements were obtained for the test sequence. Figure 5 shows the time history responses for displacements of the first and second floor when specimens were tested with the ground acceleration scaled to 400 Gal. Solid line plots the displacement of the first floor while dashed line plots the top displacement of the second floor.

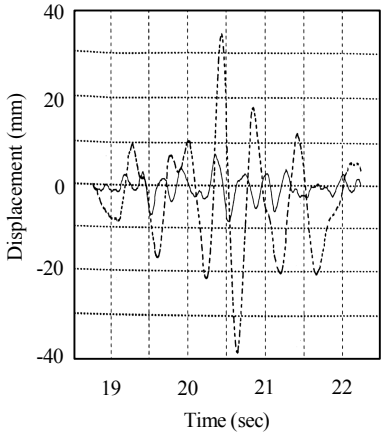

Figure 5 Time history displacement response (IGP-66, 400 Gal)

Figure 6 shows the load-displacement curves obtained for the input motion scaled to 400 Gal. It can be observed that the shape of the hysteretic loop shows large energy dissipation. These pattern were observed in all test performed with 100 Gal, 200 Gal, 400 Gal and 600 Gal respectively.

The failure of the specimen was by shear in the walls of the first floor. The adobe-quincha model resisted the 400 Gal earthquake and even the 600 Gal earthquake. However, very large displacement was observed in the second floor with considerable lost of stiffness. This excessive displacement produced during large earthquakes requires additional research to control and keep the lateral displacement of the second floor below a reasonable value.

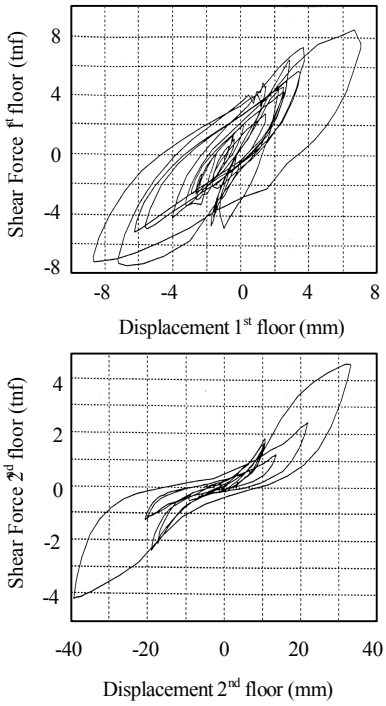

Figure 6 Load-displacement curves (IGP-66, 400 Gal)

The maximum values of shear forces and shear stress that were observed during the tests are presented in Table 1. It can be observed that even for 600 gal earthquake the maximum shear stress in the walls of the first floor was 0.3 kg/cm^2 that is slightly larger than the allowable design shear stress specified in the current Peruvian code on adobe constructions.

Table 1. Maximum shear forces and shear stress

Input Motion	Shear force (tonf)	Shear stress (kg/cm^2)
IGP-66-100 gal	6.13	0.21
IGP-66-200 gal	7.42	0.26
IGP-66-400 gal	8.47	0.29
IGP-66-600 gal	8.75	0.30

Maximum relative displacements that were observed in each run are presented in Table 2. It can be observed that the adobe-quincha model is very flexible, specially the second floor reaching a displacement of 50.56 mm when the model was subjected to the input motion of 600 Gal. of maximum acceleration. This displacement represents a drift angle of 1/50 approximately, which could be excessive for this type of constructions, although the specimen has not collapsed.
These results have permitted to analyze the general behavior of the typical traditional constructions of two-story in Peru, and show that the appropriate use of a lightweight material in the upper story could be an appropriate solution to get a better behavior of these buildings during earthquakes. However the excessive relative displacement of the upper floors could be a problem during earthquake occurrence.

Table 2. Maximum displacements observed during tests

Input Motion	1st floor (mm)	2nd floor (mm)
IGP-66-100 gal	2.32	9.40
IGP-66-200 gal	3.68	20.12
IGP-66-400 gal	8.70	39.17
IGP-66-600 gal	12.54	50.56

3.2 Ambient vibration measurements

As example a building that correspond to an old hotel is presented where ambient vibration measurements were performed to estimate its period of vibration. This building can be observed in Figure 7. The walls of the upper stories (second and third floors) are made of quincha and the first story is made of adobe walls. The building presents some partial collapse of interior walls and serious deterioration of the quincha walls.

Figure 7 Adobe-quincha building at historic centre of Lima

Results of ambient vibration show a predominant frequency of the order of 3.3 Hz. Figure 8 shows the predominant frequencies for NS and EW directions respectively. The NS direction was taken as the direction parallel to the façade and the predominant frequency is 3.37 Hz. In the EW direction that is perpendicular to the façade the predominant frequency is 3.21 Hz. These frequencies represent reasonable values for a building of 12 m of height however more detailed measurement are necessary to detect the local vibration of portions of the building that could indicate the condition of deterioration.

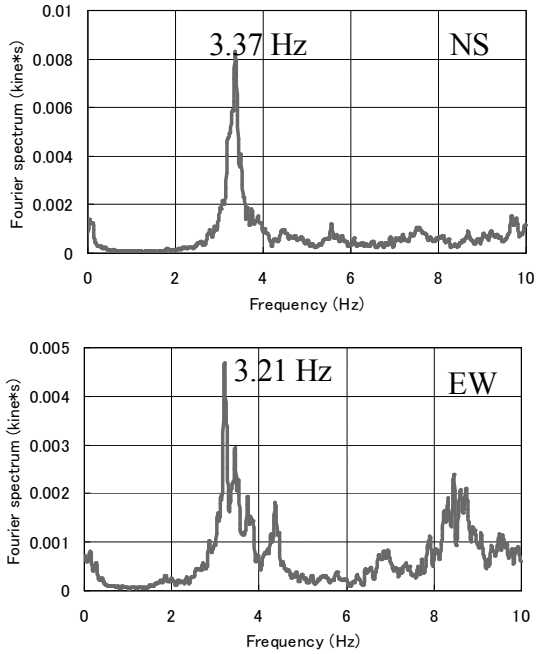

Figure 8 Predominant frequency of selected historical building of centre of Lima

3. CONCLUSIONS

Vibration characteristics of heritage architecture made of traditional adobe-quincha system that is located in Lima city were discussed. Since the heritage architecture is exposed to the action of earthquakes, the understanding of the dynamic properties of these constructions is very important as a first step for future recommendations in relation to conservation, repair and maintenance works. The adobe-quincha heritage architecture is mostly in a state of disrepair and therefore the seismic risk and other kind of risks are particularly acute.

The mixed adobe-quincha system could represents a suitable alternative for two-story traditional constructions in Peru since the lightweight second floor reduces the base shear force during earthquake motions having a better seismic behavior than heavy two-story adobe buildings. However the large displacement that can occur at the upper floor needs more research to be controlled appropriately.

Microtremor measurements at typical adobe-quincha construction have permitted to determine the predominant period of vibration of this building which falls in a reasonable value considering the building height. This value could be used to construct and calibrate analytical models for future analysis on seismic behavior of this kind of buildings.

Abstract: Partially grouted masonry shear walls are common structural systems in North America. This research examines the shear behavior of six partially grouted masonry shear walls. The walls have an aspect ratio of 0.58, vertical reinforcement ratio of 0.33% and axial force of 49 kN (11 kips). They were subjected to in-plane lateral cyclic loading in a displacement control. The walls had grout horizontal spacing of 610, 813, and 1219 mm (24, 32, and 48 in., respectively). Horizontal reinforcement ratios ranging from 0.127% to 0.254% were investigated as well. The test results showed that the shear strength of the walls significantly depends on the grout horizontal spacing. In addition, there seems to be a threshold horizontal reinforcement ratio beyond which any increase in the reinforcement ratio does not result in increase in the shear strength of partially grouted shear walls. The measured shear strengths of the test specimens were compared to those predicted shear strengths using MSJC (2008) shear design equations. The comparisons showed that the MSJC overestimated the shear strength of partially grouted walls having grout horizontal spacing greater than 610 mm (24 in.).

1. SHEAR STRENGTH OF PARTIALLY GROUTED MASONRY WALLS

Partially grouted masonry wall (PG-MW) is a common form of construction throughout the Unites States, including seismic zones. Most of the currently available test results on PG-MWs are credited to Matsumura (1986) who tested 51 PG-MWs and developed empirical expressions to calculate the shear strength of both fully grouted and partially grouted masonry shear walls. These equations assumed that the contribution of horizontal shear reinforcement and masonry to shear strength of PG-MWs is approximately 60% of those of fully grouted walls.

Very few studies have been carried out in the United States to address the in-plane shear strength of PG-MWs. Yancey and Scribner (1989) tested ten PG-MWs under cyclic loading. Horizontal reinforcement ratio (ρ_h) ranging from 0 to 0.215% and different distributions of horizontal shear reinforcement were investigated. Fattal (1993a) investigated available literature and experimental results on PG-MW and showed that Matsumura's equations predicted lateral strengths that varied from 23% to 180% of the measured strengths of the test specimens with a coefficient of variation of approximately 33%. Fattal (1993a) improved Matsumura's equations and assumed that the contribution of the horizontal shear reinforcement and masonry to the shear strength of PG-MWs are approximately 64% and 80% of those of fully grouted walls, respectively. Using this new set of equations the predicted shear strengths ranged from 41% to 146% of the measured shear strengths with a coefficient of variation of approximately 22%. In another study, Fattal (1993b) analyzed the test data of PG-MWs available in the literature and found that the lateral strengths of PG-MWs increased with increasing horizontal reinforcement ratio, but there is a threshold horizontal reinforcement ratio of 0.2%, beyond which additional horizontal reinforcement did not appear to be as effective in increasing the lateral strength. Ghanem et al. (1992 and 1993) investigated six one-third scale partially grouted shear walls under in-plane monotonic loading. The effects of reinforcement distribution and applied axial load on shear strength were investigated. All the specimens had a constant horizontal and vertical reinforcement ratio of 0.12%. The distribution of horizontal and vertical reinforcement as well as the level of the applied axial force had significant effects on the mode of failure, strength, and displacement ductility. As the vertical and horizontal reinforcement were more uniformly distributed, both the strength and ductility of the walls improved. Schultz (1996) and Schultz et al. (1998) tested twelve PG-MWs, having aspect ratios of 0.5, 0.7, and 1.0, to examine the effects of distribution and ratio of horizontal reinforcement. It was shown that increasing the aspect ratio from 0.5 to 0.7 significantly increased the ultimate shear stresses. However, increasing the aspect ratio from 0.7 to 1.0 had a negligible effect on the ultimate shear stresses. In addition, increasing the shear reinforcement ratio was found to increase the ultimate strength of slender walls but decrease those of the squat walls. Finally, it was concluded that the failure mechanism of PG-MWs differs from that of fully grouted shear walls. PG-MWs behaved similar to masonry infilled reinforced concrete frames. Recently, four partially grouted masonry shear walls have been tested (Minaie et al. 2010). It was found that the MSJC (2008) shear design

equations overestimated the shear strengths of the four test specimens by a factor of approximately two.

Maleki (2008) tested five PG-MWs built according to the Canadian Standard (CSA 2004). Out of them, four walls failed in shear while the fifth wall failed in flexure. All the walls had a ρ_h of 0.05% and vertical reinforcement ratio of 0.18%. The horizontal distance between the vertical grouted cells ranged from 0.56 m to 1.70 m. The constructed walls had two aspect ratios (height/width), 1.0 and 0.5, and were tested under zero normal force. The MSJC (2008) shear design provisions provided a good prediction of the shear strengths of the test specimens.

2. SHEAR STRENGTH PROVISIONS OF MSJC (2008)

The MSJC (2008) provisions use expressions 1 through 5 for calculating the nominal shear strength of masonry shear walls (V_n). These expressions recognize the contribution of masonry (V_m) and horizontal shear reinforcement (V_S). Unlike Matsumura's and Fattal's expressions, the MSJC shear provisions do not distinguish between PG-MW and fully grouted masonry walls.

$$V_n = V_s + V_m \tag{1}$$

$$V_m = (4 - 1.75\frac{M}{Vd})A_n\sqrt{f'_m} + 0.25P \tag{2}$$

$$V_s = 0.5\frac{A_{sh}}{s}d_v f_{yh} \tag{3}$$

$$V_n \leq 6A_n\sqrt{f'_m} \qquad for\ {}^{M}/_{Vd} \leq 0.25 \tag{4}$$

$$V_n \leq 4A_n\sqrt{f'_m} \qquad for\ {}^{M}/_{Vd} \leq 1.00 \tag{5}$$

Where M/Vd = effective moment to shear ratio, A_n = net cross sectional area, f'_m= specified compressive strength of masonry, P = applied axial load, A_{sh} = cross sectional area of shear reinforcement, and f_{yh} = yield strength of horizontal shear reinforcement.

3. TEST SPECIMENS

A total of six masonry shear walls were tested. To achieve shear dominated behavior an aspect ratio of approximately 0.58 was selected for the test specimens. The aspect ratio is defined as the height between point of application of the lateral loading and the wall base divided by the wall length. The wall length was selected based on the available testing facilities at the Wood Materials and Engineering Laboratory at Washington State University. In addition, the wall length was selected to allow for symmetrical distribution of vertical reinforcement with maximum horizontal spacing between vertical grouted cells of 1219 mm (48 in.). This resulted in wall length of 2642 mm (104 in.) and height of 1626 mm (64 in.). Each wall consisted of 8 courses high, and 6½ blocks long. In addition, two more courses were added above course No. 8 to act as a cap beam that uniformly distributes the applied axial and lateral loads. The test specimens were built by experienced bricklaying crew in a running bond pattern with 203 mm (8 in.) hollow concrete masonry units using face shell mortar bedding. Standard 406 mm x 203 mm x 203 mm (16 in. x 8 in. x 8 in.) for full units and 203 mm x 203 mm x 203 mm (8 in. x 8 in. x 8 in.) for half-unit concrete masonry units (CMUs) were used for the construction of the test specimens. Knockout units were used in the 4th and 8th to 10th masonry courses to form bond beams where the shear reinforcement was fully embedded in grout.

Every specimen was assigned a name in the form of PG (partially grouted) followed by XXX-SP where XXX is the horizontal reinforcement ratio (ρ_h) multiplied by 100000, followed by the horizontal grout spacing in inches. For example, specimen PG127-48 was a partially grouted specimen reinforced using a horizontal reinforcement ratio of 0.00127 and a horizontal grout spacing of 1219 mm (48 in.).

The specimens were reinforced horizontally and grouted at courses No. 4, 8, 9, and 10. Each one of these courses included a single leg D 16 (No. 5) rebar, except for specimens PG180-48 and PG254-48, where a single D 19 (No. 6) and 2 D 16 (No. 5) were used, respectively. This resulted in a horizontal reinforcement ratio (ρ_h) of 0.127% for all specimens except specimens PG180-48 and PG254-48, where ρ_h of 0.180% and 0.254% were used, respectively. The horizontal reinforcement ratio was calculated as the cross sectional area of the shear reinforcement in a bond beam divided by (203 mm x 1219 mm) i.e. the wall thickness and distance between the bond beams.

The horizontal reinforcements were hooked according to MSJC (2008) using a 180^o hook around the outermost vertical rebar located at 102 mm from the ends of each wall (Figure 1). The walls were reinforced vertically using identical reinforcement ratio of 0.33% at horizontal spacing of 610 mm (24 in.), 813 mm (32 in.), and 1219 mm (48 in.). As shown in Figure 2, all specimens except specimens PG127-32 and PG127-24 were reinforced using 2#6 at 1219mm (48 in.). Specimens PG127-32 and PG127-24 were reinforced using 2#6 in each outermost cell. The inner cells were reinforced using either 1# 6 @ 813 mm (32 in.) or 1# 5 @ 610 mm (24 in.) in the case of specimen PG127-32, and PG127-24, respectively. Each cell containing vertical reinforcement was grouted.

Each wall was constructed on over-designed reinforced concrete foundation. The vertical flexural reinforcement rebar were extended from the foundation completely through the full

Figure 1 The 180^o hook as used in the specimens

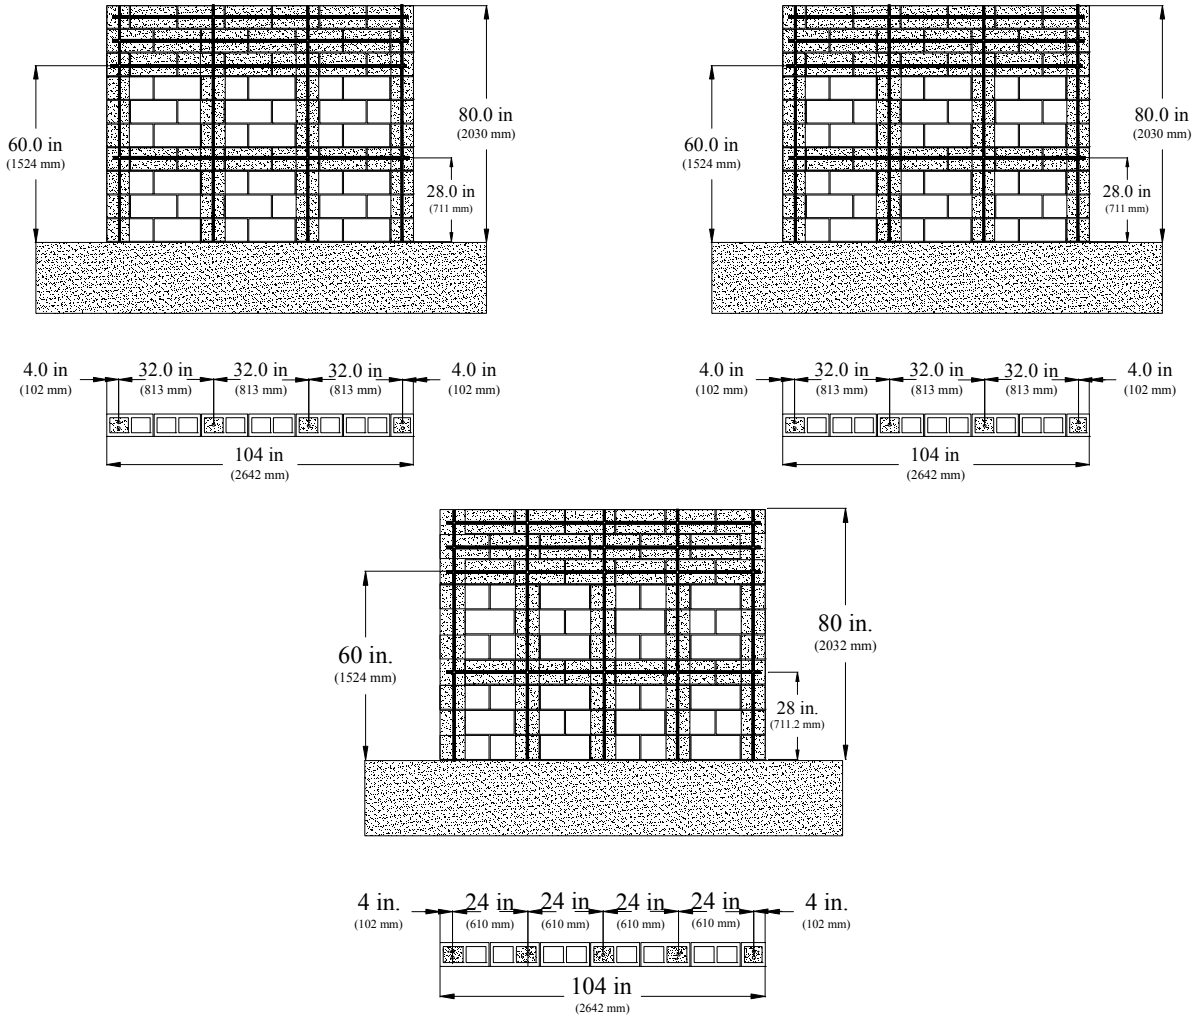

Figure 2 Typical dimensions of test specimens

height of the wall without lap splice to avoid strength degradation due to splice rupture. The wall longitudinal rebar were hooked around the longitudinal rebar of the foundation using a 90° hook.

2.1 Construction Material Properties

A high slump fine grout was mixed and used to grout the reinforced cells and bond beams of the walls. Four grout-prisms 102 x 102 x 203 mm (4 x 4 x 8 in.) were prepared and tested according to ASTM C1019-07. The grout had an average compressive stress of 35.85 MPa (5200psi) with a standard deviation of 3.5 MPa (511 psi).

The specimens were built using Portland cement lime type S mortar. Five 51 mm (2 in.) diameter by 102 mm (4 in.) high mortar cylinders were casted and tested according to ASTM C780 (2090). The mortar had an average compressive strength of 14.89 MPa (2160 psi) and standard deviation of 1.3 MPa (185 psi).

Five grouted and five un-grouted two-block high single-block long prisms were tested according to ASTM C1314-07 to determine the masonry compressive stress (f'_m). The tested ungrouted prisms had an average f'_m of 17.44 MPa (2530 psi) with standard deviation of 2.0 MPa (290 psi). The tested grouted prisms had an average f'_m greater than 24.40 MPa (3540 psi) since the compression machine reached its ultimate capacity without rupture of the grouted prisms (Table 1).

The steel rebar used in the walls construction were Grade 60 for both vertical and horizontal reinforcement and had measured yield stresses of 452 MPa (65.6 ksi) and 427 MPa (61.9 ksi) for #5 and #6, respectively.

3. TEST SETUP AND LOADING SYSTEM

The RC footing of each wall was post-tensioned to the laboratory strong floor using eight high strength steel bars (Figure 30. A superimposed gravity load of approximately 49.4 kN (11.1 kips) was applied to the specimen using two jacks operated by a manual hydraulic pump. To uniformly distribute the applied axial load, the actuators were connected at their

bottoms to stiff hollow square steel section that was mounted on top of the wall, i.e. at the 10th masonry course.

Figure 3 Test Setup

Table 1 Prism test results

Type	Sample No.	Load (Ib)	Area (in^2)	(f'_m) (psi)	Corrected (f'_m) (psi)	Avg. of corrected f'_m psi (MPa)
Ungrouted	1	193,300	67.04	2883.3	2874.6	2530 (17.44)
	2	151,940	67.04	2266.4	2259.6

	3*	424342	119.15	3561.4	3551	
	4*	424198	119.15	3560.2	3549	
	5	414872	119.15	3482	3471.5	

Correction factor =0.997

* Sample reached the machine's maximum load without rupture.

The tops of the hydraulic jacks were connected to the main cross beam of the strong steel frame using a slippery plate to allow lateral movement of the actuator while applying the axial load. The applied normal force corresponds to a stress of 0.10 MPa (14 psi).

As described earlier courses No. 8, 9, and 10 in each wall were grouted and reinforced to act as a stiff cab beam. The lateral load was applied through a 1000 kN (225 kip) capacity hydraulic actuator with its centerline aligned at the middle of the 8th masonry course as shown in Figure 2. The actuator was fixed from one end to the steel strong frame and from the other end to two stiff C-shaped built-up steel sections which were bolted at the 8th masonry course to both sides of each wall. The C sections were bolted using 19 mm (¾ in.) diameter shear studs passing through the thickness of each masonry wall. The holes for these studs were drilled after the walls had grouted and cured for approximately 7 days. A high strength anchorage epoxy was used to fill any tolerance between the bolts and holes.

In order to eliminate any sliding in the concrete base during the cyclic loading, the concrete base was braced using two stiff built-up steel angles bolted to the laboratory strong floor, as shown in Figure 3.

Each specimen was subjected to the displacement-controlled reversed cyclic loading shown in Figure 4. The typical cyclic loading sequence adopted for the tests consisted of three cycles at lateral displacement levels of ± 0.5 Δ_y, ± 1.0 Δ_y, ± 1.5 Δ_y, ± 2.0 Δ_y, ± 2.5 Δ_y, ± 3.0 Δ_y, ± 3.5 Δ_y, ± 4.0 Δ_y, ± 5.0 Δ_y, ± 6.0 Δ_y, ± 6.0 Δ_y, ± 8.0 Δ_y, and ± 10.0 Δ_y, etc. Δ_y is the theoretical yield displacement and was determined as 1.27 mm (0.05 in.) using Equation 6 (Priestley et al. 2007):

$$\Delta_y = 0.6\varepsilon_y h_e \frac{h_e}{L_W} \quad (6)$$

Where h_e= height of wall = 1524 mm (60 in.), L_w = wall length = 2631 mm (103.6 in.), ε_y = yield strain of the flexural steel = 0.00207 for grade 60. The loading rate was 4.76 mm/min (0.1875 in/min). In this experimental program, failure of a specimen was defined as the point on the loading curve where the wall strength reduced to 80% of the peak strength of this specimen.

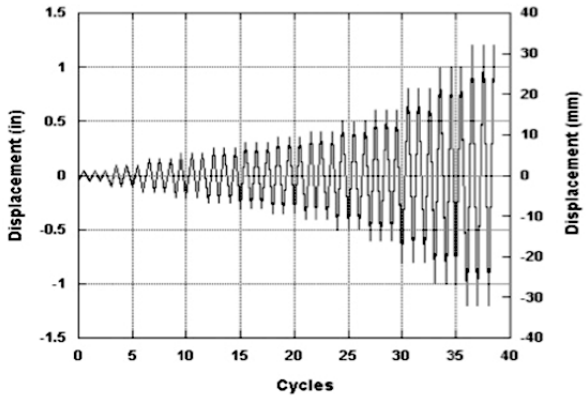

Figure 4 Loading protocol

3.1 Instrumentations

The specimens were instrumented with several devices. The lateral displacement at masonry course No. 8 was measured using string potentiometers. The applied lateral forces were measured using the load cell of the actuator.

4. EXPERIMENTAL RESULTS

4.1 Specimens PG127-48 and PG-127-48I

PG127-48 and PG-127-48I are identical specimens having grouted vertical cells at horizontal spacing of 1219 mm (48 in). Each wall was reinforced horizontally using 1 No. 5 (D 16) in courses No. 4, and 8 to 10 (ρ_h= 0.127%). The first crack was a diagonal crack in the form of stair-step cracks passing through mortar bed and head-joints along the bottom three brick courses. The crack appeared at lateral loads of 178 kN (39.9 kips) and 164 kN (36.8 kips) for specimens PG127-48 and PG127-48I, respectively. These loads correspond to lateral drift angle of approximately 0.09%. More stepped cracks occurred while the applied lateral displacement was increased. Specimen PG127-48 reached its peak strength of 253 kN (56.84 kips) at a drift angle of 0.22%. At this drift angle, 45° cracks occurred through the masonry units at the 2nd and 3rd masonry courses of the vertical grouted cells at the wall mid-length. Beyond that drift angle, more 45° cracks passing through the masonry units at the specimen's toes occurred. These diagonal cracks were initiated by diagonal tension splitting of masonry in the compression struts. At a lateral drift angle of 0.51% and lateral load of 203kN (45.72 kips), vertical splitting cracks occurred at the middle bond beam on the outer grouted cells in both load directions (Figure 5). Testing continued and spalling of CMU and mortar occurred. By a drift angle of 1.1% and lateral load of 158 kN (35.5 kips), the vertical splitting crack width significantly increased and led to spalling of the masonry end shells of the end blocks at the third and fourth masonry courses as shown in Figure 6. At this damage level, the test was stopped and the lateral strength of the specimen dropped by 45% of the measured specimen's peak strength.

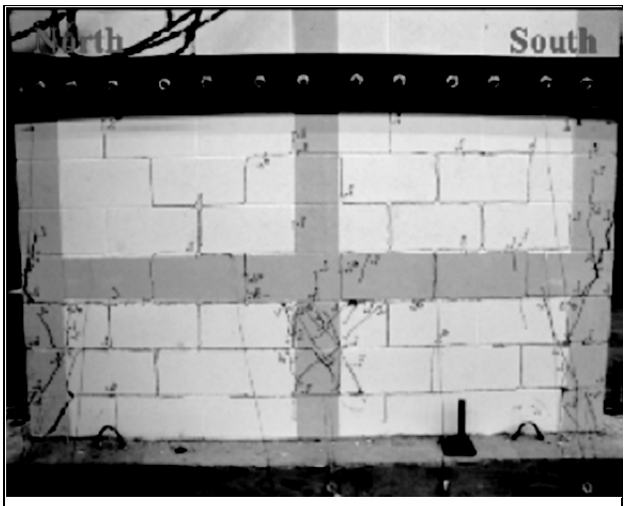

Figure 5 Specimen PG127-48 at drift angle of 0.51% during testing

Specimen PG127-48I behaved similar to specimen PG127-48 with a peak strength of 231 kN (51.9 kips) at lateral drift angle of 0.3%. At drift angle of 0.88%, vertical cracks were observed at the outermost blocks in the 3rd through the 5th masonry courses leading to a reduction in the lateral strength of the specimen by approximately 35% and the specimen reached a lateral strength of 170 kN (38.17 kips).

4.2 Specimens PG180-48

Specimen PG180-48 had grouted vertical cells at horizontal spacing of 1219 mm (48 in). The wall was reinforced horizontally using 1 D 19 (No. 6) in courses No. 4, and 8 (ρ_h= 0.180%). Courses No. 9 and 10 were also reinforced using 1 D 19 (No. 6), each, to act as rigid beam where the axial and the

lateral loads were applied. The first crack was stepped crack in the bottom masonry panel and it occurred at a drift angle of

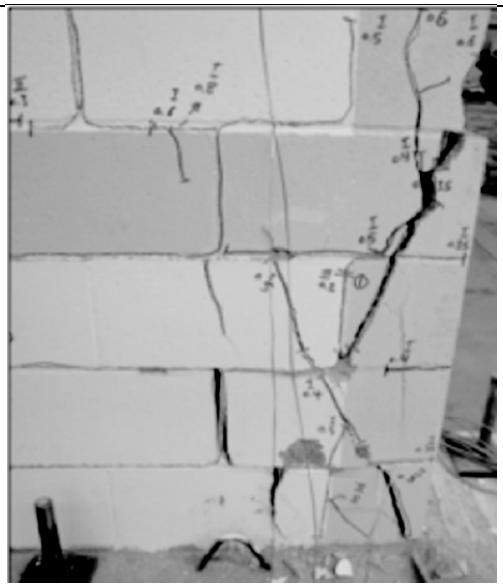

Figure 6 Toe crushing of specimen PG127-48 at drift angle of 1.1%

0.09% and lateral load of 188 kN (42.3 kips). Stepped cracks continued to occur by increasing the applied lateral drift. At a drift angle of 0.36% and lateral load of 266 kN (59.1 kips), diagonal cracks appeared in the CMUs at the toes of the wall. At a drift angle of 0.42% and a lateral load of 289 kN (65.03 kips), the specimen reached its ultimate strength. At a drift angle of 0.58% and a lateral load of 279 kN (62.8 kips), a significant diagonal crack approximately 2-block high passing through the bond beam and outermost grouted cells appeared through the 4th and 5th masonry courses. Cycling continued and vertical cracks 3-block high appeared in the outermost grouted cells in the north and south directions. Face shells spalling of the masonry blocks surrounding the toes of the wall occurred at a drift angle of 0.88% and a lateral load of 252kN (56.7 kips) (Figure 8). By a drift angle of 0.91%, the lateral resistance of the specimen dropped by 40% and the test was stopped.

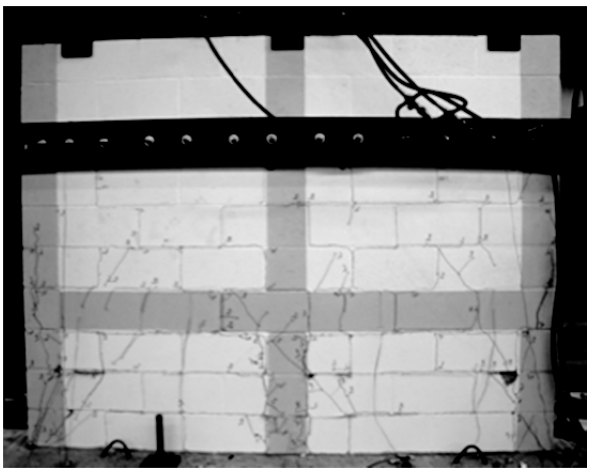

Figure 7 Specimen PG127-48I at drift angle of 0.88%

4.3 Specimens PG253-48

Specimen PG253-48 had grouted vertical cells at horizontal spacing of 1219 mm (48 in). The wall was reinforced horizontally using 2 D 16 (No. 5) in courses No. 4, and 8 (ρ_h= 0.253%). Courses No. 9 and 10 were also reinforced using 2 D 16 (No. 5), each. The first crack was stepped crack occurred in the top and bottom masonry panels and it occurred at a drift angle of 0.06% and lateral load of 186 kN (41.75 kips). Stepped cracks continued to occur by increasing the applied lateral drift. At a drift angle of 0.30% and lateral load of 271 kN (61.0 kips), diagonal cracks appeared in the CMUs at the toes of the wall. At a drift angle of 0.42% and a lateral load of 291 kN (65.50 kips), the specimen reached its ultimate strength. Cycling continued and vertical cracks 5-block high appeared in the outermost grouted cells in the north and south directions (Figure 9). By a drift angle of 0.80%, the lateral resistance of the specimen dropped by 47% and the test was stopped.

Figure 8 Specimen PG180-48 at drift angle of 0.88%

4.4 Specimen PG127-32

Specimen PG127-32 had grouted vertical cells at horizontal spacing of 813 mm (32 in). The wall was reinforced horizontally using 1 D 16 (No. 5) in courses No. 4, and 8 (ρ_h= 0.127%). Courses No. 9 and 10 were also reinforced using 1 D 16 (No. 5), each. The first observed crack was a stepped crack passing through mortar joints in the top middle masonry panel and it occurred at drift angle of 0.08% and lateral load of 219 kN (49.26 kips). While pulling the specimen to a drift angle of 0.25% and lateral load of 315 kN (70.9 kips), diagonal cracks occurred in the wall toes. At a drift angle of 0.47% and lateral load 357 kN (80.2 kips), the specimen reached its peak strength. Beyond that the strength of the specimen started to degrade due to substantial widening of exiting diagonal cracks. At a drift angle of 0.85% and lateral load of 347kN (77.5 kips), new vertical cracks appeared in the outermost cells in the 4th and 5th masonry course (Figure 10). Finally, at a drift angle of 1.29%, the resistance of the specimen dropped by 28% of its peak

resistance and the test was stopped.

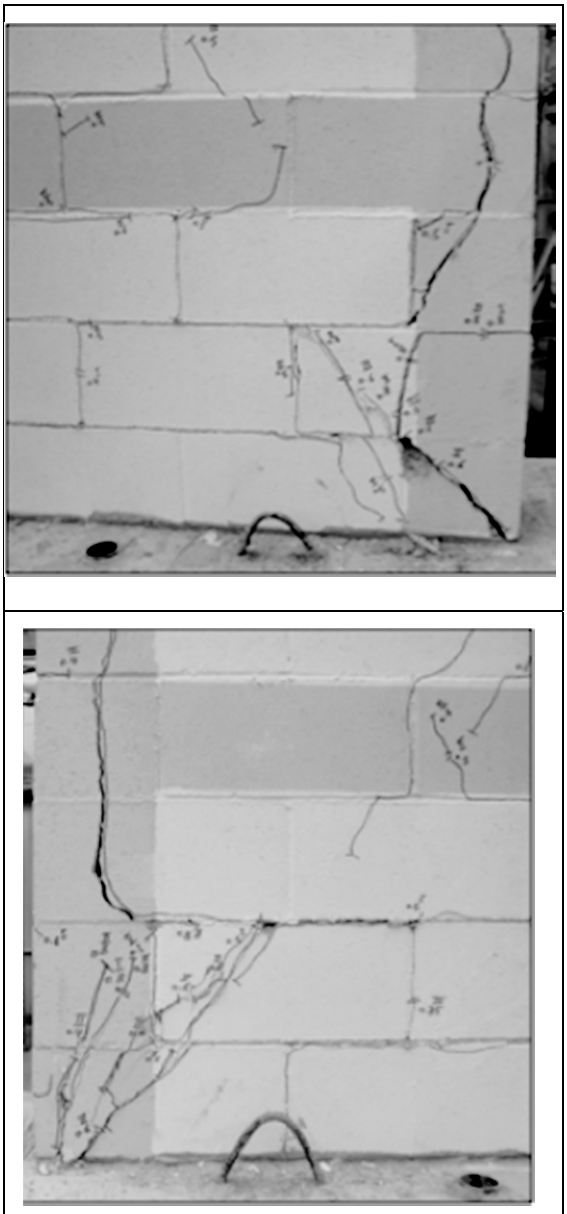

Figure 9 Vertical and diagonal cracks at drift angle of 0.70% in the toes of specimen PG253-48

4.4 Specimen PG127-24

Specimen PG127-24 had grouted vertical cells at horizontal spacing of 610 mm (24 in). The wall was reinforced horizontally using 1 D 16 (No. 5) in courses No. 4, and 8 (ρh= 0.127%). Courses No. 9 and 10 were also reinforced using 1 D 16 (No. 5), each.

Specimen PG135-24 behaved similar to the rest of the other specimens and had a dominant shear response, as indicated by diagonal stepped cracks. The first crack was a diagonal stepped crack occurred at the top masonry panels while loading the specimen to a drift angle of 0.12% and a lateral load of 254 kN (57.2 kips). While pulling the specimen to a drift angle of 0.23% and lateral load of 309 kN (69.5 kips), a diagonal crack passing through the CMUs in the bottom four courses of the

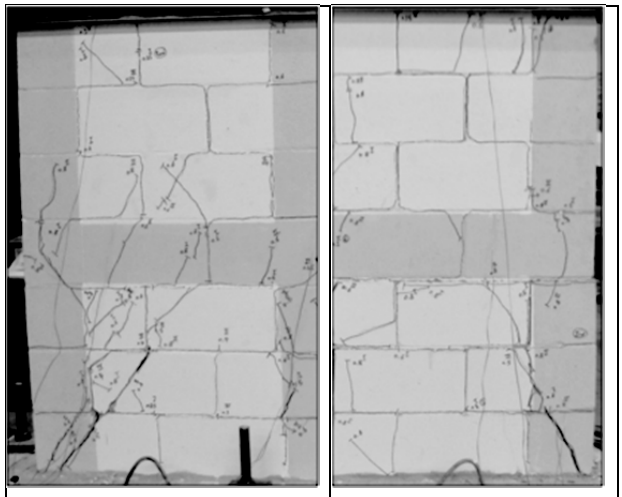

Figure 10 Damage of the toes of specimen PG127-32 at drift angle of 0.85%

northern masonry panel occurred. By a drift angle of 0.71%, diagonal cracks passing through CMUs were everywhere in the specimen and the specimen reached its ultimate strength of 430 kN (96.8 kips). By a drift angle of 1.00% and load of 299 kN (67.3 kips), substantial vertical cracks appeared in the outermost grouted cells and the toes were significantly damaged as well as the lateral strength of the wall dropped by 30% of its peak strength. (Figure 11).

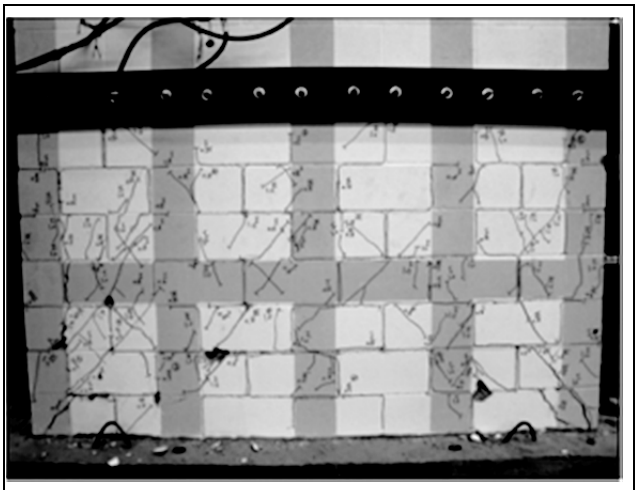

Figure 11 Specimen PG127-24 at drift angle 1.00%

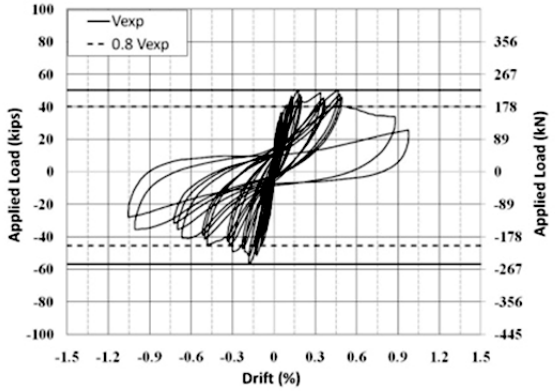
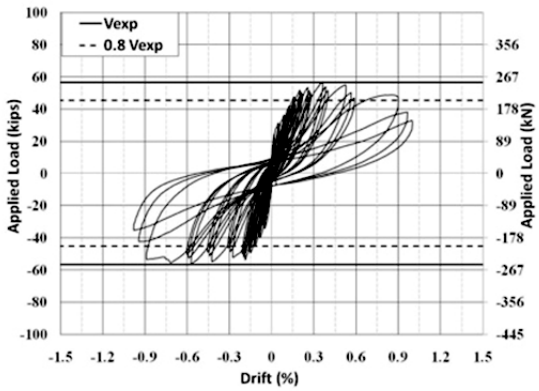


5. DISCUSSION

The shear strength of each shear wall was calculated using the shear provisions of the current MSJC (2008). The MSJC (2008) predicts the nominal shear strength (V_n) of partially grouted masonry shear walls (PGMW) using Equations 1 to 5. V_n is calculated as the summation of the nominal shear strength provided by shear reinforcement (V_{ns}) and masonry panel (V_{nm}). The only distinction between partially and fully grouted



masonry walls is that, in the case of partially grouted walls the MSJC (2008) uses the net grouted area (A_n) instead of the gross cross sectional area (A_g), as in the case of fully grouted masonry walls.

Table 2 presents the parameters used to calculate the shear strength for the tested specimens. It is worth noting that the net cross sectional area was calculated using the sum of the areas of the face shells and the grouted cells for each specimen. In addition, Table 2 shows the calculated and measured strength values. Finally, the hysteretic loops of the test specimens as well as the calculated values for V_n and V_n times the shear strength reduction factor $\phi = 0.8$ are also presented on Figure 12. As shown in the figure and the table, the MSJC (2008) shear design equations are highly un-conservative and over-estimated the shear strength capacity for the tested walls. The measured shear strengths ranged from 60% to 91% of the predicted values.

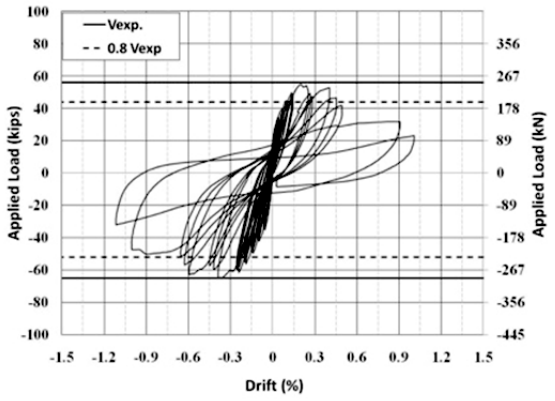


Figure 13 shows the relationship between the horizontal reinforcement ratio and V_{exp}/V_n which represents the ratio between the measured and the predicted nominal shear strength. As shown in the figure, the error in predicting the nominal shear strength slightly decreased with increasing the provided shear reinforcement. For specimens having reinforcement ratio of 0.127% (i.e. specimens PG127-48 and PG127-48I), the error was approximately 38%. Doubling the reinforcement ratio to 0.254% (i.e. specimen PG254-48), decreased the error in the prediction of V_n to 30%.

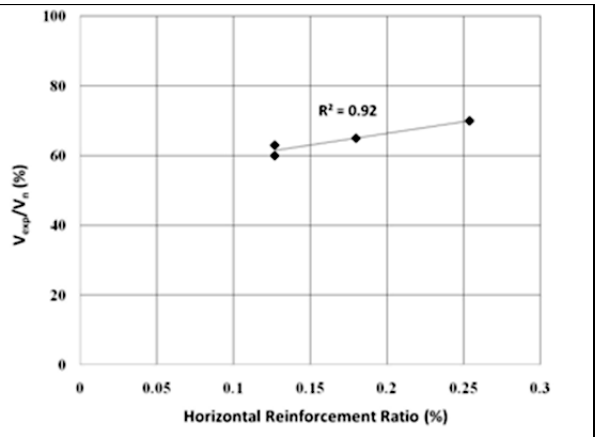

Figure 13 Effect of horizontal reinforcement on the predictions using MSJC (2008) shear equation for specimens with grout horizontal spacing of 1219 mm (48 in.)

Specimens PG127-48, PG127-48I, PG127-32, and PG127-24 have constant horizontal reinforcement ratio of 0.127%, but different grout horizontal spacings of 1219 mm (48 in.), 813 mm (32 in.), and 610 mm (24 in.), respectively. Figure 14 shows the relationship between the net cross sectional area and the measured shear strengths. Also, the figure shows predictions using MSJC (2008) shear design equations. As shown in the figure, by decreasing the grouted cross sectional area, the differences between the predicted values using MSJC (2008) shear design equations and the measured shear strengths increased. This finding indicates the need to modify the shear strength of partially grouted masonry shear walls with respect to grout horizontal spacing and net cross sectional area.

6. CONCLUSIONS

The experimental work presented in this thesis revealed that:

- There seems to be a threshold horizontal reinforcement ratio beyond which any increase in the shear reinforcement does not yield any increase in the strength of the shear walls since failure occurred due to compression strut failure.
- Decreasing the grout horizontal spacing significantly improved the strength of the investigated shear walls.
- The current MSJC (2008) shear design equation for partially grouted masonry shear walls is highly un-conservative and over-estimated the shear strength capacity for the tested walls. The over-estimation in the predicted shear strengths using the current MSJC (2008) ranged from 60 to 91%.

The experimental work presented in this thesis revealed that:

Abstract: This paper presents shear strengthening method for reinforced concrete (RC) beams using Engineered Cementitious Composite (ECC) panels. ECC is one of the cementitious materials which are known as its pseudo strain hardening behavior and crack dispersibility. ECC panels were attached on both sides of RC beam specimen by stainless anchor bolts. Experimental parameters were presence of shear keys at the interface between panels and steel mesh inside of the panels. Non-strengthened RC beam was also prepared as a reference specimen. The specimens were subjected to 4-point loading. As a result of the experiment, ECC panels could considerably increase shear capacity of RC beams. Especially shear capacity of the beam strengthened by ECC panels with providing shear keys was increased up to 150% of that of non-strengthened specimen. This is because shear keys enable to transfer stress in perpendicular direction of member axis, and hence diagonal compression forces were formed across the interface between the panels.

1. INTRODUCTION

In the Great Hanshin (Kobe) earthquake 1995 Japan, shear failure of reinforced concrete (RC) structure occurred and a lot of human lives were lost because of its brittle behavior. Another problem of shear failure is its difficulty for rehabilitation. In the Great Hanshin earthquake, RC piers of highway bridge were collapsed and it took long time to restore. It inhibited rescue activities for the disaster victims. Shear capacity of RC structures is therefore one of the most important issues to mitigate seismic risk of urban cities.

To reduce social damage in the next coming great earthquake, Japan Society of Civil Engineers (JSCE) and Architectural Institute of Japan (AIJ) have revised their design specification for shear of RC members. Thus, newly-constructed structures satisfy safer structural performance, however, more practical problem is repairing and strengthening of existing structures because of the financial situation in Japan and other countries.

As methods for repairing and strengthening of RC members, surface treatment, resin injection for cracks, patch repair, steel plate attachment, FRP sheet attachment, and external cable prestressing have been proposed and started to be used. However, these methods have some problems such as corrosion and heavy weight of steel plate and brittle failure of FRP material. On the other hand, Engineered Cement Composite (ECC) is an advanced cementitious material which is known as its pseudo strain hardening behavior and crack dispersibility (Li 1998). Yamamoto et al. (2010) conducted uni-axial tensile loading tests and resonant frequency tests of damaged early-age ECC after wet-dry cycles. They reported that self-healing of pre-induced cracks was observed and tensile strength and resonant frequency were recovered. Thus, ECC has a possibility to enhance not only mechanical performance but also durability of structures.

Because of the above point of view, this study explored shear strengthening method for RC beams using ECC panels. ECC was cast in panel shape, and then attached on both sides of RC beams by anchor bolts. Four-point bending tests of strengthened beams were carried out. Strengthening effect and shear resisting mechanism of ECC panels were investigated.

2. EXPERIMENTAL PROGRAM

2.1 Materials

Table 1 shows mix proportion of ECC used in this study. The pre-mix binder contained ordinary Portland cement, limestone powder, fly ash and expansion agent. Properties of the used polypropylene fiber were length = 12 mm, density = 0.91 g/cm^3, tensile strength = 482 N/mm^2, and elastic modulus = 5000 N/mm^2, respectively.

Table 2 shows mix proportion of concrete. Early strength cement was used. Water to cement ratio (*W/C*) and

Table 1 Mix proportion of ECC

W/P [%]	V_f [Vol. %]	Unit quantity [kg/m^3]		
		W	*PM*	*Ad*

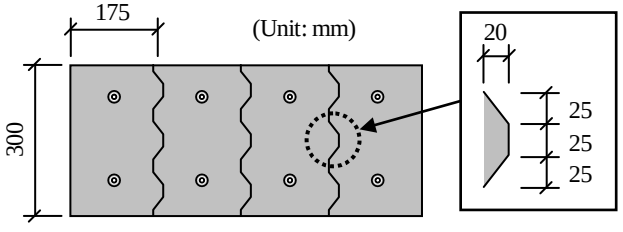

Figure 2 Size of the ECC panels and shear leys.

maximum size of coarse aggregate (G_{max}) were 0.6 and 20 mm, respectively.

2.2 Specimens

Figure 1 shows dimension and reinforcing bar arrangement of RC beams and location of the ECC panels. The shear span and the effective depth were 700 mm and 250 mm, respectively. The concrete mentioned in section **2.1** was used and the specimen was cured during 1 week. Tables 3 and 4 list specification of the RC beam and material properties of the reinforcing bars, respectively. For all specimens, failure side was controlled in the right span with putting stirrups into the left span. Stirrups were not provided in the test span.

Figure 2 shows dimension of the ECC panels. Totally 16 pieces of ECC panels whose size is 175 mm in width, 300 mm in height and 14 mm in thickness were attached on both sides of the both shear spans by using stainless anchor bolts. In this paper, the ECC panels attached on the test span are called panel [A], [B], [C] and [D], depending on the attached location. Presence of shear keys provided between the ECC panels and steel mesh at the inside of the ECC panels were the experimental parameters. Shape of the shear keys were trapezoid with 20 mm in height, 25 mm in upper base and 75 mm in lower base. Figure 3 illustrates arrangement of the steel mesh.

2.3 Experimental Cases

Table 5 lists the experimental cases in this study. Totally 5 RC beams were prepared. Two of them are the specimen tested in the authors' previous study (Matsumoto et al. 2010). REF is the reference specimen which ECC panels were not provided. NK-WM is the specimen in which shear keys were not provided but the steel mesh was used. WK-NM is the specimen in which shear keys were provided but the steel mesh was not used. WK-WM is the specimen in which both shear keys and the steel mesh were provided. NK-NM(UFC) is the other reference specimen conducted in the authors' previous study in which panels made of Ultra High Strength Fiber Reinforced Concrete (UFC) were attached.

2.4 Loading method

Load was applied by 2000 kN Amsler type loading machine. As illustrated in Fig. 1, the specimen was subjected to 2-point loading under simply supported condition. To satisfy simple supporting condition, steel plate whose width is 65 mm was put on the pin hinge supports and antifriction pad, which is consisted of two layers Teflon sheet and grease,

NK-NM(UFC)	32.3	2.2	29.5	211.9	50.1	64.6	52.3	23.5

f'_c is compressive strength of concrete, f_t is tensile strength of concrete, E_c is elastic modulus of concrete, f_{panel} is compressive strength of UFC or ECC, E_{panel} is elastic modulus of UFC or ECC, V_u is shear capacity, V_{REF} is Shear capacity of non-strengthened specimen considering the variation of compressive strength of concrete, and n is ratio of shear capacity increase to the shear capacity of non-strengthened specimen.

was inserted between the steel plate and the specimen. On the top surface of the specimen, gypsum was applied at the loading points, and loading plates whose width is 100 mm, steel rollers and load distribution beam were set.

2.5 Measuring Items

Measuring items were applied load, displacements at the mid span and supporting points, strain of tensile reinforcing bar at mid span and strain of the ECC panels. Displacements were measured by displacement transducers. Strain of tensile reinforcing bar at the mid span was measured by strain gauge whose length was 2 mm. In addition, for the ECC panels having shear keys, tri-axial strain gauges were attached to measure the principal strain and its direction.

3. RESULT OF THE EXPERIMENT

3.1 Increase Rate of Shear Capacity

Table 6 tabulates the material property of concrete and ECC and the results of loading tests. The ratio of shear capacity increase to the shear capacity of non-strengthened specimen n was calculated by Eq. (1).

$$n = \frac{V_u - V_{REF}}{V_{REF}} \times 100 \quad (1)$$

In Eq. (1), V_{REF} is the value expressed by the Eq. (2) which eliminates the effect of variation of compressive strength of concrete among the RC beams.

$$V_{REF} = \left(\frac{f'_c}{f'_{c_REF}} \right)^{\frac{1}{3}} \times V'_{REF} \quad (2)$$

where, f'_{c_REF} is the compressive strength of concrete used in the non-strengthened specimen (=33.2 N/mm^2), and V'_{REF} is the shear capacity of the non-strengthened specimen obtained in the loading test (=52.8 kN).

From Table 6, the specimens can be arranged as WK-NM, WK-WN, NK-NM(UFC) and NK-WM in order of increase in n. That is, the shear strengthening effect was prominent in specimens with providing shear keys to the panels (WK series). The noteworthy point is that the shear capacities of WK-NM and WK-WM were higher than that of the specimen strengthened by UFC which has much higher strength and modulus of elasticity. In addition, WK-NM showed the higher shear capacity than WK-WM which had the steel mesh for strengthening. The construction of anchor bolts could be the reason as discussed in detail later.

3.2 Load-Deflection Relationships and Crack Patterns

Figure 4 shows the relationship between applied load and the mid-span deflection. Figure 5 illustrates the crack patterns after the loading tests. The bold lines seen in each RC beam represent the most distinguished crack. The fracture process in each specimen will be discussed below.

(1) NK-WM

After the initiation of the flexural crack, the load reached the maximum value, 105.4 kN. No cracks were observed in ECC panels as seen in Fig. 5(a-1).

From Fig. 5(a-2), it is seen that cracks were connecting the holes for anchor bolts. In addition, crack penetration from the upper hole for panel [B] to the compression fiber was confirmed. This is because micro cracks were induced during the making holes. Regarding the following specimens, the embedded length of anchor bolts was shortened from 70 mm to 60 mm in order to prevent micro crack formation while making holes.

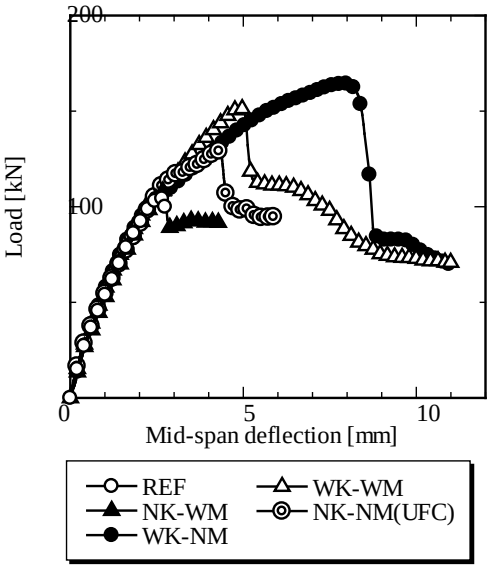

Figure 4 Load-deflection relationships.

(2) WK-WM

After the initiation of the flexural crack, the diagonal crack occurred in the RC beam when the applied load reached 107.0 kN. The load continuously increased up to 151.6 kN. As seen in Fig. 5(b-1), no cracks were observed in the ECC panels. After the loading test, some anchor bolts were pulled out.

(3) WK-NM

After the initiation of the flexural crack, the diagonal crack occurred in the RC beam at 107.0 kN. The load continuously increased to 164.4 kN. As seen in Fig. 16(c-1), some cracks were observed in panel [A]. After the loading tests, some anchor bolts were pulled out as well as observed in WK-WM.

4. SHEAR RESISTING MECHANISM

4.1 Strengthening Effect due to the Strain-Hardening Property

Figure 6 shows the maximum and minimum principal strain in panel [A] and panel [B] of WK-WM

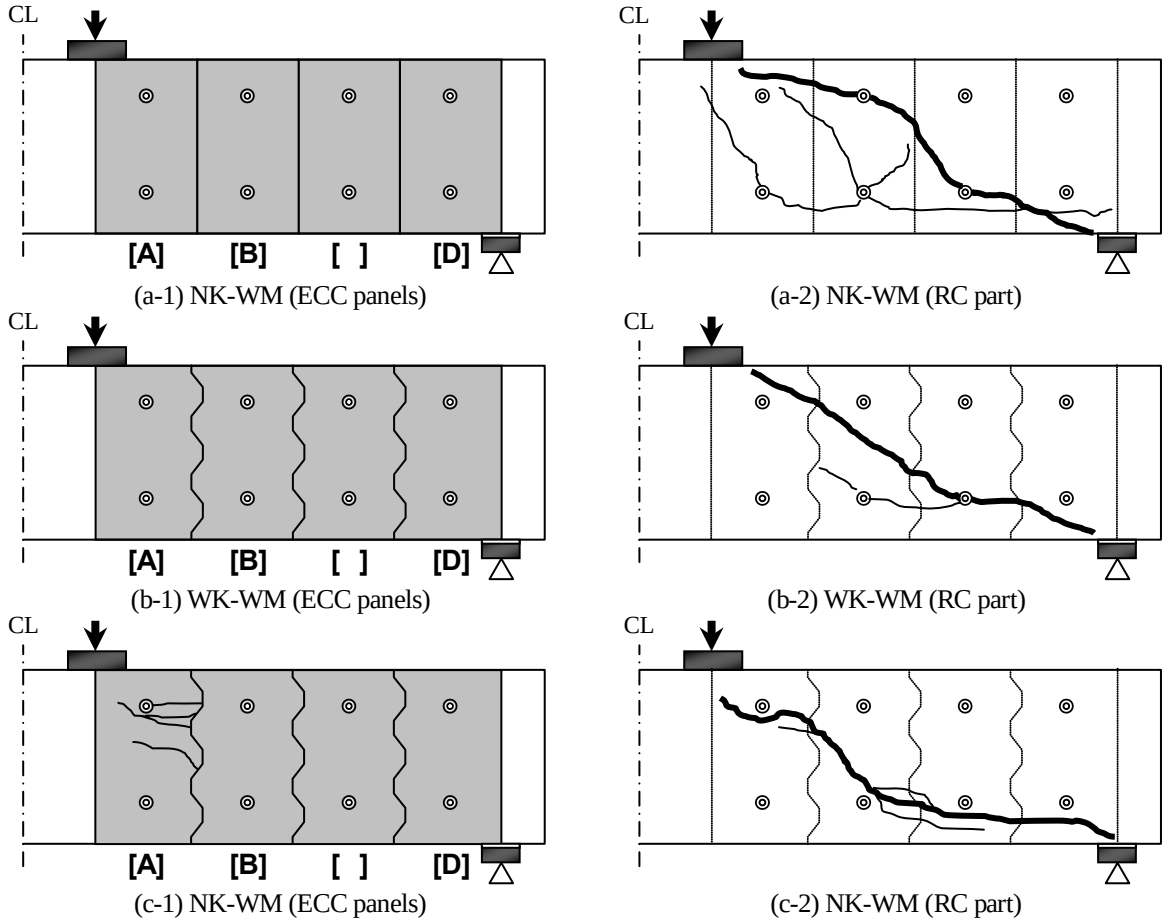

Figure 5 Crack patterns after the loading tests.

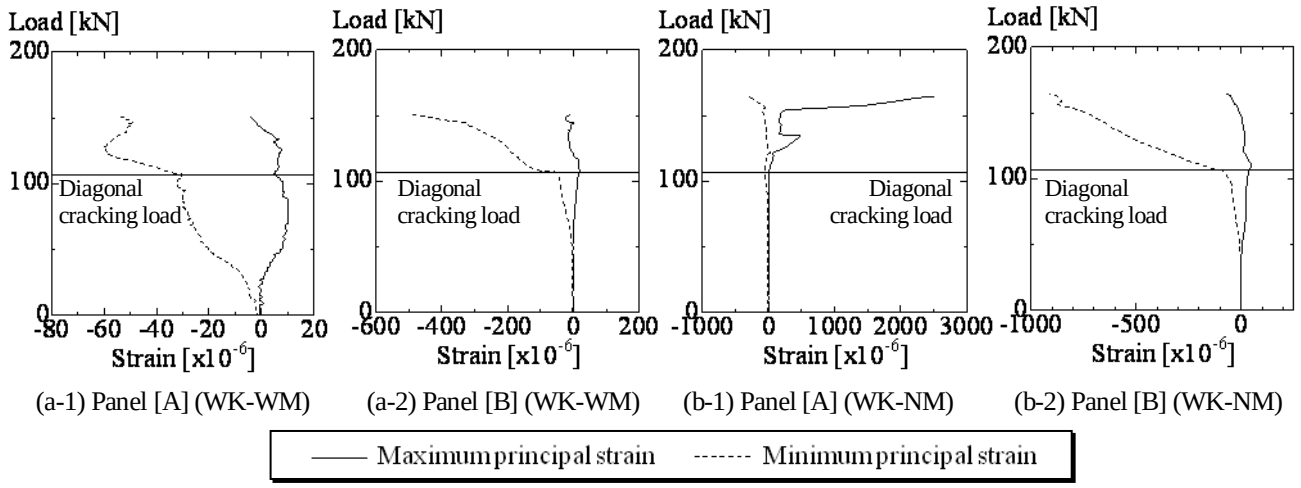

Figure 6 Principal strain in the specimens strengthened by ECC panels with shear keys.

Table 7 Angle of principal strain.

Specimen name	Panel	Angle of maximum principal strain, θ_{max} [degs]	Angle of minimum principal strain, θ_{max} [degs]
WK-WM	[A]	171	81
	[B]	179	89
WK-NM	[A]	28	118
	[B]	3	93

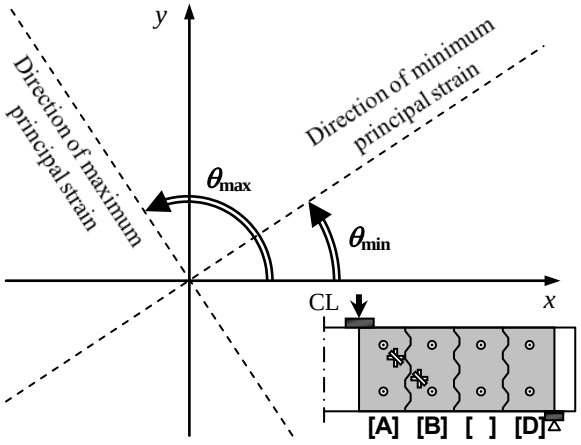

Figure 7 Definition of angle of principal strain.

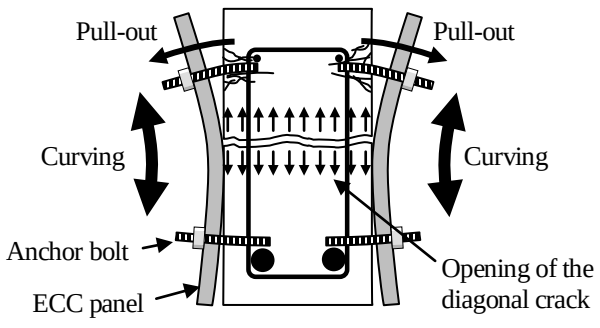

Figure 8 Pull-out of anchor bolts and panel curving.

and WK-NM. Here, the tensile strain is shown as positive value and the graphs are drawn until the load reached the maximum value. The angle of the principal strain at the maximum load is summarized in Table 7. The angle of the principal strain is the rotation angle from the horizontal direction of a specimen in a counterclockwise direction as shown in Fig. 7.

From Fig. 6(a-2) and (b-2), it can be seen that the minimum principal strain changed to the compressive direction in panel [B] of both WK-WM and WK-NM after the diagonal crack occurred. From Table 7, it is also seen that the direction of the minimum principal strain in panel [B] is almost vertical to the beam axis. In addition, significant peeling was observed between panel [B] and RC part in both WK-WM and WK-NM.

Considering the above points, the failure mechanism shown in Fig. 8 could occur in panel [B] of both specimens. Due to the initiation and widening of the diagonal crack in a RC part, the forces, which push out the two anchor bolts connecting the panel [B], occur. Due to these forces, the two anchor bolts are yielded or surrounding concrete is crushed. As a result, pull-out failure of the anchor bolts is caused. ECC panels are curved due to the pull-out failure of the anchor bolts. This panel curving results the wide opening between the RC part and ECC panels. In addition, no crack occurrence on the surface of ECC panels is also ascribable to this panel curving because the compression stress is induced on the outer surface of the panels.

On the other hand, given the increase in shear capacity of RC beams due to the contribution of ECC panels, it can be thought that the tensile force in the vertical direction also acted to the ECC panels. In other words, tensile force as the contribution to the increase in the shear capacity and bending moment as shown in Fig. 8 acted at the same time. Consequently, there is a possibility that cracks occurred in the back side of a panel which was the attached surface to the RC beam. The fiber bridging at these cracks could transfer the load and contribute to the increase in the shear capacity.

Next, the behavior of panel [A] in WK-NM is focused.

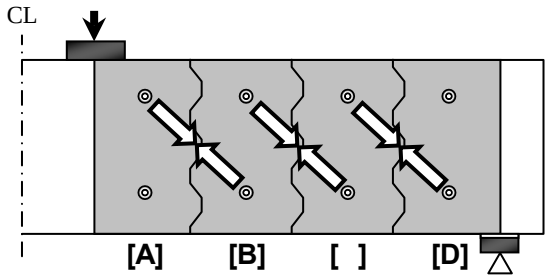

Figure 9 Flow of the diagonal compression force.

From Fig. 6(b-1), only a small amount of principal strain is seen before the diagonal crack occurred in RC part. However, the maximum principal strain started to increase in the tensile direction at the load of 122.0 kN. Afterward, the maximum principal strain showed the sharp decrease at the load of 135.0 kN. The cause of this decrease can be explained that the cracking in the back side of the ECC panel as discussed above temporary reduces the vertical force of panels. The maximum principal strain continued to increase at the load of 154.0 kN. This is caused by the cracking on the surface of the panel. It is inferable that there is less curving in panel [A] of WK-NM and therefore cracks on the surface of panel happened.

4.2 Role of the Shear Keys

From Fig. 6(b-1), it can be confirmed that the minimum principal strain in panel [A] of WK-NM increased in compression at the load of 157.0 kN. In addition, as seen in Table 7, the angle of the minimum principal strain was different from that of the other panels.

This is because the interlock of shear keys provided the diagonal compression force. The diagonal crack in RC part was widened as the loading test proceeded. With the widening of the diagonal crack, ECC panels moved up or down and the adjacent ECC panels were interlocked each other. This helped the diagonal compression force could be transferred. As a result, the flow of the compression force is formed from the upper and lower anchor bolts in the adjacent ECC panels as shown in Fig. 9.

5. CONCLUSIONS

In this study, shear behavior of RC beams strengthened by ECC panels was investigated. Loading tests of RC beams with attaching ECC panels on both sides by using anchor bolts were carried out. Presence of shear keys between panels and steel mesh inside the panels were the experimental parameter. Strengthening effect was verified by comparing to non-strengthened beam and the beam strengthened by UFC panels. As a result, following conclusions were obtained.

1) Shear capacity of the RC beams strengthened by ECC panels with shear keys drastically increased compared to the non-strengthened beam. Even though the material strength of UFC is much higher than that of ECC, the shear capacity was larger than that of the beam strengthened by UFC.
2) Curving of the ECC panels and pull-out of the anchor bolts lead to the failure of the RC beams strengthened by ECC panels with shear keys. The cause of panel curving and pull-out of anchor bolts was the force generated due to the occurrence and widening of the diagonal crack. The force acted vertically to push out the anchor bolts and resulted the yielding of anchor bolts or crushing of surrounding concrete. It caused the pull-out force of the anchor bolts.
3) When shear keys were provided between the ECC panels, the principal strain of the ECC panel increased in compression after the occurrence of the diagonal crack. In addition, direction of the compressive principal strain was inclined. It indicates that the formation of diagonal compressive force caused by interlocking of shear keys contributed to the shear resisting mechanism.

Abstract: Shear failure in reinforced concrete (RC) beams is well known as the brittle behavior happening without any warnings. This failure can be prevented by improving the shear capacity of the structures. The use of steel fibers as a shear reinforcement is one of the alternatives to enhance the shear resistance and ductility of the structures and this type of structures is called reinforced concrete with steel fibers (RSF). However, the current equation of Japan Society of Civil Engineers (JSCE) design guidelines for RSF members has not considered the post cracking behavior of reinforced concrete with steel fibers in details. The objective of this paper is to evaluate the contribution of steel fibers to shear resistance of RSF beams using the tension softening curves. Eight RSF beams with various steel fiber volume fraction and stirrup ratio were tested. The crack surface displacement was investigated from the image analyzing system. Length of the diagonal crack was measured for computing the area of stress transfer. The tension softening curves were used to calculate the stress transferred across the diagonal crack. Finally, the shear carried by steel fibers was investigated.

1. INTRODUCTION

The standards specifications of Japan Society of Civil Engineers (JSCE) for seismic design of reinforced concrete structures (2002) have been revised after the 1995 Hyogoken-Nambu earthquake resulting in high requirement for steel bars in the structures. This leads congestion of steel bars; thus, it is difficult to fill concrete during the construction. The use of steel fibers is one of the solutions for this problem. Many researchers (Narayanan and Darwish 1987 and Watanabe et al. 2009) have reported that the addition of steel fibers can improve the shear resistance and the ductility of reinforced concrete (RC) beams. Steel fibers enhance the energy dissipation capacity. Hence, reinforced concrete with steel fibers (RSF) beams provide higher seismic performance than ordinary RC beams.

In JSCE design guidelines for RSF members (1999), the increment of the shear strength by steel fibers has been expressed as a value κ, which is defined as a ratio of the shear carried by steel fibers to the shear carried by concrete and κ is considered as 1.0. However, the current equation underestimated the shear capacity of RSF beams. Watanabe et al. (2009) concluded that the values of κ observed in the experiment were more than 1.0. In addition, there was an optimized combination of steel fibers volume fraction (SF) and the stirrup ratio (r_w) to increase the value of κ. It was suggested that the optimized combination would be related to the crack surface displacement and the length of the diagonal crack. Nevertheless, there was no verification for the influence of crack surface displacement and length of the diagonal crack on the shear carried by steel fibers of RSF beams.

The purpose of this research is to evaluate the shear carried by steel fibers of RSF beams. Eight RSF beams with different SF and r_w were tested. The crack surface displacement (u), which was the displacement of crack in the direction of crack's movement, was evaluated by using the displacements of targets obtained through the image analyzing system. The tension softening curve, which was one of the fracture parameters, was used to explain the shear resistance mechanism of RSF beams. The tensile stress transferring at the diagonal crack surfaces was calculated from measured crack surface displacement by using the relationship of the tension softening curves. The shear carried by steel fibers was evaluated. The comparison between the experimental values and the calculated values was presented for the validation of the proposed method.

2. TENSION SOFTENING CURVES

In order to estimate the tension softening curves, the bending tests of notched beams were conducted according to the standard of Japan Concrete Institute (JCI) (2003). The tension softening curve represents the relationship between tensile stress and crack opening displacement in the fracture

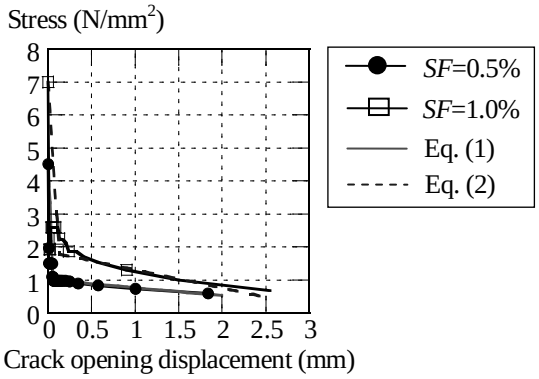

Figure 1 Tension Softening Curves

zone. The tension softening curves of fiber reinforced concrete having SF = 0.5% and 1.0% of concrete full volume were examined as shown in Figure 1. The compressive strength of concrete was 59.6 and 56.5 N/mm^2; in addition, the fracture energy of concrete was 2.03 and 3.26 N/mm when SF = 0.5 and 1.0%, respectively. From the tension softening curves, the relationships between the crack surface displacement (u) and tensile stress of concrete (σ) can be obtained by the regression analysis. The bilinear curves for $\sigma(u)$ of 0.5 and 1.0% of steel fiber volume fraction are given by Eqs. (1) and (2), respectively.

$$\sigma = \begin{cases} 4.5 - 58.6u & \text{for } u < 0.06\,\text{mm} \\ 1.0 - 0.24u & \text{for } u \geq 0.06\,\text{mm} \end{cases} \quad (1)$$

$$\sigma = \begin{cases} 7.0 - 40.2u & \text{for } u < 0.13\,\text{mm} \\ 1.85 - 0.55u & \text{for } u \geq 0.13\,\text{mm} \end{cases} \quad (2)$$

3. EXPERIMENTAL PROGRAM

3.1 Test Specimens

The test program consisted of eight RSF beams with different SF and r_w. SF was 0.5 and 1.0% of concrete volume. r_w was varied (i.e. r_w=0.00, 0.12, 0.18, 0.24, and 0.30%). The detail of a RSF beam is illustrated in Figure 2. The shear span (a) was 700 mm and effective depth (d) was 250 mm. The shear span to effective depth ratio (a/d) was 2.8. The longitudinal reinforcement ratio (p_w) was 2.7%. The number of stirrups used in each specimen was changed corresponding to the stirrup ratio. The specimen cases are summarized in Table 1. Specimens were named according to SF and r_w; e.g. SF10-r18 corresponded to the specimen with SF=1.0% and r_w=0.18%.

3.2 Material

The detail of mix proportion of concrete is summarized in Table 2. The concrete was designed with average 7-day age strength of 50 N/mm^2. The steel fibers used in this research had hook-ends. The length was 30 mm, the diameter was 0.62 mm, the aspect ratio was 48, the yield strength was 1050 N/mm^2, the density was 7850 kg/m^3, and

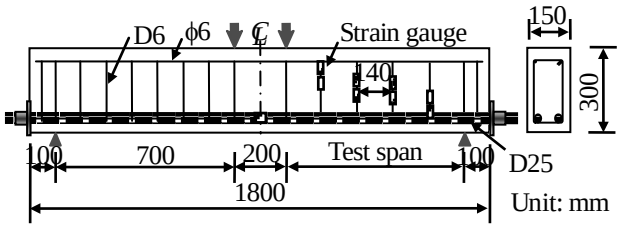

Figure 2 Outline of a RSF Beam

Table 1 Experimental Cases

Case	Steel fiber volume fraction (%)	Stirrup ratio (%)
SF05-r00	0.5	0.00
SF05-r18		0.18
SF05-r30		0.30
SF10-r00	1.0	0.00
SF10-r12		0.12
SF10-r18		0.18
SF10-r24		0.24
SF10-r30		0.30

the elastic modulus was 210 kN/mm^2. The longitudinal reinforcing bars were deformed steel with 25.4 mm of the nominal diameter. The yield strength was 1016 N/mm^2. The stirrups with deformed steel of 6 mm in the diameter were arranged as the shear reinforcement. The yield strength was 336 N/mm^2. Two round bars with the diameter of 6 mm were used as compression bars. The yield strength was 293 N/mm^2.

3.3 Loading Method and Measurement Items

Specimens were subjected to a four-point bending. Locations of loading and supporting points are illustrated in Figure 2. Specimens were placed on the roller supports.

During the loading test, the applied load was measured. Mid-span deflection was measured using four transducers. The strain gauges were used for measuring strain of longitudinal steel bars at mid-span. Besides, the strains of stirrups were measured at the locations that diagonal crack was expected to occur as shown in Figure 2.

3.4 Image Analysis and Crack Surface Displacement

The image analyzing system developed by Higashi et al. (2009) was conducted in order to measure the crack surface displacements of specimens. Red targets with diameter of 5 mm were attached on the specimen surface with an interval of 20 mm. The white light-emitting diodes (LED) were used to increase accuracy of the image analysis. During the loading test, photos of the specimen were taken by every 5 kN of the shear force by using three digital cameras fixed on tripods. A picture of loading test is shown in Figure 3. The coordinates of targets were investigated by the image analysis.

Crack surface displacement (u) is defined as the relative displacement of targets on the principal tensile strain direction, which is the direction of crack's movement. The calculation procedure of u is shown in Figure 4. First, the

Table 2 Mix Proportion of Concrete

Maximum size of coarse aggregate (mm)	Water-cement ratio *W/C* (%)	Sand-aggregate ratio *s/a* (%)	Unit weight (kg/m^3)				
			Water	Cement	Fine aggregate	Coarse aggregate	Superplasticizer

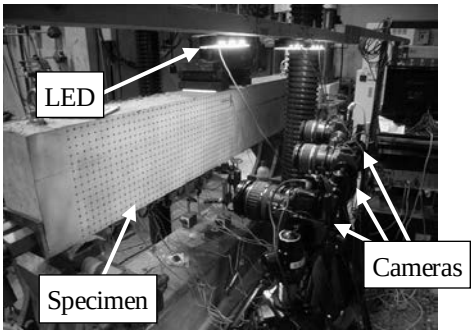

Figure 3 Loading Test

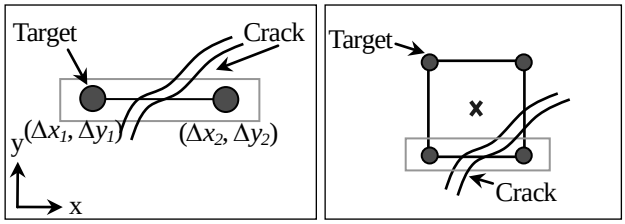
displacements of targets in x and y directions are examined. The displacements of targets are the difference of coordinate of targets between first photo and any photos. Second, the relative displacement between two targets that the crack passed (Δx, Δy) (Figure 4 (a)) is calculated using Eq. (3). Third, the angle of principal tensile strain (θ) is calculated at the center of square that the crack passed (Figure 4 (b)) by using Eq. (4). Finally, crack surface displacement, u, is determined by Eq. (5) as shown in Figure 4 (c).

$$\Delta x = \Delta x_1 - \Delta x_2\,, \quad \Delta y = \Delta y_1 - \Delta y_2 \tag{3}$$

$$\theta = 0.5\tan^{-1}\left\{\frac{\gamma_{xy}}{(\varepsilon_x - \varepsilon_y)}\right\} \tag{4}$$

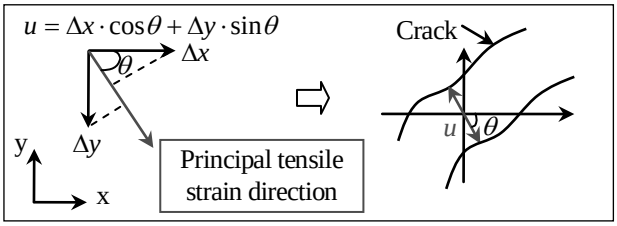
$$u = \Delta x \cdot \cos\theta + \Delta y \cdot \sin\theta \tag{5}$$

where, Δx is the relative displacement in x direction, Δy is the relative displacement in y direction, (Δx_1, Δx_2) is the displacement of targets in x direction, (Δy_1, Δy_2) is the displacement of targets in y direction, θ is the angle of principal tensile strain, γ_{xy} is the shear strain, ε_x is the strain of x-axis, and ε_y is the strain of y-axis.



3.5 Measurements of Length and Angle of Diagonal Crack

The length and angle of diagonal crack were measured from the visible diagonal crack at the peak load by using the image processing software. The images taken for measuring the crack surface displacements were also used to measure the diagonal crack length and angle of diagonal crack.



4. EXPERIMENTAL RESULTS

4.1 Load-Deflection Relationship of RSF Beams

The load-mid span deflection relationships of RSF beams are presented in Figure 5. These diagrams show

(a) Targets that Crack Passed (b) Square that Crack Passed

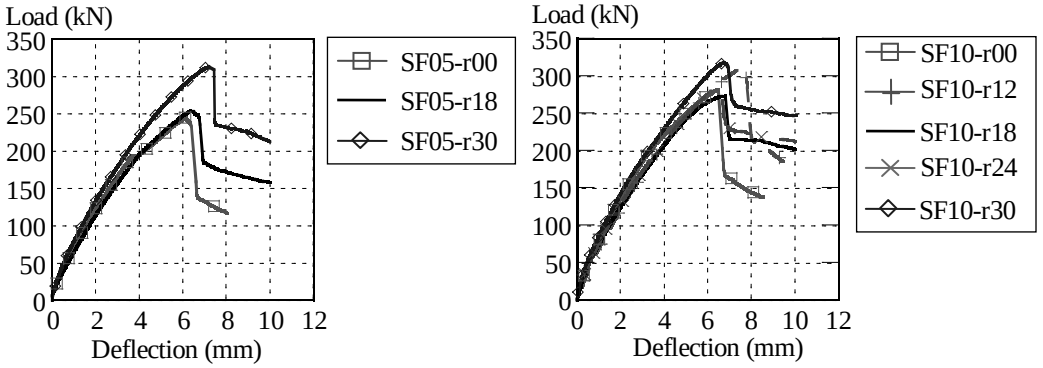
(c) Crack Surface Displacement

Figure 4 Calculation of Crack Surface Displacement

clearly that the shapes of the load-deflection curve of the corresponding beams were basically similar in all specimens. All the beams exhibited similar linear behavior from the initial loading up to the first flexural crack. After the first flexural crack, the curve still increased linearly until the initiation of a diagonal crack occurred in a shear span. The diagonal crack was observed around the middle height of the specimen. After the initiation of a diagonal crack, the diagonal crack propagated to supports and to the top of specimens. In addition, the appearance of the diagonal crack reduced the slope of load-deflection curves of RSF beams. All of the stirrups, which the diagonal crack passed, showed the yielding strain in this stage. The propagation of the diagonal crack length stopped when the diagonal crack reached to the compression zone. From this stage, the rate of load increment became slight and the load-deflection curves showed nonlinear behavior. Then, the load reached to the peak and suddenly dropped due to the crushing of the concrete in compression zone. Similar process of shear failure was observed in all beams.

4.2 Diagonal Cracking Behaviour

One critical diagonal crack was remarkable in each specimen. This study focuses on the tensile force along this diagonal crack. Specimens were divided to 15 elements with a height of 20 mm corresponding to the interval of targets of the image analysis as shown in Figure 6. Crack surface displacement (u_i), length (L_i), angle of principal tensile strain (θ_i), and angle of a diagonal crack (β_i) of each element were investigated based on the pictures taken at peak load.



1. *Crack surface displacement (u)*

The value of u along the height of specimens at the maximum load is shown in Figure 7. Unlike the flexure

Table 3 Summary of the Experimental Results

Figure 5 Load-Deflection Curves

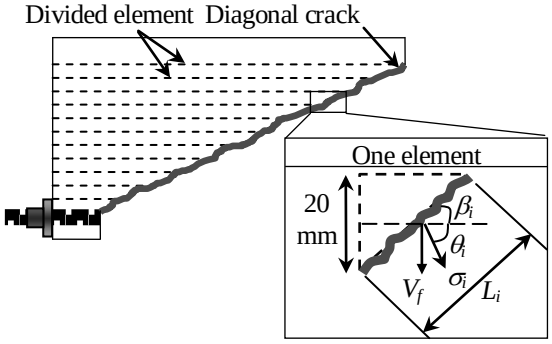

Figure 6 Free Body Diagram

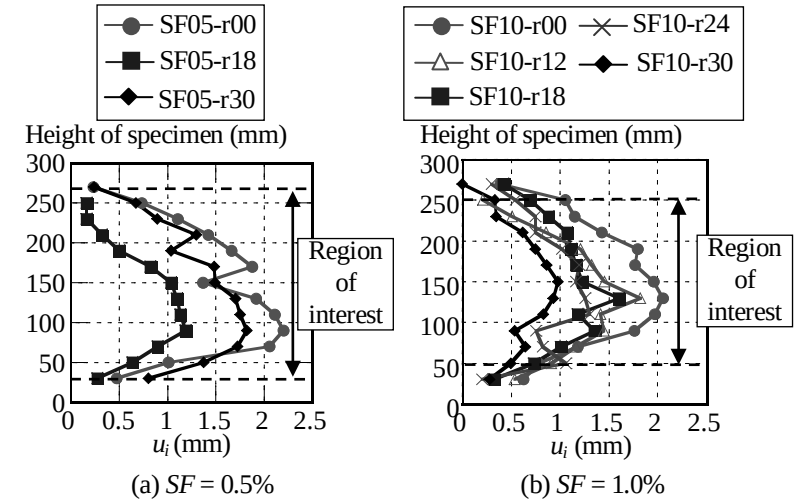
crack, the diagonal crack surface displacement was larger at around the middle height of specimens compared with the u at the top and the bottom of specimens because there was compression zone at top of specimens and restraint by longitudinal reinforcing bars at the bottom fiber. Table 3 shows the average value of crack surface displacement (u_{avg}) of diagonal crack in the region of interest. The region of interest is from the height below the compression zone until the tip of the diagonal crack in the tension zone, which is the same position with the location of tensile bars in specimens having SF=1.0%. In specimens which SF=0.5%, the diagonal crack propagated into the concrete cover zone and stopped at 30 mm from the bottom fiber because of the less shear reinforcement. The compression zone is the height of specimens from the top fiber to the location of neutral axis. The neutral axis was calculated from the displacements of targets obtained through the image analysis. The region of interest is shown in Figure 7. The results showed that u_{avg} increased with the increase in the steel fiber volume fraction and decreased with the increase in the stirrup ratio.

2. *Diagonal crack length (L)*

The crack length (L) is the length of a diagonal crack in the region of interest. L decreased with the increase in SF and r_w as shown in Table 3.



3. *Angles of principal tensile strain (θ) and diagonal crack (β)*

The angles of principal tensile strain (θ) and diagonal crack (β) were measured at the same position with the crack surface displacement. Table 3 presents the average value of these angles in the region of interest. θ_{avg} and β_{avg} did not change significantly among these specimens.

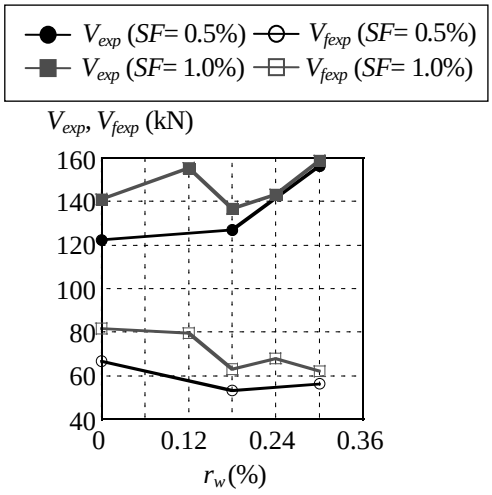
5. SHEAR FORCES

5.1 Calculation Method and Experimental Values of Shear Forces

According to JSCE design guidelines (1999), the shear capacity of RSF members (V_{cal}) and the shear carried by concrete (V_c) can be calculated from Eqs. (6) and (7). The

(a) SF = 0.5% (b) SF = 1.0%

Figure 7 Distribution of Crack Surface Displacement at Peak Load



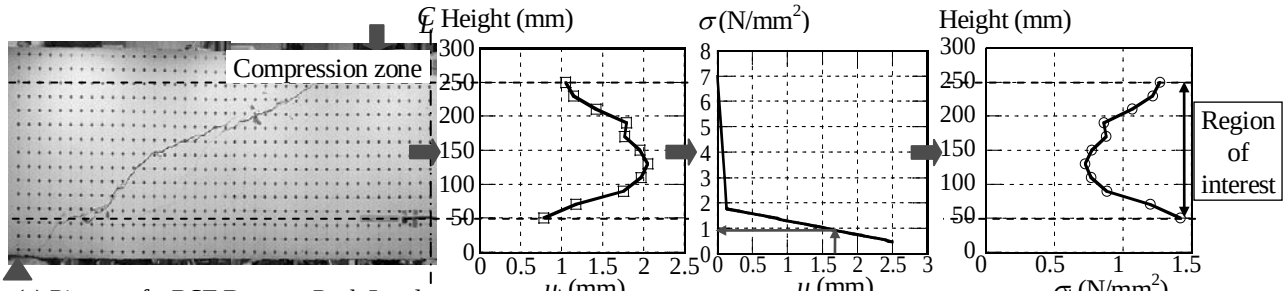


Figure 8 Effect of SF and r_w on V_{exp} and V_{fexp}

(a) Picture of a RSF Beam at Peak Load (SF10-r00) (b) u Distribution (c) Tension Softening Curve (d) Stress Distribution

Figure 9 Investigation Procedures of Tensile Stress Transferred across the Diagonal Crack

shear carried by stirrups (V_s) was calculated from the yielding stress of stirrups that diagonal crack passed as shown in Eq. (8). The experimental value of shear carried by steel fibers (V_{fexp}) was investigated by Eq. (9) while experimental value of κ was calculated by using Eq. (10).

$$V_{cal} = (1+\kappa)\cdot V_c + V_s \quad (6)$$

$$V_c = 0.2\cdot\sqrt[3]{f_c'}\cdot\sqrt[4]{1000/d}\cdot\sqrt[3]{100\,p_w}\cdot b_w\cdot d \quad (7)$$

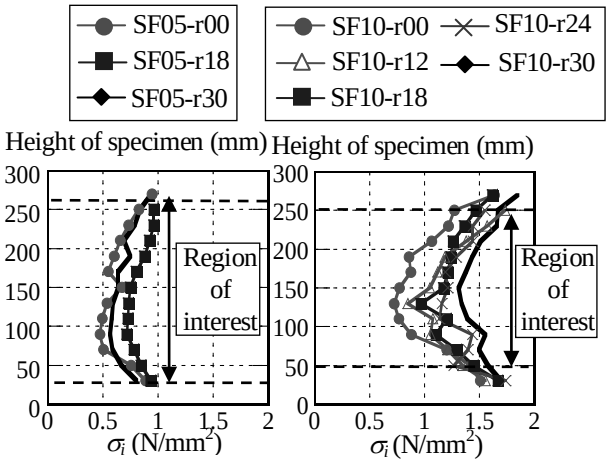
$$V_s = \sum A_w f_{wy} \quad (8)$$

$$V_{f\,exp} = V_{exp} - V_c - V_s \quad (9)$$

$$\kappa_{exp} = V_{f\,exp}/V_c \quad (10)$$

where, κ is coefficient representing the effect of fibers (κ=1.0), f_c' is compressive strength of concrete (N/mm^2), d is effective depth (mm), p_w is longitudinal reinforcement ratio (%), b_w is web thickness (mm), A_w is cross section area of stirrups (mm^2), and f_{wy} is yield strength of stirrups (N/mm^2).

The shear forces from experimental results are listed in Table 3. The shear capacity of RSF beams (V_{exp}) was higher than the calculated value obtained from Eq. (6). κ_{exp} was more than 1.0 except SF05-r30. The values of V_{exp} and V_{fexp} varied depending on SF and r_w.



5.2 Influences of Steel Fiber Volume Fraction and Stirrup Ratio

The effect of SF and r_w on V_{exp} and V_{fexp} of RSF beams is shown in Figure 8. V_{exp} showed the maximum value in SF10-r30, while the maximum value of V_{fexp} was SF10-r00. By comparing V_{exp} and V_{fexp} of specimens with the same r_w, it was found that the increase in the SF from 0.5 to 1.0% enhanced the values of V_{exp} and V_{fexp}. However, the improvement of V_{exp} and V_{fexp} due to the effect of SF became less significant with the increase in r_w. This implies that the effect of steel fibers as the shear reinforcement is dominant in case of smaller r_w.

On the other hand, beams with the same SF but different in r_w showed another tendency. That is, the value of V_{exp} in RSF beams will not necessarily increase with the increase in r_w as shown in Figure 8. This is because of the reduction of V_{fexp} in specimens with high r_w. This result confirms that there is a combination effect of stirrups and steel fibers to increase the value of V_{fexp}.

6. EVALUATION OF SHEAR CARRIED BY STEEL FIBERS

The shear carried by steel fibers was investigated using tension softening curves. Calculation procedures of the shear carried by steel fibers in this study are shown in Figure 9. The crack surface displacement of each element was

(a) SF = 0.5% (b) SF = 1.0%

Figure 10 Stress Distribution along the Diagonal Crack

converted to the tensile stress transferring along the diagonal crack by using the relationship of tension softening curves (Eqs. (1) and (2)). The results of tensile stress along the height of diagonal crack at peak load are shown in Figure 10. The larger stress could be resisted at top and bottom parts of specimens due to the smaller crack surface displacement.

By considering the force acting at a diagonal crack in a RSF beam due to the effect of steel fibers (Figure 6), the tensile force along the diagonal crack of each element can be obtained by multiplying σ_i with the area of crack surface normal to the direction of σ_i. The shear force was calculated for element by element. The vertical component of the force with the consideration of θ_i is the shear carried by steel fibers. According to Figure 6, the force along the diagonal crack is obtained from the portion below the compression zone to the tip of diagonal crack in the tension zone. The numbers of elements in the region of interest were 13 elements for specimens having SF=0.5% and 11 elements for specimens having SF=1.0%. The shear carried by steel fibers (V_{fcal}) can be expressed as Eq. (11).

$$V_{fcal} = \sum_{i=1}^{n} \left(\sigma_i \cdot b_w \cdot L_i \cdot \cos\left(\theta_i + \beta_i - 90\right) \cdot \sin\theta_i\right) \qquad (11)$$

where, n is number of elements in the region of interest, σ_i is the tensile stress of element i (N/mm^2), L_i is the length of diagonal crack of element i (mm), θ_i is the angle of principal tensile strain of element i (degree), and β_i is the angle of diagonal crack of element i (degree).

The result of calculated shear carried by steel fibers (V_{fcal}) using Eq. (11) and the experimental value (V_{fexp}) given by Eq. (9) is summarized in Table 3. Figure 11 presents the comparison of the experimental results and calculated values. A total of eight specimens were used to validate the proposed method. The mean value of the experimental value to calculated value of the shear carried by steel fibers was 1.00 with the coefficient of variation (*C.V.*) of 8.5%. The comparison demonstrates that V_{fcal} corresponded with V_{fexp}. This finding implies that the shear carried by steel fibers can be evaluated by using the tension softening curves.

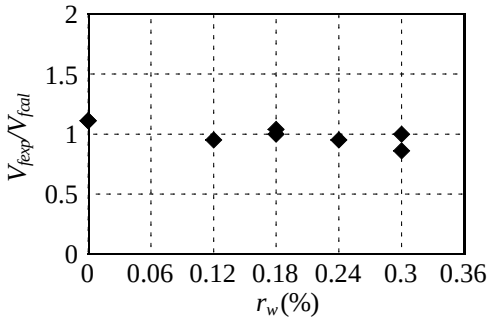


Figure 11 Comparison of V_{fexp} and V_{fcal}

7. CONCLUSIONS

The following conclusions were drawn from the study on the contribution of steel fiber to the shear capacity of reinforced concrete beams with steel fibers by considering the steel fiber volume fraction and the stirrup ratio.

(1) The crack surface displacement of diagonal crack around the middle height of specimens was larger than those at top and bottom fibers because there was the compression zone at the top fiber and restraint by the longitudinal steel bars at the bottom fibers.

(2) The crack surface displacement increased with the increase in the steel fiber volume fraction and decreased with the increase in the stirrup ratio.

(3) The length of diagonal crack decreased when the steel fiber volume fraction and the stirrup ratio increased.

(4) By comparing with the tensile stress around the middle of specimens, the tensile stress transferred across the diagonal crack was higher in top and bottom fibers due to the smaller crack surface displacement.

(5) The shear carried by steel fibers calculated by using the crack surface displacement, the diagonal crack length and the relationship of the tension softening curves corresponded with experimental values.

Abstract: The utilization of recently developed high strength materials can satisfy the need for improving seismic performance of infrastructures. However, in case of reinforced concrete (RC) beams, the combination of thin web T- or I-shaped cross section and high strength shear reinforcing bars will lead to an uncommon type of shear failure known as the diagonal compression failure. This research aims to investigate the influence of various parameters on diagonal compressive capacity of RC beams using high strength materials. Eight I-beams were tested by three-point bending. Verification of the effect of compressive strength of concrete, stirrup spacing, flange width to web width ratio and effective depth was performed. As a result, the effect of compressive strength of concrete and stirrup spacing were interrelated while the effect of the other factors cannot be observed. Finally, the accuracy of the existing equations for the diagonal compressive capacity was revealed.

1. INTRODUCTION

The improvement of seismic performance of infrastructures is required in order to mitigate the seismic risk and build a safe society. This demand can be satisfied by the utilization of the recently developed high strength materials, e.g. high strength concrete with the compressive strength (f'_c) greater than 100 N/mm^2 and high strength reinforcing bars with the yield strength (f_y) greater than 685 N/mm^2. Because of their high strength properties, cross-sectional area of bridge girders can be reduced which resulting in the reduction of dead load transferred into substructure. However, in case of reinforced concrete (RC) beams, the combination of thin web T- or I-shaped cross section and high strength shear reinforcing bars will lead to an uncommon type of shear failure known as the diagonal compression failure. It is caused by the crushing of web concrete prior to the yielding of stirrups. This type of failure is hazardous because of its brittle behavior.

The research on the mechanism of diagonal compression failure is insufficient since it is usually avoided. On top of that, there are some concerns regarding the applicability of the existing predictive equation for diagonal compressive capacity to high strength concrete since most of them were based on experimental results of beam specimens with normal strength concrete. The design equation for the diagonal compressive capacity of RC beams in the current Japan Society of Civil Engineers (JSCE) standard specifications for concrete structures (2002) only considers the effect of compressive strength and limits the applicability to concrete with f'_c up to 50 N/mm^2.

Besides, there are limited studies on diagonal compression failure in high strength RC beams except for Kobayashi et al. (2009). They reported that the factors affecting the diagonal compressive capacity are the compressive strength (f'_c), the stirrup ratio (r_w) and the shear-span to effective depth ratio (a/d). However, in regard to some factors, e.g. f'_c and r_w, there is a lack of experimental data especially in both $f'_c > 100$ N/mm^2 and $r_w < 2\%$. As well, the effect of the flange width to web width rato (b_f/b_w) and effective depth (d) or size effect on the diagonal compressive capacity has not been clarified yet. From these reasons, further study is required.

The main objectives of this research are to investigate the mechanism of the diagonal compression failure of thin web RC beams using high strength materials. In this study, eight I-shaped RC beams were tested by three-point bending. The effect of f'_c, r_w, b_f/b_w and d on the diagonal compressive capacity was evaluated. Finally, the accuracy of the existing equations was verified.

2. REVIEW OF THE EXISTING EQUATIONS FOR DIAGONAL COMPRESSIVE CAPACITY

2.1 The equation by Placas and Regan

Placas and Regan (1971) proposed an empirical

equation for evaluating the diagonal compressive capacity as the following:

$$V_{Placas} = (1.04 + 0.21 r_w)\sqrt{f'_c}\, b_w d \qquad (1)$$

Factors involving the diagonal compressive capacity in this equation are f'_c and the stirrup ratio, r_w (%). Although there is no upper limit of f'_c stated in this equation, the experimental evidences used to derive this equation approximate 35 N/mm^2.

2.2 JSCE Standard Specifications

In JSCE standard specifications (2002), only f'_c is considered as the influential parameter of diagonal compressive capacity. Therefore, this equation is quite conservative and only valid for concrete with f'_c not exceeding 50 N/mm^2.

$$V_{JSCE} = 1.25\sqrt{f'_c}\, b_w d \qquad (2)$$

2.3 Eurocode2 1992-1-1:2004

In Eurocode 2 (2004), the strut inclination method based on a truss model was used to design members with shear reinforcement. Designers can select the values of angle of concrete strut (θ) freely from 21.8 to 45 degrees. In this paper, to study the most extreme cases, θ was assumed to be 45 degrees. Hence, the maximum shear capacity which can be sustained by the member, limited by crushing of the compression struts, becomes the following:

$$V_{EC2} = 0.45 \nu f'_c\, b_w d \qquad (3)$$

where; ν is a coefficient that takes into account the increase of fragility and the reduction of shear transfer by the aggregate interlock with the increase of f'_c. It may be taken to be 0.6 for $f'_c \leq 60$ N/mm^2 and the minimum between 0.9-(f'_c/200) and 0.5 for $f'_c > 60$ N/mm^2.

3. EXPERIMENTAL PROGRAM

3.1 Specimen details

The experimental program prepared eight RC beams with I-shaped cross section. Three-point bending tests were conducted by a 2000kN capacity hydraulic testing machine. The summary of experimental cases and details of specimens are provided in Table 1 and Figure 1. The specimens were designed based on the study of Kobayashi et al. (2009) in order to discuss and compare with their results. The web width (b_w) and effective depth (d) of all specimens were 40 mm and 220 mm, except for U-s100L which has b_w=58 mm and d=319mm. The main parameters were f'_c, r_w, s, b_f/b_w and d. The experimental cases can be classified into four series. Series I is the effect of r_w and s in high strength concrete beams with various diameters of stirrups. Series II is the effect of s with different f'_c. Series III is the effect of b_f/b_w by varying the flange width. Series IV is the effect of d or size effect.

All specimens were designed to be symmetric. The combination of thin web cross section and high strength shear and tensile reinforcements (f_y, f_{wy} > 930 N/mm^2) will cause specimens to exhibit the diagonal compression failure. In order to avoid the local failure, the web width outside support was increased to that of the bottom flange. Anchor plates and nuts were used to ensure the sufficient anchorage of the tensile bars and prevent the anchorage failure.

3.2 Instrumentation and test procedures

For all specimens, the applied load, mid-span deflections and strains of concrete, tensile bars and stirrups were measured. Strain gauges were attached at the mid span to measure the strain of longitudinal bars whereas at the distance of d/2 from the top fiber for all stirrups in the shear spans. The additional strain gauges

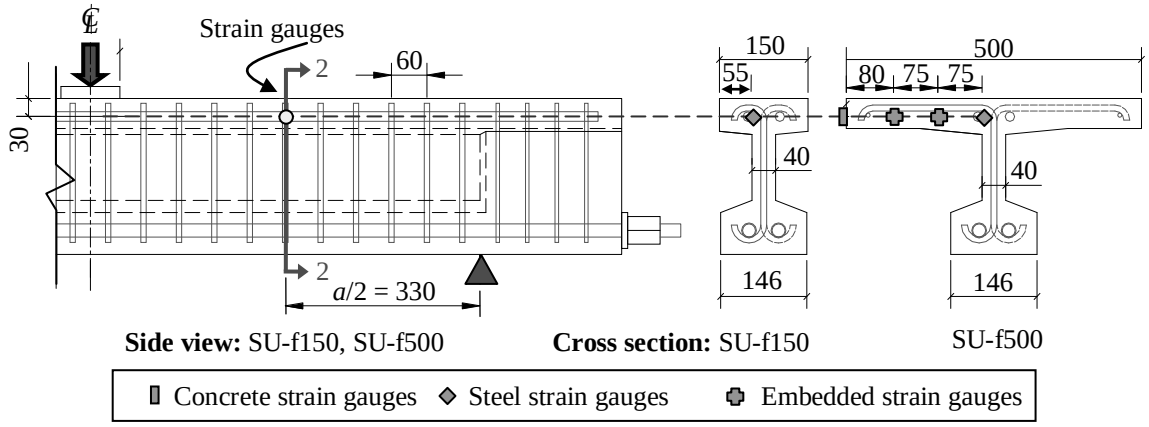

Figure 2 Location of the strain gauges of SU-f150 and SU-f500

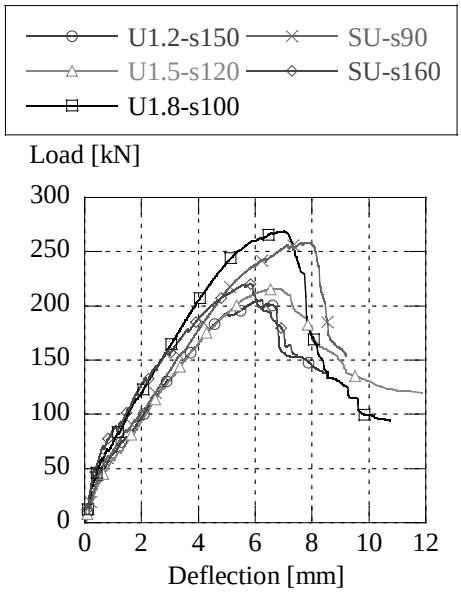

Figure 3 Load-deflection curves of series I and II

were provided in SU-f150 and SU-f500 as shown in Figure 2. As for SU-f500, embedded strain gauges were installed inside the concrete in the flange portion to measure the strain distribution in the flange. Besides, both surfaces of all specimens were painted by white color to ease the drawing and observation of crack during the experiments. The load at first flexural crack (P_{cr}), the average horizontal crack spacing at the peak load ($s_{c,avg}$) as well as the average crack angle (β_{avg}) were measured at the middle height of the web.

4. EXPERIMENTAL RESULTS

4.1 Load-deflection relationship

Load-deflection relationships of series I and II are illustrated in Figure 3. Firstly, specimens behaved in elastic manner until the first flexural crack occurred in the bottom flange near the mid span, which is reflected in the graph as a rate of inclination decreases. After the first flexural crack, the load-deflection curve remains to advance linearly with the initiation of diagonal cracks at the web concrete in the order from the loading point to the support. In the pre-peak region, the deflection

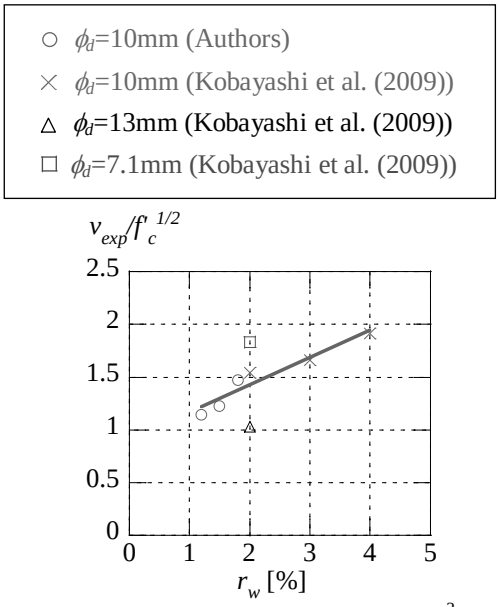

Figure 4 Effect of r_w (f'_c=100N/mm^2)

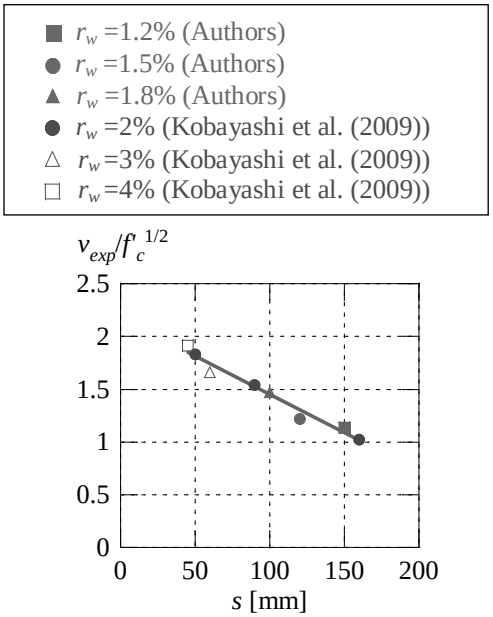

Figure 5 Effect of s (f'_c=100N/mm^2)

increased with a relatively small increase in applied load until the web concrete began to crush. Afterwards, the applied load reached to the peak. The experimental results are summarized in Table 2. Data of the strains of longitudinal bars and stirrups revealed no yielding and the values were much less than their yield strength. It implies that the failure mode was neither flexure failure nor diagonal tension failure. As concrete crushing occurred, the failure mode of all specimens was diagonal compression failure. After the peak load, applied load rapidly decreased. From Table 2, it is revealed that small variation of β_{avg} can be observed in all specimens.

4.2 Effect of stirrup ratio with different diameters

Kobayashi et al. (2009) adapted a method to eliminate the effect of f'_c by normalizing the obtained shear capacities by $f'_c{}^{1/2}$ which is used in the design equation of JSCE (2002) and the predictive equations by Placas et al. (1971). This method is also applied in this study. The relationships between r_w and $v_{exp}/f'_c{}^{1/2}$ for the specimens with f'_c = 100 N/mm^2 are demonstrated in Figure 4, where v_{exp} is the shear strength ($=V_{exp}/b_w d$). With the increase in r_w, the diagonal compressive capacity increases when using diameter of stirrups (ϕ_d) = 10 mm. A linear relationship agrees well with the test results. However, in the case of constant value of r_w = 2% with different ϕ_d and s, $v_{exp}/f'_c{}^{1/2}$ differs significantly. From Table 2, $s_{c,avg}$ among these three specimens is also different. With the increase in stirrup spacing, $s_{c,avg}$ also increases. Furthermore, the results of the same set of data are plotted against s despite of r_w in Figure 5. Notwithstanding ϕ_d and r_w are different, the diagonal compressive capacities are distributed along the same linear line. It means that the diagonal compressive capacity can be represented by not r_w but s. Therefore, the diagonal compressive capacity will be discussed by s

in the following section.

The difference in the diagonal compressive capacity with the change in s can be explained by two mechanisms (Kobayashi et al. 2009). One is the increase of confinement effect on cracks by providing closer shear reinforcements. It results in smaller diagonal crack width (w); therefore, the critical average stress in web concrete (σ_{2max}) would be greater because w affected the diagonal compressive capacity as reported by Schäfer et al. (1990) and Reineck (1989). The other is the localization of compressive strut. Figure 6 explains the model of compressive strut formation under different stirrup spacing proposed by Kobayashi et al. (2009). Figure 6(a) demonstrates that the diagonal stress generates uniformly along the beam with close-spacing stirrups. While in Figure 6(b), the diagonal stress is concentrated in a local portion of the beam with wide-spacing stirrups. This stress concentration causes early crushing in the web concrete; hence the diagonal compressive capacity decreases.

This mechanism can be observed in this study as well. The $s_{c,avg}$ shows decreasing trend with closer stirrup spacing. It implies that the failure localization occurred in U1.2-s150 and SU-s160 as higher $s_{c,avg}$ were observed. Since the confinement effect of stirrups helps the stress to transfer across a crack after the crack initiation, the stress can distribute along the beam. Therefore, the localization of compressive strut was induced by a lack of the confinement effect. However, further study by some analytical approach is required to clarify the actual stress flow.

4.3 Effect of stirrup spacing with different compressive strength

Figure 7 shows $v_{exp}/f'_c{}^{1/2}$ as a function of s for specimens with different f'_c. It is confirmed that the effect of s depends on f'_c. There is slight variation in $v_{exp}/f'_c{}^{1/2}$ by the change in s when using normal strength concrete while the greater effect of s can be observed in high strength concrete beams. As for beams with f'_c > 65 N/mm^2, the diagonal compressive capacity reduces as s increases in linear relationship. With higher f'_c, the inclination of trend line increases with a limitation when f'_c approximates 100 N/mm^2. It can be explained by considering that the diagonal compressive capacity depends on not only f'_c but also the width of compressive strut. If the width of compressive strut becomes smaller with higher f'_c, the area loss of the struts reduces the diagonal compressive capacity. Thus the diagonal compressive capacity is limited.

Figure 8 plots the shear strength v_{exp} as a function of f'_c. Since there is slight effect of s when using f'_c = 30 N/mm^2, the specimen NH3 (Kobayashi et al. 2009) is used as a representative of specimen with f'_c = 30 N/mm^2 and s = 60 mm in this figure. It can be observed that v_{exp} increases with the increase in f'_c with different incremental rate depending on s.

4.4 Effect of flange width to web width ratio

Series III comprises of three specimens SU-f150, UH3 (Kobayashi et al. 2009) and SU-f500. The web width was designed to be constant and b_f/b_w was varied by increasing the upper flange width. From Table 2, slight differences in $s_{c,avg}$ and β_{avg} can be noticed. $v_{exp}/f'_c{}^{1/2}$ against b_f/b_w is drawn in Figure 9. It can be seen that $v_{exp}/f'_c{}^{1/2}$ shows nearly constant value with the increasing of b_f/b_w. Hence, there is no effect of b_f/b_w on the diagonal compressive capacity of RC I-beams. It can be explained by that the increase in the upper flange width becomes ineffective. The strain distribution at mid span (see Figure 3) in the upper flange at different load level of SU-f500 is shown in Figure 10. The positive

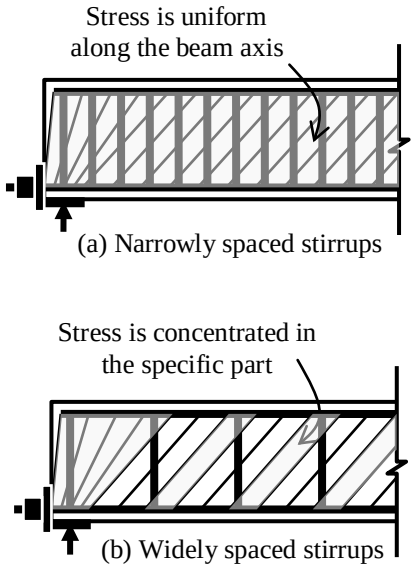

Figure 6 Effect of spacing of stirrups (Kobayashi et al. (2009))

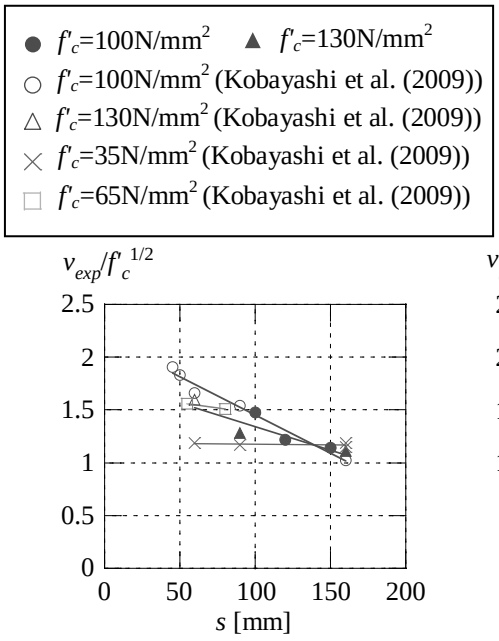

Fig. 7: Effect of s with different f'_c

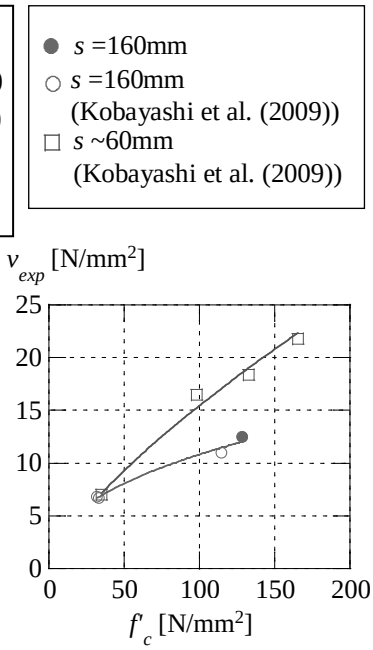

Figure 8 Effect of f'_c (v_{exp}-f'_c)

value indicates tensile strain. The strain concentration can be observed at the zone near center of the beam. This tensile strain is resulted from the development of high diagonal compressive stress in the web. As the distance from the beam center increases, the strain decreases and becomes comparatively small at some distance. Thus the outside flange portion resists less stress and can be considered as an ineffective area.

4.5 Effect of effective depth

Size effect was examined by comparing between U1.8-s100 and U-s100L. Size of U-s100L was magnified by 1.45 scale factors in three dimensions. The f'_c, p_w, a/d, b_f/b_w as well as s in this series were designed to be constant. As a result of series I, s was chosen to be constant, rather than r_w. From Table 2, $s_{c,avg}$ is wider in larger specimen and approximate 1.45 times larger. Figure 11 plots the shear strength v_{exp} as a function of d. It exhibits slight variation of the shear strength with the change of d. Therefore, the effect of d from 220 to 319 mm on the diagonal compressive capacity cannot be observed.

5. ACCURACY OF THE EXISTING EQUATIONS

The shear capacity from the experimental results of the total of 41 beams including Kobayashi et al. (2009), Placas et al. (1971), Reineck (1989), Rangan (1991), and Leonhardt et al. (1963) was used to illustrate the accuracy of the existing equations. All specimens were reported to fail in diagonal compression failure. The ratio between the shear capacity from experiments and results obtained by the existing equations were calculated. The average of these ratios (*avg.*) with a coefficient of variation (*C.V.*) is presented in Figure 12.

Figure 12(a) compares the diagonal compressive capacity from test results with those obtained by the equation by Placas et al. (1971). The average of V_{exp}/V_{Placas} = 0.98 with a *C.V.* of 18.3%. It implies that Placas equation can evaluate an average value of the diagonal compressive capacity including the case of f'_c > 100 N/mm^2. In contrary, this equation exhibits quite large variation as *C.V.* = 18.3%.

JSCE standard specifications (2002) demonstrate the average of V_{exp}/V_{JSCE} = 1.18. Figure 12(b) indicates that JSCE equation underestimates the capacity in almost all specimens. The specifications may be conservative

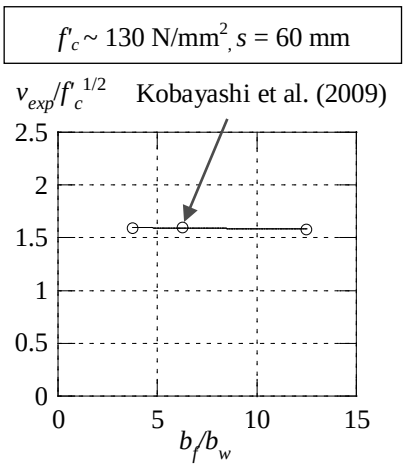

Figure 9 Effect of b_f/b_w

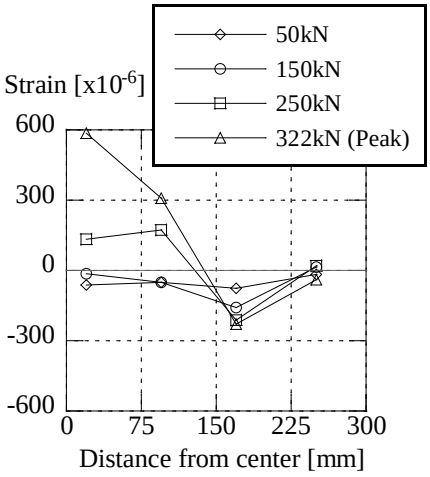

Figure 10 Strain distributions in upper flange

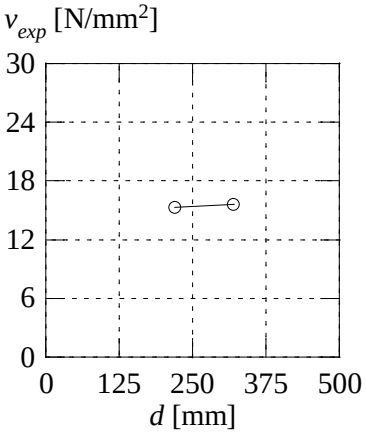

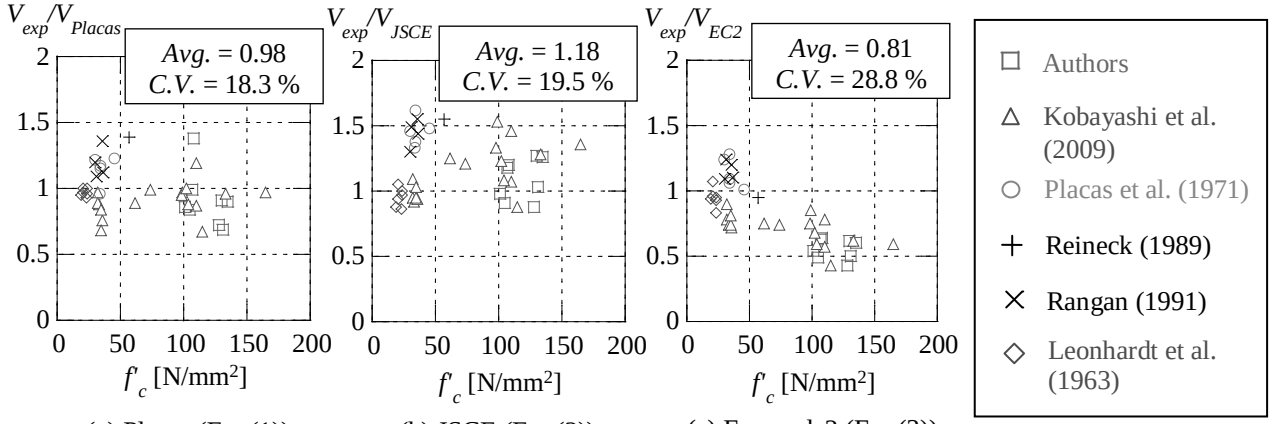

Figure 11 Effect of d

(a) Placas (Eq. (1)) (b) JSCE (Eq. (2)) (c) Eurocode2 (Eq. (3))

Figure 12 Accuracy of the existing equations

for safety reason. Similar as Placas equation, JSCE standard specifications shows large variation as *C.V.* = 19.5%.

The accuracy of the Eurocode 2 (2004) is shown in Fig. 12(c). The average of V_{exp}/V_{EC2} is 0.81 with a *C.V.* of 28.8 %. The Eurocode 2 severely overestimates the capacity in case of high strength concrete. Likewise, the Eurocode 2 does not consider the presence of stirrups. Thus it shows huge scattering.

From the reasons mentioned above, the current equations are not accurate enough to evaluate the diagonal compressive capacity of RC beams, especially in high strength concrete. Besides, the evaluation for r_w in the existing equation is not appropriate as explained in section 4.2.

5. CONCLUSIONS

(1) Stirrup spacing is prominent, not stirrup ratio, for evaluating diagonal compressive capacity of RC beams because of the localization of compressive stress in a strut.
(2) The effect of compressive strength and stirrup spacing on the diagonal compressive capacity of RC beams is interrelated. The greater effect of stirrup spacing is observed in high strength concrete.
(3) The diagonal compressive capacity increases as compressive strength of concrete increases with different increment ratio depending on stirrup spacing.
(4) The ratio of flange width to web width from 3.75 to 12.5 has almost no influence on the diagonal compressive capacity because the addition flange portion is not effective.
(5) The effect of effective depth on the diagonal compressive capacity cannot be observed in the range from 220 mm to 319 mm.
(6) The existing equations are not accurate enough to predict the diagonal compressive capacity, especially in high strength concrete.

Abstract: The experimental results of three one-sixth scaled knee joints of a railway bridge are presented in this paper. Following the design and detailings of the existing railway bridge in Japan, the first specimen was prepared. In other two specimens, the amount of steel reinforcements was reduced and 1.5% of hooked end steel fibers were added. The tests were performed under the displacement controlled quasi-static cyclic loading. Observing the crack patterns, yielding of rebars, buckling and rupture of rebars, the failure mode of the specimens were decided. The load-displacement curves and energy dissipation capacities of the specimens were also compared and found that the strength deficit caused by the reduction of steel reinforcements can be restored by using steel fibers.

1. INTRODUCTION

Beam-column joints have been recognized as one of the important structural elements to effectively transfer load between the connecting members, beams and columns. The integrity of beam-column joints highly governs the overall performance of the structures. After experiencing severe damages to the structures during past major earthquakes, many researches were conducted for retrofitting, strengthening of existing structures and to propose design guidelines for new structures to withstand the probable big earthquakes. Many countries around the world revised the seismic codes and raised the level for the structural design requirements of new structures. Accordingly, amount of steel reinforcements were increased in beams and columns due to which mainly at the beam-column joints congestion of steel reinforcements occurred. The congestion at the joints resulted in the poor workability and poor performance of joints during earthquakes. To some extent, the hooks provided at the end of steel rebars also contribute in congestion. The provision of hooks can be eliminated by using headed steel rebars, however, the headed rebars cannot improve the strength of the joints. Also, headed rebars cannot address the congestions caused by longitudinal and shear reinforcements in the joints. Use of steel fiber reinforced concrete (SFRC) can be promising in reducing longitudinal and shear reinforcements, as it is capable of enhancing the flexural and shear capacities. In addition, steel fibers can improve ductility and energy dissipation capacity of concrete along with improvement of bond between concrete and steel reinforcements.

A large portion of railway bridges in Japan have been constructed as framed bridges (Figure 1) in which dense reinforcement are provided at the beam-column joints. Hence, to reduce the amount of steel reinforcement for the avoidance of congestion at the knee joints of railway bridges, this research is conducted. Three one-sixth scale specimens were prepared. One of which was constructed based on the existing railway bridge in Japan and in other two specimens steel reinforcements were reduced and 1.5% of hooked-end steel fiber were added. The tests were conducted under displacement controlled quasi-static cyclic loading. The performances of different specimens were compared in terms of crack patterns, load-deflection relationship and energy dissipation.

2. RELATED RESEARCH

The conventional beam-column joints without joint reinforcements are vulnerable to shear. With variation in

steel reinforcement arrangement at beam-column joint causes different mechanisms of shear transfer in knee and T-joints (Priestley et al. (1996)). During seismic events high shear forces are subjected to the joints. Hence, beam-column joints should withstand such shear forces. Since, steel fibers are capable of increasing the shear strength of concrete through the bridging action across the cracks, use of steel fibers can be a possible alternative to conventional confining reinforcements to provide adequate ductility (Filiatrault et al. (1995)). Also, it can enable the increase of the spacing of closely spaced. In addition to shear, the bond between concrete and steel reinforcements and anchorage can highly influence the performance of beam-column joints. Conducting experiments on numerous beam-column connections, Hamad et al. (2011) investigated the effects of steel fibers in the performance hooked bars embedded in normal strength concrete specimens and reported the significant improvement in bond performance and the ductility of failure mode. Although efforts have been made to reduce the longitudinal reinforcements in beams by using steel fibers, no study has been conducted regarding the reduction of longitudinal steel reinforcements in beam-column joints. Based on the experiments performed on the beams, Oh (1992) stated that on neglecting the contribution of steel fibers, the flexural capacity of fiber-reinforced concrete beams are considerably underestimated. To estimate the flexural capacity of doubly reinforced concrete beams containing steel fibers, an analytical method was also proposed. It is also shown that when 2% of steel fibers were added, about 60% increase of the flexural strength could be achieved.

3. EXPERIMENTAL SETUP AND MEASUREMENT SYSTEM

3.1 Material properties

The material properties were chosen based on the existing railway bridges in Japan. The considered existing bridge was designed following the Japanese Code, "Design Standards for Railway Structures and Commentary (Concrete Structures)", April, 2004, and is referred as a prototype structure. The compressive strength of concrete used in the prototype structure was 30 N/mm^2 and accordingly the mix proportion of concrete were designed. The average compressive strength of concrete used in the specimens are shown in Table 1. Three numbers of 100 mm × 200 mm were cast and cured for compressive strength test. The maximum size of the coarse aggregate was 10 mm. D6 bars having nominal diameter of 6.35 mm were used for both longitudinal and shear reinforcements. From tensile strength test of rebars, the yield strength and ultimate strength were found to be 325 N/mm^2 and 470 N/mm^2, respectively. The steel fibers, a cold drawn wire fiber glued in bundle, with hooked ends were used. The aspect ratio was

Table 2 Percentage reduction of steel rebars

Specimen	KJ-ED	KJ-1.5	MKJ-1.5
Column longitudinal rebar	Existing design	27.3%	9.1%
Hoops	Existing design	15.0%	29.2%
Beam longitudinal rebar	Existing design	26.1%	17.4%
Stirrups	Existing design	26.0%	31.25%

48. The length and diameter of steel fibers were 30 mm and 0.62 mm respectively. The tensile strength of steel fibers were 1050 N/mm^2.

3.2 Test specimens

Figure 2 shows one-sixth scaled knee joint specimen. Considering a half of the column height and a half of the beam span of a rigid-framed railway bridge, the height of a column and the length of a beam from column face for the specimens were chosen as 1030 mm and 850 mm, respectively. The cross-sectional size of column was 250 mm × 250 mm and that of beam was 250 mm × 330 mm. All together three specimens, KJ-ED, KJ-1.5 and MKJ-1.5, were casted. Here, KJ, ED, 1.5 and MKJ stand for Knee Joint, Existing Design, percentage of steel fibers by volume and Modified Knee Joint, respectively. In the control specimen, KJ-ED, the amount of steel rebars in beam and column including rebar detailings were provided analogous to the considered existing railway bridge. In KJ-1.5, the amount of rebars were reduced but the rebar detailings were kept unchanged. However, along with reduction of steel rebars, the hook length of bottom beam rebars were modified in MKJ-1.5. The amount of steel rebars and its properties are tabulated in Table 1. The reduced amount of steel rebars were different in KJ-1.5 and MKJ-1.5. The reduction of steel rebars in KJ-1.5 was made based on authors' previous study on T-joints of a railway bridge (Shakya et al. (2010)) and in MKJ-1.5, the steel in beam and column were reduced in such a way that the flexural capacity of beam and column are equal. In both KJ-1.5 and MKJ-1.5, 1.5% of hooked end steel fibers by volume were added. The percentage reduction of steel rebars in KJ-1.5 and MKJ-1.5 compared to KJ-ED are tabulated in Table 2.

In KJ-ED, 22 numbers of rebars in column, 11 numbers of top beam rebars, 9 numbers of bottom beam rebars and 3 numbers of side face rebars were provided. The column rebars were reduced to 16 numbers in KJ-1.5. In addition, all the side face rebars were removed. Only 9 numbers of top beam rebars and 8 numbers of bottom beam rebars were provided. In MKJ-1.5, 20 numbers of column rebars, 9 numbers of top beam rebars, 8 numbers of bottom beam rebars and 2 numbers of side face reinforcements were provided. In all the column rebars 180° hook were provided at the end of rebars. In top beam rebars of KJ-ED, out of 11 rebars, 3 rebars with 180° hook, 3 rebars with 90° hook having hook length 35ϕ (ϕ is rebar diameter), 3 rebars with 90° hook having hook length 15ϕ and 2 rebars without hook

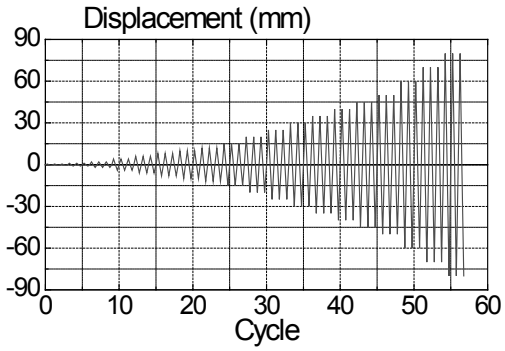

Figure 3 Applied displacement cycle

were provided. All the 9 numbers of rebars in bottom of beam were provided with 90° hook having hook length of 3ϕ. No hooks were provided in the side face rebars. All the hooks and hook lengths were decided as per reinforcement detailing of the existing railway bridge. In comparison to KJ-ED, 2 top beam rebars without hook and 1 bottom beam rebars were removed in. KJ-1.5 and MKJ-1.5. In MKJ-1.5, the hook length of bottom beam rebars were increased to 12ϕ, which is minimum hook length required by JSCE standard. The spacing of hoops in KJ-ED, KJ-1.5 and MKJ-1.5 were 85 mm, 100 mm and 120 mm, respectively. Similarly, the stirrups were spaced at 110 mm, 150 mm and 160 mm in KJ-ED, KJ-1.5 and MKJ-1.5, respectively.

3.3 Loading and instrumentation

Using displacement controlled 200 kN capacity actuator, a cyclic horizontal quasi-static load was applied at the end of beam (Figure 2). The displacement amplitude was varied from 0.5 mm to 80 mm (Figure 3) and each displacement amplitude was exerted for 3 cycles. Displacement transducers and strain gauges were attached at various locations of the specimens to record displacements and strains so that the structural behavior could be understand. Transducers were also attached in the steel column and hinge support, so that the displacement of supports can be monitored and if supports were displaced, correction in displacement at other locations could be made.

4. EXPERIMENTAL RESULTS AND DISCUSSIONS

4.1 Crack pattern and failure mode

The observed crack patterns in the specimens by the end of the tests are shown in Figure 4. In all the specimens, the first flexural crack (FFC) was observed during application of 2nd loading cycle of 4 mm displacement amplitude. On further loading, the number of cracks increased rapidly until peak load was observed. After 40 mm displacement amplitude, no cracks were generated in all the specimens, however, only opening and closing of cracks were noticed. As indicated in the Figure 4, wider cracks were observed throughout the beam and the column of KJ-ED and KJ-1.5. The cracks were propagated throughout the column at first and then crack propagation took place

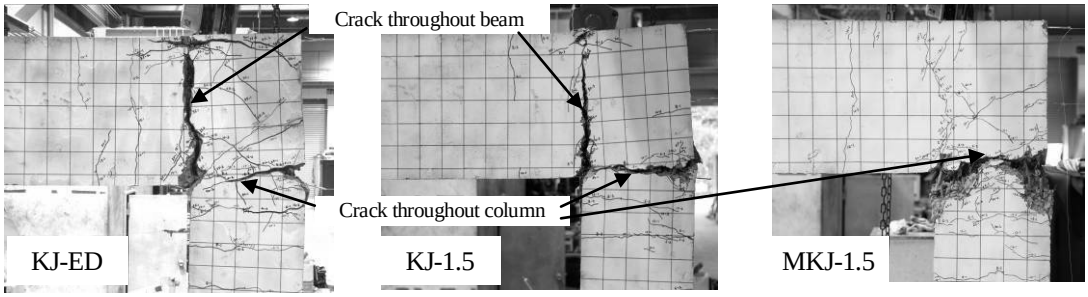

Figure 4 Crack patterns after the loading test

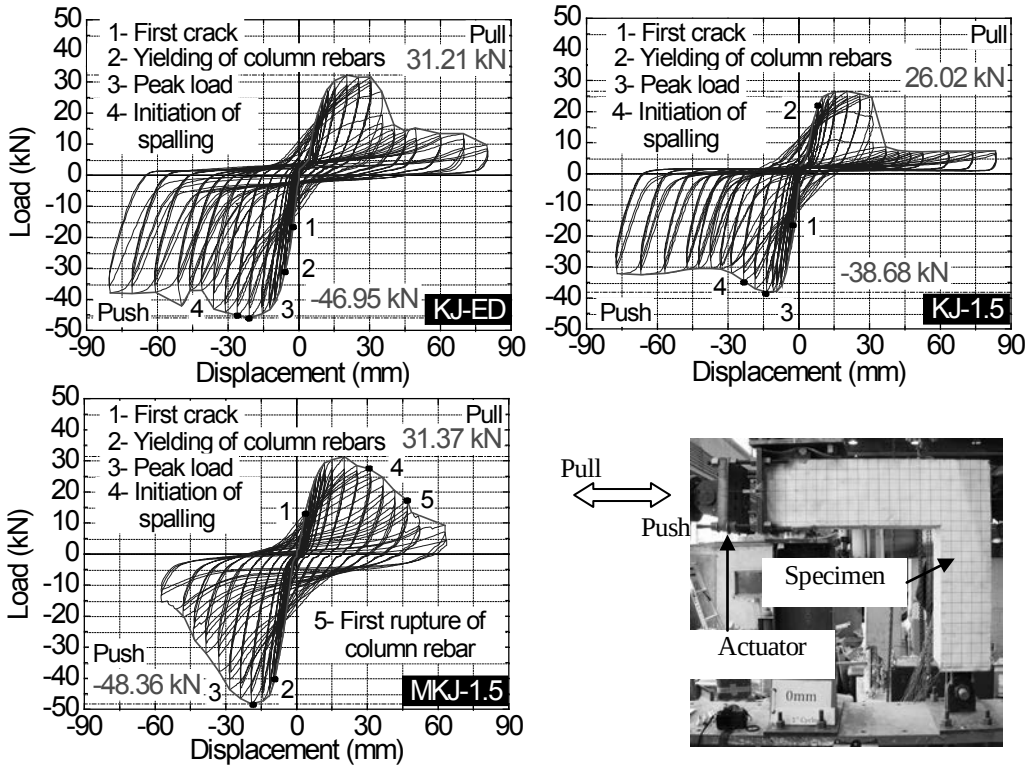

Figure 5 Load-displacement curve

throughout the beam of both KJ-ED and KJ-1.5. The bond deterioration and anchorage failure due to insufficient hook lengths were the main cause of formation and widening of crack along the column. The presence of side face rebars in the beam delayed the crack opening in the beam in KJ-ED compared to that in KJ-1.5. Significant shear cracks were also observed within the beam-column joint of KJ-ED. Although the amount of steel rebars were reduced in KJ-1.5, the number of cracks were significantly reduced due to addition of 1.5% of steel fibers. Also, no shear cracks were observed in the beam-column joint. However, the absence of side face rebars caused the rapid propagation and widening of cracks in the beam. The anchorage failure was prevented in MKJ-1.5 after increasing the hook length of beam bottom rebars and adding 1.5% of steel fibers. However, bond failure between concrete and beam bottom rebars could not be prevented due to which longitudinal crack along the beam bottom rebars within the column section was generated. Also, the number of shear cracks in the beam-column joints were reduced compared to those in KJ-ED. The application of repeated cyclic load resulted in crumbling of concrete at the junction of beam and column. The absence of concrete at the junction and further loading caused the buckling of column rebars and finally column rebars were ruptured. Hence, the failure mode of MKJ-1.5 was depicted as the flexural failure.

4.2 Load-displacement relationships

In Figure 5., the relationship between applied displacement at the end of beam and corresponding load recorded during the quasi-static cyclic load is expressed in terms of load-displacement curve. The displacement was considered as positive when the specimen was pulled towards the actuator and vice-versa. The envelope curves along with some important points are also presented. The experimental results of all the specimens are summarized in Table 3.

In all the specimens, the FFCs were formed during 2nd cycle of 4 mm displacement, however, the magnitudes of

Table 3 Comparison of experimental results

	KJ-ED	KJ-1.5	MKJ-1.5
First cracking displacement cycle	4 mm – 2nd cycle	4 mm – 2nd cycle	4 mm – 2nd cycle
First cracking load	-17.25 kN	-17.47 kN	13.68 kN
Yield displacement of column rebars	12 mm	10 mm	10 mm
Yield load	-37.57 kN	22.99 kN	-40.65 kN
Peak load	-46.95 kN	-38.68 kN	-48.36 kN
Displacement at concrete spalling at column face	25 mm	25 mm	30 mm
Pull out of rebars in beam	All bottom rebars	All bottom rebars	No pull out
Column rebar rupture	No rupture	No rupture	10 out of 20 rebars
Failure mode	Anchorage	Anchorage	Flexural

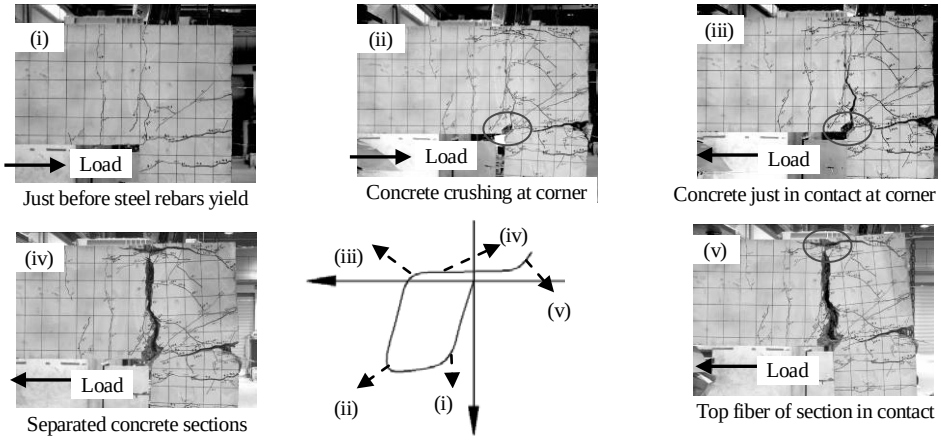

Figure 6 Post yield behavior

cracking load were different. On increasing the displacement amplitude to 12 mm, the column rebars at the junction of beam and column yielded in KJ-ED whereas yielding of column rebars took place in KJ-1.5 and MKJ-1.5 when the applied displacement was 10 mm. The lowest yield load was observed in KJ-1.5 as the provided amount of steel rebars was the least. Although the amount of steel rebars in MKJ-1.5 were less compared to KJ-ED, the largest yield load of 40.65 kN was observed by the virtue of addition of steel fibers. It indicates that the addition of steel fibers in concrete was capable of improving the flexural capacity of concrete. Moreover, the largest peak load of 48.36 kN was also observed in MKJ-1.5. Due to inappropriate amount of reduction of steel rebars, the load capacity of KJ-1.5 was less than that of KJ-ED although 1.5% of steel fibers were added. In the post peak region, sharp decrease in load capacities were noticed in KJ-ED and KJ-1.5, due to the anchorage failure at the displacement of 30 mm and 35 mm. The anchorage failure was of brittle nature and are not desirable in structures. The addition of steel fibers along with increase in hook length of beam bottom rebars prevented the anchorage failure in MKJ-1.5. Instead buckling of column rebars were observed. The first column rebar ruptured when 45 mm displacement amplitude was applied. Finally 10 out of 20 column rebars were ruptured by the end of 60 mm displacement amplitude. Due to significant loss in load capacity, the test on MKJ-1.5 was terminated once 3 cycles of 60 mm displacement was exerted.

When the positive displacement was applied in the specimen, an axial tensile force was induced in the column due to which micro flexural cracks were formed at the lower amplitude of applied displacement. At the higher amplitude of displacement, the wider cracks were formed at the junction of beam and column. Due to these reasons, the load capacity of the specimens in the positive loading cycles were lesser than that in negative loading cycles. Also, on comparing the load-displacement curves in Figure 5, it can be clearly seen that the post yield behavior of KJ-ED and KJ-1.5 are quite similar. The behavior in the post yield region can be clarified through Figure 6 where the crack patterns including situation of concrete and steel rebars in KJ-ED during different stage of loading are shown. In this region, big opening of cracks, crushing of concrete, plastic deformation of rebars, buckling and rupture of rebars can be expected. The load displacement relationship is linear (phase i) before the rebars yield. On increasing the displacement, the column rebars yield and due to excessive compression, the concrete at the junction of beam and column starts crushing resulting in deterioration of bond between bottom beam rebars and concrete. Only marginal increase in load capacity can be observed (phase ii) in this phase and also this phase is responsible for the formation of plateau in the load-displacement curve. Upon reversing the loading direction, the linear unloading curve can be observed till the instance when the concrete in the beam and the column are just in contact (phase iii). Once, the contact between concrete of beam and column vanishes, all the applied load is resisted only by steel rebars. During this phase almost horizontal load displacement curve can be observed (phase iv). On further increasing the displacement, the top fiber of

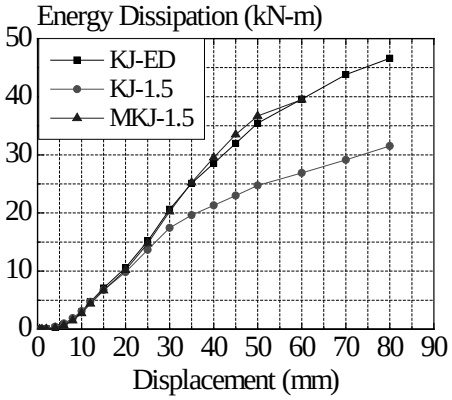

Figure 7 Energy dissipation

beam and column came into contact and again load starts increasing. In KJ-ED and KJ-1.5, all of these five phases were observed. The crushing of concrete at the junction of beam and column resulted the plateau in both positive and negative loading cycles of the load-displacement curves. However, in MKJ-1.5, due to buckling of column rebars, the plateau could not be observed. The buckling and rupture of rebars caused the gradual decrease in load capacity after the peak load.

4.3 Energy dissipation

On subjecting large cyclic displacements to a specimen, the concrete components in the beam-column joint experiences significant degradation of strength and stiffness. Reinforcing rebars also undergo inelastic deformations. The inelastic behavior of rebars is the primary source of energy dissipation. Hence, energy dissipation occurs due to induced damage in the specimens and depends on concrete cracking, yielding and buckling of rebars. The energy dissipation capacity of each specimen can be obtained by computing external work, W_e which refers to the area enclosed by the load-displacement curve and is given by

$$W_e = \int P\,dx \tag{1}$$

where, P is a load and x is an applied lateral displacement. The relationship between cumulative energy dissipation and applied displacement is shown in Figure 7. Among all the specimens, the energy dissipated by KJ-1.5 was the least. Nevertheless, the energy dissipated by KJ-ED and MKJ-1.5 were almost equal. Therefore, the performance of MKJ-1.5 in terms of energy dissipation was also satisfactory. The comparable energy dissipation capacity also justifies that the certain amount of steel rebars in knee joints can be reduced if steel fibers are used.

5. CONCLUSIONS

Displacement controlled cyclic quasi-static loading test were conducted on three one-sixth scaled knee joint specimens. One of the specimens was analogous to the existing railway bridge in terms of section properties, concrete strength, amount of steel reinforcements and its detailings. While in other two specimens, amount of longitudinal and shear reinforcements were reduced and steel fibers were added. Based on the experimental results following conclusions are drawn:

(1) Due to the insufficient hook length in the beam bottom rebars, the specimen designed and detailed based on the existing railway bridge and the specimen with 1.5% steel fibers but without modification in hook length failed in anchorage.
(2) The delay in anchorage failure and spalling of concrete show the enhancement in anchorage and bond between concrete and steel rebar upon using steel fibers.
(3) Flexural failure was observed on using 1.5% volume fraction of steel fibers and providing steel rebars in beam and column such that the flexural capacities of beam and column were equal.
(4) The shear capacity of the concrete was enhanced as the shear cracks were reduced in the beam-column joints after providing steel fibers in concrete.
(5) SFRC can contribute in enhancing flexural capacity, and energy dissipation capacity.

Hence, based on obtained results, it is concluded that the use of steel fibers is effective in restoring the capacity without compromising the overall performance of structures even after reducing certain amount of longitudinal and shear reinforcements in beam and column of knee joints.

rproano@uni.edu.pe

Abstract: The building of Municipal Theatre of Lima started in 1920. Since then, the structure has experienced at least four major earthquakes and a fire in 1998 had damaged roof of the building. Since 2008 a restoration project that includes a structural retrofitting have been carried out. The Lima´s municipal theatre has a plan area of 1190m^2. It is a concrete structure constructed with a theatre purposes. It has a Hall and a Reception salon in front and a Pit area and stage. This five story building has a 17m high. The roof structure was made of steel in area of 396m^2. The total weight of the structure is about 5,940 metric tons. This paper presents results of the seismic vulnerability study for the old and the retrofitted structure carried out in the Japan-Perú Earthquake Engineering Research and Disaster Mitigation Center (CISMID) of the National University of Engineering of Perú. The most vulnerable components of the old structure were front wall in the upper part and the lateral concrete frames with infill blocks of plaster masonry existing in the second and third floor. Some parts of the concrete frames structure show damage in steel bars due to humidity and poor maintenance. The old roof steel structure was severity affected due to fire. Numerical simulations on the old building show irregularities that affect its seismic response. The retrofitting carried out on the building pretend to correct these irregularities trying to enhance its seismic behavior.

1. INTRODUCTION

The lot assigned to the Municipal Theatre of Lima was built with theatre purposes in the early 1920´s. It is a five story concrete building. Since then, at least four major earthquakes and a fire occurred 1998 have affected the roof of the structure. After 1998 the building is closed because the fire badly damages the steel roof structure and the stage.

Before the retrofitting the concrete structure presented cracks and exposed steel bars in the third floor of the gallery for the audience. There is also some damage due to past earthquakes and structural deficiencies which were never completely corrected. The whole structure seems to be rigid whereas the concrete elements were not accorded with the quantities of steel recommended in ours actual seismic standards. Also there is some deterioration mainly as a result of environmental effects, humidity and poor maintenance.

The roof structure of the theatre were composed by five steel truss that were severe badly damage due to the fire. Above this structure were two wood stories that had been removed. Numerical simulations on the old building show irregularities that affect its seismic response. The retrofitting carried out on the building pretend to correct these irregularities trying to enhance its seismic behavior.

Development of an effective methodology for future repairs and strengthening of upon important historical constructions require an integration of knowledge at least in the areas of seismology, geotechnics, structural engineering, material science, architecture, art as well as social, cultural and economic aspects. This paper presents the results of the earthquake response analysis for the original building and the retrofitted one. Some details in the retrofitting process will be discussed.

2. ABOUT THE THEATRE

The building of the theatre was built under the influence of French later neoclassic style. It has two important main areas: In front, the span of the three levels with the entrance, the principal hall and cafeteria (basement); inside the building, the five's levels gallery for the audience with a common shape plan view of horse-shoe. The imperial ladder is a singular element that connects both main areas. Architectonically, the main chamber presents a great number of blaster ornaments cover with gold sheets.

The structural configuration of the theatre is irregular in plan and elevation. It is made on reinforced concrete frames and concrete walls in the first two floors. In the third and fourth floor of the auditorium presents a concrete frame system with some masonry infill walls made of plaster and clay blocks. The density of concrete walls on the first floor

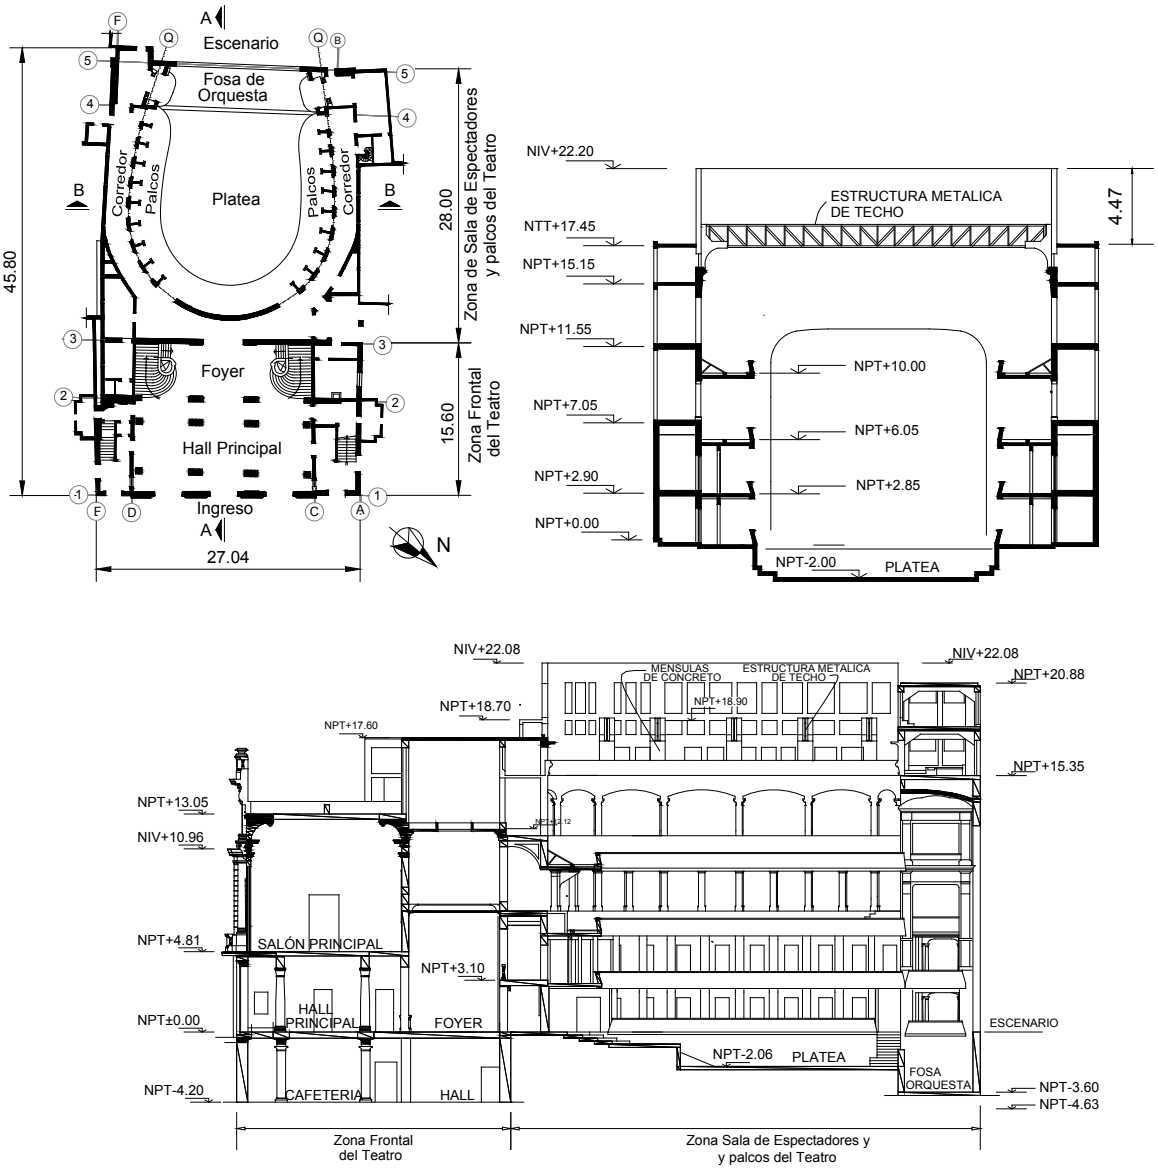

Figure 1 a) Plan view of the structure, b) elevation of the building, c) Lateral elevation of the building.

of the building is about 9%.

The main entrance hall is 4.65m height and structurally consists of walls of concrete, masonry and 12 circular columns; the roof slab is supported on reinforced concrete beams. The second floor reference area for the reception hall is 8.3m height and has walls of concrete and masonry, the roof slab is supported by inverted beams. On the other hand, auditorium zone of the building have five levels. Each level has an area of corridors and flown slabs corresponding private rooms (first and second floors) and area galleries (third and fourth floor). The old roof structure of the theatre was composed by five 20.0m steel truss. This steel truss was simply supported at the ends.

3. STATE OF THE STRUCTURE

The structure of the theater shows structural damage in specific areas of it. The steel structure of the roof of the auditorium has obvious structural damage by fire (see photo 2 (i)).

The front area of the building area is better preserved and the one with less damage, however, the 4m height no confined front masonry wall above the upper story presents little horizontal cracks at the bottom showing its seismic vulnerability

The frames of the axes A and F of the second, third & fourth floor have 10cm infill walls made of brick units of plaster. Some of the beams and columns of these frames have exposed reinforcing steel and an advanced grade of corrosion. (see photo 2 (e) and (f)).

Some columns located at the third and fourth floor of the auditorium area presents shear reinforcement distribution (stirrups) does not reach the standards for concrete in seismic regions (see photo 2c).

The 20cm concrete shear wall have a steel ratio of about 0.12%, which is much smaller than specified in current codes of reinforced concrete (see photo 2 (g)).

Figure 2 a) Internal view of the building. b) Principal Hall c) Third floor column, d) Floor system of fourth level of galleries e) y f) Lateral views of building, g) view of the concrete wall at the back of the building. h) Back view of the building i) Old steel roof structure of the building.

Defects such as cracks and material deterioration due to steel corrosion were often repaired aiming only at aesthetics, rather than correcting the structural causes of damage. It is then important to make an exhaustive review of the structural elements and contrast this information with the analysis results. There is no evidence of differential settlement in the walls. There is no evidence of humidity.

4. SOIL CONDITIONS

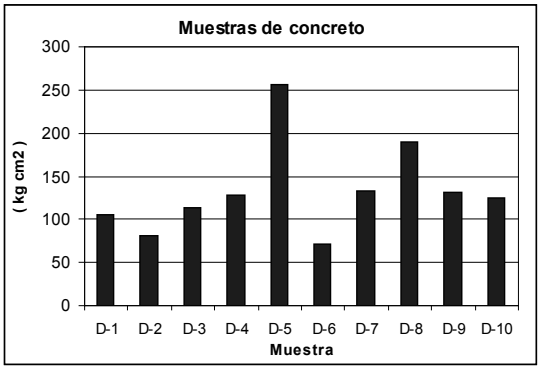
The theatre stands on firm soil formed from well graded sediments like gravel, sands and pebbles of alluvial nature, coming from resistant rocks like granodiorite, gabbrodiorite, diorite and granite. The thickness of this dry and compacted material is estimated as several hundred of meters. For the purpose of the seismic analysis the soil profile is qualified as rigid, with a characteristic period less than 0.4s.

5. MATERIAL PROPERTIES

Most structural elements in the building were made of reinforced concrete. In order to quantify the strength and stiffness of concrete, compression tests were performed in CISMID. The maximum compressive strength of concrete were 9.07MPa (99kgf/cm^2) in 1st floor plate, 11.82MPa (113kgf/cm^2) in the 2nd floor plate, 25.1MPa (256kgf/cm^2) on the 2nd floor beams, 12.06MPa (123kgf/cm^2) on the 3rd floor beams, 6.96MPa (71kgf/cm^2) and 13.04MPa (133kgf/cm^2) in the columns of the 3rd and 4th floor, and 18.73MPa (191kgf/cm^2) in the columns of the structure above portal of the stage.

The steels bar used in the building has a modulus of elasticity of 2.0 x 109 MPa (2.1x1010 kgf/cm^2) and the yield stress is 274MPa (2800kgf/cm^2).

6. MICROTREMOR MEASUREMENTS



We performed a study of environmental microtremors purpose of obtaining fundamental modes of vibration of the structure at various points and levels of the building. The Fourier transforms obtained from measurements in the building have peaks at 3.3 – 3.5 Hertz (0.28s). This value of fundamental period has been the basis for calibration of the period of vibration of corroborating mathematical model of mass and stiffness ratios referred to in it.

7. STRUCTURAL MODEL

A special effort was made for the development of an appropriate mathematical model for the analysis of this building of complex geometry. The building mainly consists of walls of concrete and masonry, and concrete frames. A linear elastic analysis was considered a reasonable tool for the structural investigation, providing at least a basic understanding of the existing building response.

Figure 5 depicts the mathematical model for the analysis. 5,808 frame elements were used to represent beams and columns. The walls and the roof covers were modeled with 26,197 two dimensional shell elements.

The structural walls of the building are composed of at least two materials: brick and cement mortar. Although they are strictly non-homogeneous and anisotropic, they were modeled as homogeneous and isotropic, with equivalent linear properties based on tests. The walls were supposed fixed at their base. This is consistent with the observation that; even for extreme conditions, there are not vertical tensile stresses at the base of the walls

The plaster masonry walls of the third and four floors were no performed in the present analysis due to its architectonic more than structural nature.

The adequacy of the model was corroborated by its ability to predict not only the results of the microtremor tests but also to identify the portions of the structure which may be more severely stressed by earthquake loads, which are in agreement with the damage observed in past events.

8. NUMERICAL ANALYSIS AND RESULTS

An elastic analysis of the building was carried out for dead and live loads and earthquake effects. Wind loading is not important in this case. The analysis provided essential information about stress distributions and an estimate of the seismic response of the structure, helping to identify the most vulnerable zones in the building and to interpret the existent damage. The seismic analysis was based on a seudo acceleration spectrum as defined in the Peruvian seismic code, with the following parameters: Z=0.4 (zone factor), U=1.3 (importance factor), S=1.0 (soil factor), C=2.5Tp/T 2.5 (dynamic amplification factor), R=3/4*(4) (for reduction factor).

The fundamental periods obtained for the structure ware 0.36seg having coupled masses in both directions. The maximum displacements in the top of the building were 9.13cm in x direction analysis and 8.0cm; both of displacements occurred near to the stage of the theatre. In the front of the building the displacements were 2.6cm, greatly reduced due to the wall density and less story levels. The drift in the fifth level were 5.8/1000 at the back of the building and correspond to an intermediate damage level due to the low ductility of the structural elements.

Most of the concrete walls of the building have earthquake shear stresses which are well below their allowable capacity. However, there are some exceptions, described in what follows: the shear stress of the laterals walls in the first and second floor reaches 1.47MPa (15kgf/cm^2) and 1.079MPa (11kgf/cm^2) for the second floor.

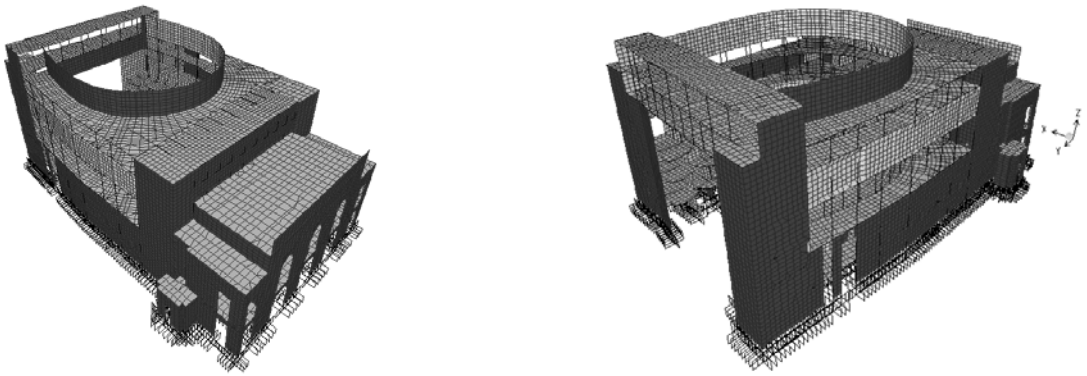

Figure 5 Mathematical model of theatre structure

The shear capacity of wall in axis 5 results below than the seismic demand.

Some shear concrete shear walls form first and second floors have levels of stress because of earthquake effects that were over its capacity due to the low compressive strength of existing concrete with a poor reinforcement.

The flexural and shear capacity of the third floor columns in the area of audience no reach the seismic demand because of the less shear reinforced and poor concrete quality.

The front non confined masonry wall in the upper part of the building have a displacement that reach 4.5cm out of the plane and have no capacity to resist out of plane excitations.

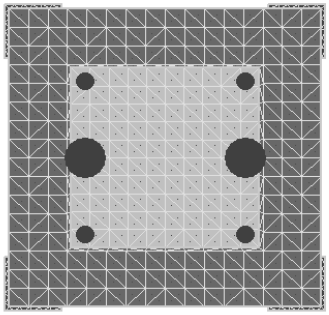
9. STRUCTURAL RETROFITTING

The process of retrofitting the building pass over the correct the deficiencies found in the analysis of seismic vulnerability considering the building with a new roof steel structure at the top of the building described in what follows:

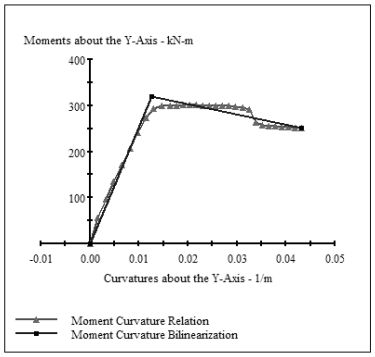
a) External retrofitting of concrete existing columns: to enhance the capacity of the columns it has been added external steel plates.

b) External retrofitting of existing concrete shear walls: It has been added steel mesh to the shear walls.

c) Addition of new infill concrete shear walls in existing concrete frames in building in Y direction.



d) Union of some floor slabs in the building



e) Reinforcement of front wall of the building

10. CONCLUSIONS

Structural analysis showed that the former theater building had some deficiencies in seismic behavior due to their configuration and poor maintenance. A deficiency is in concrete frames of the third and fourth floors parallel Y direction on the axes A and F which in some cases have exposed reinforcing the presence of moisture. The no confined front wall above last level is vulnerable to earthquakes by large out of plane displacements. The columns inside audience room in third and four floors present seismic deficiencies in shear and bending demand. Some existing concrete walls in first and second floors of the building have poor steel ratios that not agree with nowadays standard requirements. The fire damage occurred in 1998 full coverage of the former steel, but not concrete structures.

The strengthening over the building tries to introduce some capacity to supply its earthquake deficiencies. The concrete walls of the first and second floors have more steel ratio. The columns of the third and fourth floor have been reinforced by external steel plates. Also, there have been some concrete walls between the frames fill perimeter in the

third and fourth floors. It has also reinforced the front wall by a steel structure attached to it. The old steel roof has been replaced by a new one.

The reinforcement has tried to correct the major structural deficiencies found in the building and does not imply no need for further structural located intervention in case of an earthquake. However, adequate monitoring and maintenance of the structures could ensure the continued operation of the theater for many years, safeguarding the lives of people and historical value that holds the building.

Abstract: The aim of the paper is to investigate the capability of dynamic identification procedures, usually applied to reinforced concrete or steel buildings, in the estimation of the dynamic characteristics of unreinforced masonry buildings. For this purpose, the dynamic characteristics of a two story stone masonry building retrofitted by DC-90 dampers for seismic safety were evaluated by ambient and forced vibration techniques. Ambient vibrations were measured before and after retrofitting. A series of low amplitude steady state harmonic forced vibration tests were conducted after strengthening using eccentric mass shaker. The resonant frequency curves, mode shapes and damping coefficients as well as stress distribution in the steel braces of the DC-90 dampers have been investigated and could be defined. It was shown that the dynamic behaviour of the masonry building, even if not regular and with deformable floors, can be effectively represented. It can be concluded that the retrofitting of the building does not change the dynamic properties of the building due to the fact of low amplitude excitation which do not activate the dampers.

1. INTRODUCTION

Unreinforced masonry buildings have long been recognized to perform poorly under earthquake excitation. This deficient performance was clearly demonstrated in several past major earthquakes in Algeria such as the 1994 Beni-Chougrane earthquake (Naili 1996) and the 2003 Boumerdes earthquake (Oussalem et al. 2003) or over the word such as the 1989 Loma Prieta earthquake (Bruneau 1994) earthquake. In accordance with their poor performance in earthquakes, an understanding of the dynamic behaviour of unreinforced masonry buildings when subjected to seismic excitation is of major interest in many seismically active countries such as Algeria.

In Algeria, masonry buildings are a typical residential constructions type found in most Algerian urban centres. This construction, built mostly before the 1950s by French contractors, is no longer practiced (Farsi et al. 2002). Buildings of this type are typically 2 to 6 stories high. The slabs are wooden structures or shallow arches supported by steel beams, filled with earth materials. Masonry walls, usually 400 to 600 mm thick, have adequate gravity load-bearing capacity; however, their lateral load resistance is very low. As a result, these buildings are considered to be highly vulnerable to seismic hazard.

While ambient and forced vibration tests are usual applied techniques for reinforced concrete or steel buildings to understand and identify their dynamic behavior, less is known about masonry buildings. The dynamic behaviour of old masonry buildings differs from that of concrete or steel buildings, due to the historic construction typology, leading to walls and floors not rigidly attached to each other. Hence, local modes are more evident with respect to frame buildings (De Sortis et al. 2005). For the same reason, usually the dynamic forced response depends on the shaker location and applied force amplitude. Therefore, it is essential to determine dynamic parameters such as natural frequencies, damping factors and mode shapes, which are typically obtained using modal identification techniques by conducting ambient or forced vibration tests (Abdul Karim et al. 2008).

Ambient vibration can be from sources such as wind, waves, pedestrian or vehicles, with the vibration not controlled but instead considered as a stationary random process. Thus, the response data from the structure alone is used to estimate the dynamic parameters (Shabbir 2008). In contrast, forced vibration testing provides a known input force over the frequency bands of interest, which can be achieved by the excitation input motions. Thus, the dynamic characteristics of structures can be explicitly recognized.

The objectives of the testing for our masonry building were first, to investigate the change of natural frequencies of the building before and after strengthening by ambient vibration test and second, to investigate the dynamic behavior of the building after strengthening at resonant conditions (harmonic forced vibration) by forced vibration test. Based on forced vibration techniques, the resonant frequency curves, mode shapes and damping coefficients as well as stress distribution at strengthening system could be defined. These parameters are strongly related to prediction of dynamic behaviour of the structure under earthquake excitation.

2. DESCRIPTION OF THE BUILDING AND THE RETROFITTING SYSTEM

The aimed building was constructed in 1908 during the French colonization period, and now is used as a residential building. The building has an irregular shape consisting of basement, ground floor, two floors and tower, representing a part of third floor. The in plane dimensions of the building are of length 22m and 17.75m. The structural system is composed by masonry bearing walls, with mean thickness of 50cm. The floors were built with hollow clay elements supported by steel beams interspaced at 50cm. The steel beams are simply supported by the bearing walls. A main view of the building before strengthening is shown in figure 1.

Figure 1 View of the building before retrofitting (S-W façade)

There were some visible cracks, which happened during the past 2003 Boumerdes earthquake. It was obviously that some repairing and strengthening solution should be applied. The retrofitting system DC-90 consists of several steel elements such as anchors, prestressing bars, diagonal bracings and yielding type dampers (Skuber et al. 2006). Figure 2 shows details for the connection of the damper, diagonal brace and vertical bar. The appearance of the building after retrofitting is presented in figure 3.

3. TEST EQUIPMENT AND MEASUREMENT METHODOLOGY

The building dynamic behaviour has been monitored by three different types of instrumentation: seismometers for ambient vibration measurements, accelerometers for forced vibration measurements and strain gauges for recording the strains (stress) in steel bracings of the DC-90 system.

3.1 Ambient Vibration Test

The ambient vibration testing methodology is based on ambient excitation such as wind. The very sensitive seismometers are capable to catch the produced micro-tremors which is a random type of signal, consisting of excitation frequencies in broad frequency range, enough to excite several modes of structural vibration. The measurements performed in selected 15 points at level III, as shown in figure 4, give some general information about natural frequencies of the building after retrofitting. The ambient vibration equipment consists of City Shark I station (digital recorder) coupled by Lennartz seismometers type LE-3D. One by one, fifteen points have been measured in two orthogonal directions at level III. The objective was to give a first estimation of

the natural frequencies before retrofitting of the building, and to estimate the position of the centre of torsion where the shaker will be placed for forced vibration test.

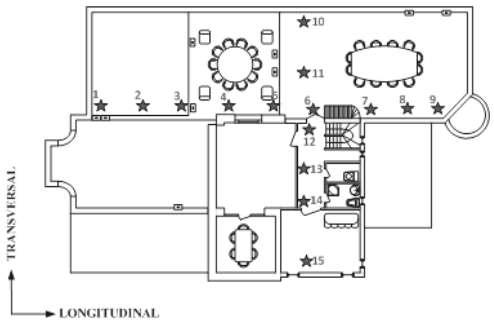

Figure 4 Measurement points position on level III for ambient vibration test.

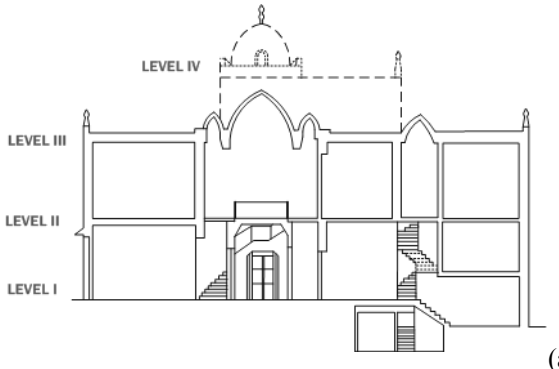
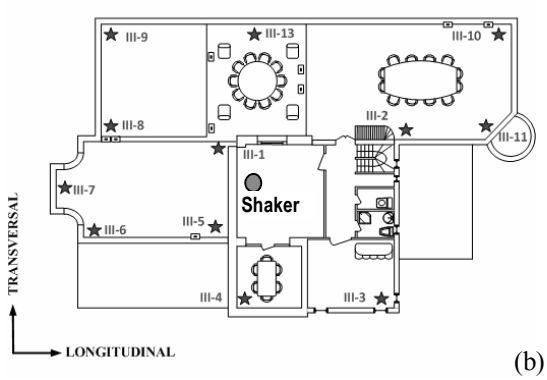


3.2 Forced Vibration Test

The forced vibration testing methodology is based on resonant concept. By the application of a dynamic harmonic force on the top of the building, it is possible to excite the resonant frequencies of the building, if the frequency of the force is equal to one of the natural frequencies of the building. The frequency of the force can be gradually changed in small steps within the range of 0.5-16.0 Hz. The resonant state is reached when the acceleration response at the measurement point become maximum and then decrease even the frequency of the force still increase. On this manner, frequency response curves can be obtained for each orthogonal direction and torsion.



The forced vibration equipment consists of an eccentric mass shaker for excitation with a harmonic sinusoidal force within the frequency range 1-15 Hz (Shenk-Germany) as well as signal recording equipment: data acquisition system 16 channels - National Instruments-USA, Kistler accelerometers 5g, and signal amplifier- Kistler-USA, for accelerometers (8 channels), signal amplifier-Kyowa, for Kyowa strain-gauges KFC-5 (8 channels). A labtop computer was used to process the digitised data. The shaker is shown in figure 5, while the measurement points position for level III and level IV is shown in figure 6.

4. AMBIENT VIBRATION TEST RESULTS

Fourier amplitude spectra recorded in measurement point 4 before retrofitting is shown in figure 7 for longitudinal and transversal directions, while thus recorded after retrofitting by DC-90 System is shown in figure 8. Comparative presentation of the frequencies is given on Table 1. The comparison between natural frequencies given by ambient vibration test before and after retrofitting shows that they become higher after retrofitting for about 5%.

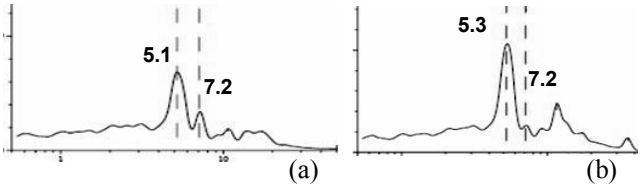

Figure 7 Fourier amplitude spectra before retrofitting: (a) Transversal direction, and (b) Longitudinal direction

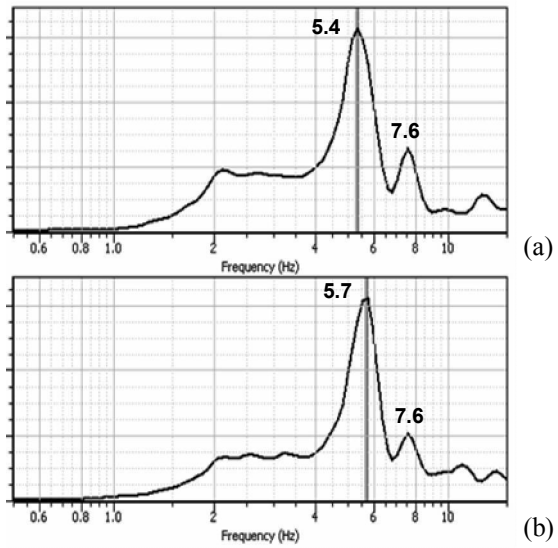

Figure 8 Fourier amplitude spectra before retrofitting: (a) Transversal direction, and (b) Longitudinal direction

Table 1 Natural frequencies of the building before and after retrofitting

Direction	Natural Frequency (Hz)	
	Before retrofitting	After retrofitting
Transversal	5.1	5.4
Longitudinal	5.3	5.7
Torsion	7.2	7.6

5. FORCED VIBRATION TEST RESULTS

5.1. Frequency response curves

Frequency response curves are obtained by recording the acceleration response at particular points on level III and IV in two orthogonal directions (Longitudinal and transversal directions). The frequency response curves for some recording points are given in figures 9 through figure 12.

The resonant frequencies defined by force vibration method as can be seen from resonant frequency curves, are smaller than the ambient frequencies for about 3-5 %, which is close to the original state before retrofitting (Table 2). It can be concluded that the retrofitting of the building does not change the dynamic properties of the building. This is mainly due to the high stiffness of the masonry walls, in which, the inserted steel bars do not change their stiffness.

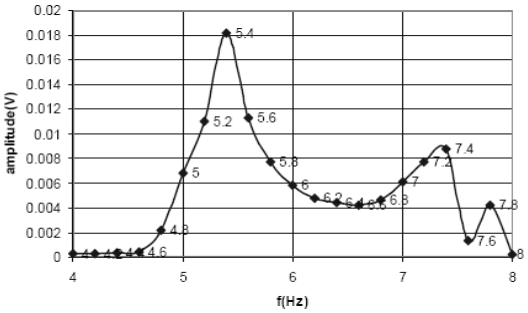

Figure 9 Frequency Response Curve for transversal excitation - point III-1

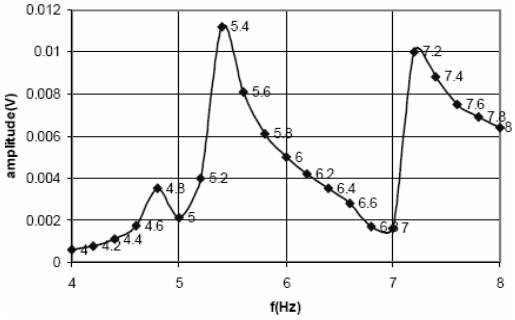

Figure 10 Frequency Response Curve for transversal excitation - point III-10

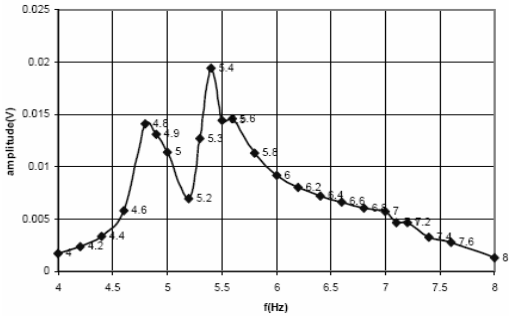

Figure 11 Frequency Response Curve for longitudinal excitation - point III-10

Direction	Natural frequency (Hz)		
	Ambient vibration		Forced vibration
	Before retrofitting	After retrofitting	After retrofitting
Transversal	5.1	5.4	4.8
Longitudinal	5.3	5.7	5.4
Torsion	7.2	7.6	7.2

5.2. Damping coefficients

As far as damping coefficients concerns, they are defined from frequency response curves based on half power method. Table 3 shows the damping ratios as a percentage of critical damping corresponding to some measured points. The damping ratios are ranging between 2.7-5.8 %. This is rather high damping, which is good for dissipation of the energy during earthquake. These values should be much higher when DC-90 dampers become active when lateral displacements reach 1-5mm during earthquake. For this low level of excitation by force vibration activation of the dampers is not expected.

Table 3 Damping coefficients

Excitation direction	Freq. (Hz)	Damping at particular points (%)					
		III-10		IV-1		IV-4	
		T	L	T	L	T	L
Transversal	4.8	3.5	3.0	3.5	/	/	/
	5.4	3.1	2.7	3.1	3.1	/	/

	7.2	3.0	3.5	/	/	/	3.6

/ No measured values at that point

5.3. Stress distribution at steel bracings of DC-90 system

Stress distribution at the steel bracings was investigated by recording the strains at 14 selected points at the level I (ground floor). The disposition of the strain gauges is given in Figure 13. The stresses, given on Table 4 for some measurement locations, are calculated based on measured strains following the Hook's low. The maximum value is obtained at point 14d for excitation in longitudinal direction with σ= 4.06 Mpa corresponding to peak strain of about 20 μstr. Considering the obtained values, it is obvious that level of dynamic excitation is very low (about 0.95 %g peak response) comparing to a real earthquake strong motion level.

	7.2	0.98	0.40	1.40	1.40	2.04	4.06

5.4. Vibration mode shapes

The main objectives of forced vibration test were to define the resonant frequencies, damping coefficients and mode shapes of vibration of the building under resonant conditions. Having in mind the irregular shape of the building (unsymmetrical in plane), the torsional effects have been expected. To record such effects, two orthogonal horizontal components at each measuring point have been measured: one in direction of excitation and other in direction transversal to excitation force. The spatial shape of vibration was estimated by application of ARTeMIS software (svibs, 2001).
Figures 14-16 show the spatial mode shapes for three defined resonant frequencies. It is obvious that torsional effect is present more-less in all three mode shapes which means that the modes are coupled i.e. for any excitation direction and frequency near resonant, the structure will vibrate torsionally. The most intensive vibration appears under the frequency 5.4Hz. It is visible from the frequency response curves and peak acceleration recorded at characteristic points of the building.

Figure 14 Vibration shape of the building at resonant frequency f=4.8Hz by excitation in the transversal direction.

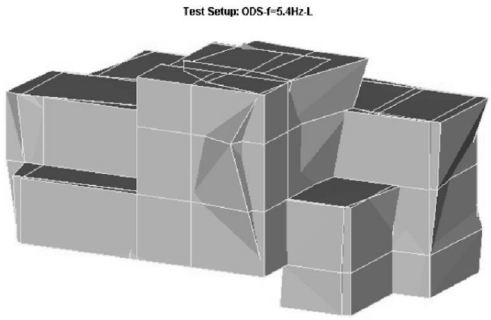

Figure 15 Vibration shape of the building at resonant frequency f=5.4Hz by excitation in the longitudinal direction.

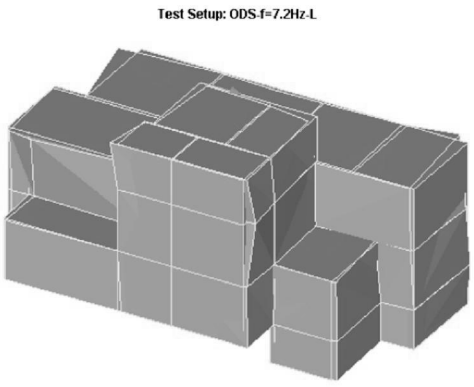

Figure 16 Vibration shape of the building at resonant frequency f= 7.2 Hz by excitation in longitudinal direction

6. CONCLUSIONS

Based on experimental testing of the masonry building by ambient and forced vibration methods, the following summarized results are obtained:

The first set of fundamental frequencies of the building is: transversal direction f1= 4.8Hz, longitudinal direction: f2=5.4 Hz and torsion: 7.2 Hz. The vibration of the building at resonance condition is of the same intensity in longitudinal and transversal directions. For both excitation directions, all three frequencies are excited i.e. the building vibrate torsionally with coupling effect between the modes.

The vibration effect produced by forced vibration test was rather small comparing to real earthquake excitation conditions. Namely, the peak acceleration on the top of the building was about 0.01g, peak displacement about 0.1 mm, peak stress at point 14d was about 4.0 Mpa and peak strain about 20 μstr, The capacity of the shaker was much bigger than it was used, but because of safety precaution, higher excitation force was not applied. The measured values at 14 points on vertical and diagonal bracings at ground floor show the distribution of the stress. If we analyze the data from Table 6, it can be concluded that the diagonal bracing at point 14d is more stressed than the others (2-5 times) and that stresses at longitudinal excitation are about two times higher then in transversal for corresponding points. This is probably because the irregular shape of the structure as well as non-uniform distribution of the inertial forces in both directions.

The damping of the structure obtained from frequency response curve based on half-power method ranges between: 3-6 % of critical damping even under low amplitude vibration level. For realistic earthquake conditions it could reach much higher level considering the presence of the DC-90 dampers. At the excited level of vibration (1%g) the dampers have not been activated.

Abstract: Although failure mechanism of strong column-weak beam is expected by Chinese Seismic Code, several collapses of RC frames occurred due to damages of columns during Wenchuan earthquake. This caused heated debate among many scholars and engineers all over the world. Investigations and researches illustrated that seismic design without consideration of diaphragm was one of the main reasons. In this paper, with flexibility-based fiber model, the seismic behaviors of RC structures with specially shaped columns which are designed according to the current Chinese codes or technical specification are analyzed under unidirectional rare earthquakes using PushOver analysis method. The beam strength is calculated with or without consideration of the diaphragm and its reinforcement. The results are compared and conclusion has been drawn that the bending capacity of beams would be increased due to the effect of diaphragm and its reinforcement, and which would change the failure mechanism of RC frames under rare earthquake, especially in high intensity areas. Therefore, the influence of the diaphragm should be considered in the seismic design of this type of structure and corresponding design code should been improved.

1. INTRODUCTION

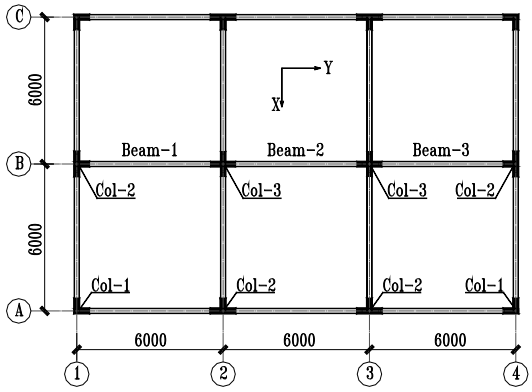
Although failure mechanism of strong column-weak beam is expected by seismic design codes for RC frames, plastic hinges at the beam ends were rarely developed during Wenchuan earthquake occurred in China on May 12th 2008 while lots of plastic hinges formed at the end of columns of RC frames. Among those buildings, many were designed strictly following the Chinese Code for Seismic Design of buildings (2001version). This phenomenon has caused much attention of the committees of Chinese Codes and many engineers. A great deal of research works were carried out to analyze the causes of this typical failure mechanism. According to the investigations of the earthquake hazard and the latest studies by the authors (Ye Lieping 2008, Wang Yayong 2008, Su Youpo 2009 and Huo Linsheng 2009 etc.), one of the important reasons is that the effect of the floor diaphragm is usually neglected in seismic design. The ratio of stiffness and strength of beam to column in the same joint would be changed because of the diaphragm and its reinforcement, i.e. the yield state and order of beams and columns would be changed, and thus the failure mechanism of strong column-weak beam might not be realized. Because the RC frames with specially shaped columns are seldom constructed in Wenchuan, their seismic behaviors have not been proved by actual strong earthquake. Meanwhile the achievements about the failure mechanism of the typical structures all over the world are very little. It is still uncertain for researchers and designers whether the failure mechanism with beams' hinges would be taken place after strong earthquakes. So it is necessary to analyze the failure mechanism of the type of RC frames affected by the floor diaphragm and evaluate the efficiency of the current Chinese codes.

In this paper, with the flexibility-based fiber model, the seismic behaviors of RC structures with specially shaped columns, designed according to the Chinese current codes including Code for Seismic Design of buildings and Technical Specification for Concrete Structures with Specially Shaped columns, are analyzed using nonlinear dynamic analysis method and PushOver analysis method. The beam strength is calculated with or without consideration of the diaphragm and its reinforcement. The results are compared and conclusion has been obtained.

2. STRUCTURAL MODEL AND CORRESPONDING PARAMETERS

Two RC model structures with specially shaped columns, which were named S-015g and S-020g respectively, were designed according to the Chinese

Technical Specification for Concrete Structures with Specially Shaped columns (JGJ149-2006) in this paper. The Site Classification is Class II. The Earthquake Group Classification which represents the fault distance is Group 1. The layout of the structure is illustrated in Figure 1. The corresponding parameters of two structures are given in Table 1.



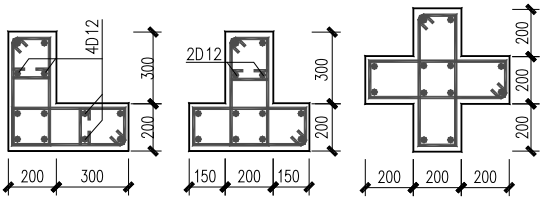


Figure 1 Layout of Model Structure

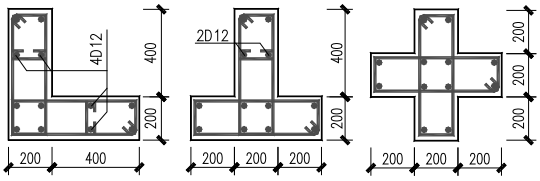
Table 1 Main Parameters of the Model Structures



Model Structure	Seismic Design Intensity	Structural Height /m	Seismic Class	Fundamental Period /s
S-015g	0.15g	18 (6 floors)	Class 3	0.93
S-020g	0.20g	12 (4 floors)	Class 2	0.55

The concrete compressive design strength is assumed to be 30MPa. The internal forces and reinforcement of structures are determined using the Chinese Business Software SATWE and CRSC. And the minimum ratio of reinforcement for columns and beams, axial compression ratio of column and elastic story drift of structures under frequent earthquake met the requirements of Chinese Codes. The thickness of floor diaphragm is 120mm and its bottom bi-directional reinforcement is φ^R10@180 (the design yield strength, fy, is 400N/mm^2) while at the top is φ^R10@100 closing to beams. The bottom bi-directional reinforcement of roof diaphragm is φ^R10@150.

(a) Col-1 (b) Col-2 (c) Col-3

Figure 2 Dimensions and Reinforcement Type of Columns of Model Structure S-015g

(a) Col-1 (b) Col-2 (c) Col-3

Figure 3 Dimensions and Reinforcement Type of Columns of Model Structure S-020g

The sectional dimensions and type of reinforcements of specially shaped columns of the two model structures are given in figure 2 and figure 3 (units: mm).

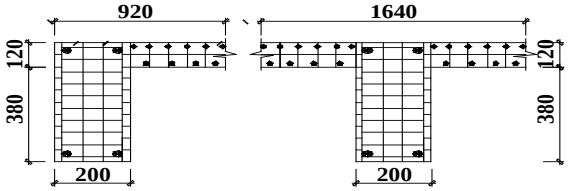
The longitudinal reinforcement of specially shaped columns corresponding to the two model structures is shown in Table 2. In the Table, "D" means the diameter of longitudinal reinforcement. For instance, "8D16" represents 8 pieces of longitudinal reinforcement whose diameter is 16mm and its designed yield strength is 300N/mm^2. The diameter of hoop reinforcement is 8mm for Col-1 and Col-2 and 10mm for Col-3. The spacing of hoop reinforcement was 100mm for all columns.

Table 2 Details of longitudinal reinforcement of columns

Columns	Floor	Model Structure	
		S-015g	S-020g
Col-1	1st floor	8D16+4D12	8D22+4D12
	others		8D16+4D12
Col-2	1st floor	10D18+2D12	10D22+2D12
	others	10D16+2D12	10D16+2D12
Col-3	All floors	12D16	12D16

3. NONLINEAR ANALYSIS OF THE MODEL STRUCTURES

The fiber model is used to simulate the behavior of the specially shaped column. The effectiveness of fiber model in simulating the behavior of RC columns had been verified by comparing the analysis results with the experimental results obtained under cyclic loading in previous research by authors (Yang Pu 2006). Fiber division of beams considering the effect of floor diaphragm is shown in Figure 4. The effective flange width of beam is assumed to be the width of beam plus six times the depth of diaphragm at each side of beam according to the work by Zheng Shiju (2009), Wu Yong (2009) and ACI 318-08. And fiber division of specially shaped columns is shown in Figure 5.



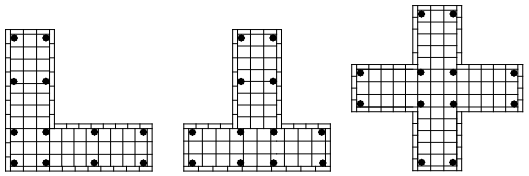


Figure 4 Fiber Division of Beams Considering Effect of Floor Diaphragm

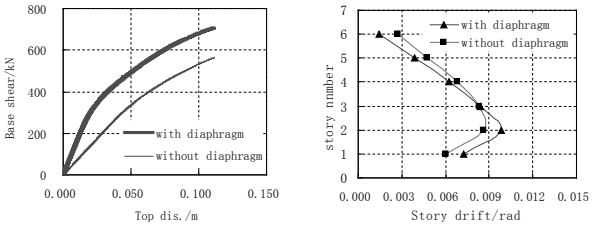
(a) Col-1 b) Col-2 (c) Col-3

Figure 5 Fiber Division of Columns

Monegotto-Pinto model which accounts for strain hardening is adopted to represent the stress-strain relationship of steel reinforcement fiber in single direction. The modified Kent-Park model is adopted to illustrate the

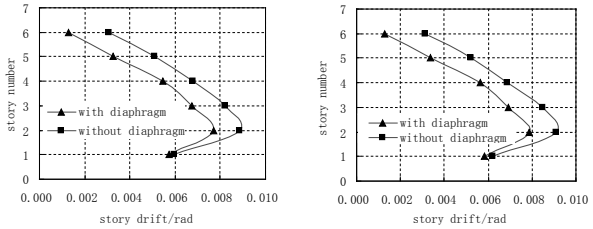


stress-strain relationship of concrete fiber in which relative slip between steel bars and concrete is not taken into account but the confinement of concrete by hoop reinforcement is considered.

The dynamic analysis was carried out by selecting three actual earthquake waves and one artificial earthquake wave. The results of dynamic analysis were different due to the difference of waves. Therefore this paper focused on the results of PushOver analysis in order to eliminate the effect of input waves and compared with results of dynamic analysis.

Because of symmetry of mass and stiffness of the two model structures, the lateral load was applied only in the direction of Y axis and the pattern of load was assumed as inversed triangle. And the target top displacement of structures was assigned the average value plus one time variance of the maximum top displacement under four earthquake waves using dynamic analysis method without considering the effect of the diaphragm.

3.1 Nonlinear Analysis Results of the Model Structure S-015g

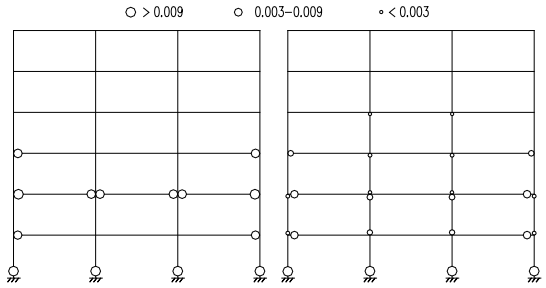


The capacity spectrum, curve of base shear vs. top displacement, of model structure S-015g were obtained and shown in Figure 6(a) using PushOver analysis method. It is obvious that the base shear is higher taking account of effect of the diaphragm than one without considering the diaphragm at the same top displacement. In other words, the diaphragm and its reinforcement increased the structural stiffness if its effect was considered.

(a) capacity spectrum (b) story drift

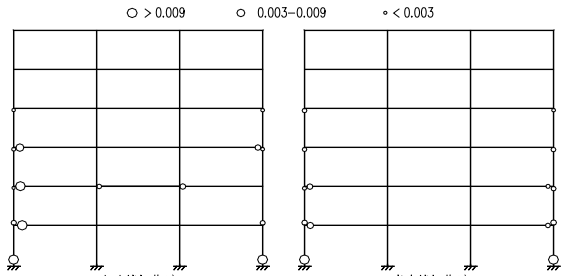
Figure 6 PushOver Analysis Results of Model Structure S-015g

The story drift of model Structure S-015g along its height is shown in Figure 6(b). It can be found that the maximum story drift is at the second story whether or not consider the effects of the diaphragm and its reinforcement. Thus the weak story of the model structure is obviously the second story.



(a) USA0021 (b) USA002755

Figure 7 Story Drift of Model Structure S-015g Using Dynamic Analysis Method



The maximum story drift is larger considering the diaphragm than not considering at the same target top displacement and the story drift is more even along the height. This phenomenon is not the same as the one using dynamic analysis shown in Figure 7 due to two possible reasons. The first one may be load pattern which may not comply with the distribution of inertia force along the height of structure under actual earthquake. Another one is the target top displacement may not equal because of effect of the diaphragm. After all, it can be concluded that the diaphragm would affect significantly the behavior of structure.

The distributions of plastic hinges of the frame on axis B of the model structure S-015g under rare earthquake by PushOver analysis and dynamic analysis under earthquake wave USA002152 with and without consideration of the effect of the diaphragm are shown in Figure 8 and 9.

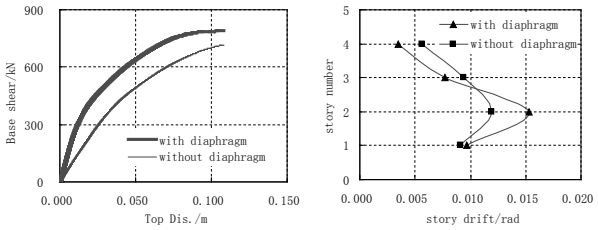
(a) without diaphragm (b) with diaphragm

Figure 8 Distribution of Plastic Hinges under Rare Earthquake by PushOver Analysis Method

(a) without diaphragm (b) with diaphragm

Figure 9 Distribution of Plastic Hinges under Rare Earthquake Using Dynamic Analysis (USA002152)

Several conclusions can be obtained from the above results:

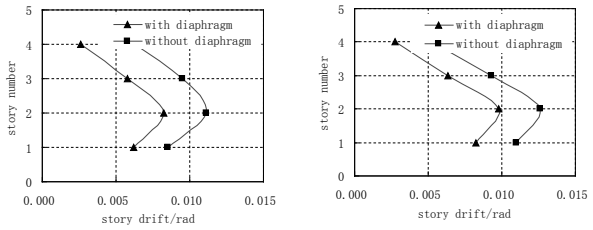


1) When the effect of the diaphragm is considered, the number of plastic hinges at the end of beams is decreased while the one at the end of columns is increased. And the angle of plastic hinges of beams is decreased while the one of columns was increased. The reason is the increase of strength of beams due to the floor diaphragm and its reinforcement.

2) According to the calculated results, the equal longitudinal reinforcement at top of beams would almost double if reinforcement of the diaphragm is considered. Therefore the plastic hinge at end of beam formed at the bottom of beam because the bottom reinforcement reached the design yield strength, while the plastic hinge at end of beam usually forms at the top of beam because the top

reinforcement reaches design yield strength if not considering the diaphragm and its reinforcement. This has not been studied in-depth by researchers in their previous studies.

3.2 Nonlinear Analysis Results of the Model Structure S-020g



The capacity spectrum and curve of base shear vs. top displacement, of model Structure S-020g were obtained and shown in Figure 10(a) using PushOver analysis method. It is obvious that the base shear is higher taking account of effect of the diaphragm than one without taking account of the diaphragm at the same top displacement. The reason is the same as the model Structure S-015g.

(a) capacity spectrum (b) story drift

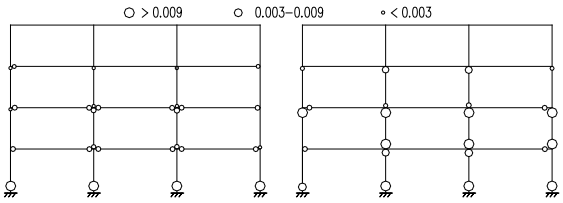


Figure 10 PushOver Analysis Results of Structure S-020g

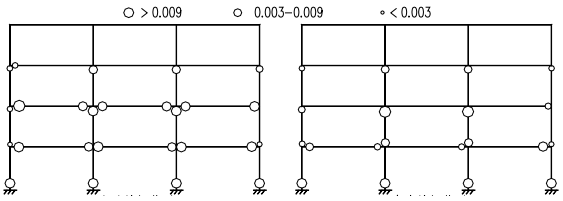
The story drift of Structure S-020g along its height is shown in Figure 10b. It can be found that the maximum story drift is at the second story whether or not considering the effect of the diaphragm and its reinforcement, so the weak story of structure is obviously the second story. And the maximum story drift is larger considering the diaphragm than not considering at the same target top displacement and the story drift is more even along the height. This phenomenon is not same as the one using dynamic analysis shown in Figure 11. The reasons are the same as the Structure S-015g.



(a) USA000535 (b) USA002551

Figure 11 Story Drift of Structure S-020g Using Dynamic Analysis Method

(a) without diaphragm (b) with diaphragm

Figure 12 Distribution of Plastic Hinges under Rare Earthquake by PushOver Analysis Method

(a) without diaphragm (b) with diaphragm

Figure 13 Distribution of Plastic Hinges under Rare Earthquake by Dynamic Analysis (USA002551)

The distribution of plastic hinges of frame in axis B of structure S-020g under rare earthquake by PushOver analysis and dynamic analysis under earthquake wave USA002551 whether or not considering the effect of the diaphragm is shown in Figure 12 and 13.

From the above figures, several conclusions can be obtained:

1) As the effect of the diaphragm is considered, the number of plastic hinges at the end of beams is decreased while the one of plastic hinges at the end of columns is increased. And the angle of plastic hinges of beams is decreased while the one of plastic hinges of columns is increased. The plastic hinges are occurred at the end of almost all columns at the second story and this is severe for seismic design. The reason, similar to the structure S-015g, is the promotion of strength of beams due to the diaphragm and its reinforcement.

2) When the reinforcement of diaphragm is considered, the plastic hinge at beam end forms at the bottom of beam because the bottom reinforcement reaches yield strength. while the plastic hinge at end of beam is usually occurred at the top of beam because the top reinforcement is up to design yield strength if not considering the diaphragm and its reinforcement.

3) Compared with structure S-015g, there are more plastic hinges at the end of columns of structure S-020g. The reason may be that the longitudinal reinforcement of columns in higher seismic design intensity areas is controlled by the internal force of combination of vertical load and earthquake action while the one in lower seismic design intensity areas is controlled by detailing requirements instead of the internal force. Therefore, the structures in higher seismic design intensity areas should be more strictly required by the codes to improve their seismic behavior.

4. CONCLUSIONS

In the paper, with flexibility-based fiber model, the seismic behaviors of RC structures with specially shaped columns are analyzed under unidirectional rare earthquakes using PushOver analysis method. The beam strength is calculated with or without consideration of the diaphragm and its reinforcement. The results of analysis considering the diaphragm were compared with the one without considering the diaphragm and several conclusions are drawn as follows:

1) The floor diaphragm is one of the most important

factors that affect the seismic behavior and failure mechanism of RC frames with specially shaped column. Therefore its effect should not be neglected in seismic design.

2) As the effect of diaphragm is considered, the number of plastic hinges at the end of beams is decreased while the one at the end of columns is increased. And the rotation angle of plastic hinges of beams is also decreased while the one of columns is increased. The reason is the diaphragm and its reinforcement would increase the strength of beams.

3) Although two structures are all designed complying with Chinese Codes, there are more plastic hinges at the end of columns of structure in higher seismic design intensity areas than one in lower seismic design intensity areas under rare earthquake. Thus the structures in higher seismic design intensity areas should be more strictly regulated by the codes.

Abstract: It is well known that the ultimate load capacity of a reinforced concrete slab can be much larger than that predicted by Johansen's Yield Line Theory (YLT). This increase in load capacity can largely be attributed to the ability of the slab to act as a membrane, allowing it to carry vertical loads through compression and tension struts rather than simple flexure. This paper discusses several attempts at capturing membrane effects in reinforced concrete slabs, varying in complexity from simple grillage to 3D finite element models. The grillage model, which is often used for bridge deck analysis, is implemented within the OpenSEES platform, using non-linear beam elements arrayed orthogonally across the slab. In parallel, a model is developed in LS-DYNA using composite shell and solid elements with embedded bar elements representing the reinforcing steel. Evaluation of the numerical model is undertaken using two series of classical experimental datasets, namely those of (i) Hung and Nawy (1971), whereby two-way square slabs with different edge conditions are tested and (ii) those of Park (1971), whereby a 2 slab panel is tested. The paper concludes by providing general suggestions regarding modeling strategies to most reasonably capture the vertical response of reinforced concrete slabs considering membrane action.

1. INTRODUCTION

1.1 Background

Reinforced Concrete (RC) slabs are an integral part of a structure and are required to transfer gravity loads to columns/shear walls. As per ACI-318, slabs are designed to carry gravity and lateral loads through flexure and shear. During analysis of a structure, it is generally assumed that the slab behaves as a rigid diaphragm and its effect on the dynamic performance of the structure is ignored. However, past experimental research (e.g. Malik and Bertero, 1976; Hwang and Moehle, 1993) has clearly demonstrated that slabs acts with other structural components and therefore considering their behavior is important to characterizing the response of an entire structure. Similarly, numerical simulations of 3D structures (e.g. Kang, 1993), whereby slab flexibility is included, indicate that although the initial elastic stiffness may not be greatly affected, slab flexibility will have a noteworthy effect on the first significant yield of the structure. The inelastic behavior of slab also contributes to the difference in base shear between internal and external columns.

In practice, the ultimate strength of slabs is often estimated using Johansen's Yield Line Theory (1962) (YLT). YLT assumes that the slabs plastic deformation is localized along predefined yield lines. Past research however has clearly shown that YLT underestimates the ultimate load carrying capacity of slab (e.g. Hopkins, 1969; Park 1970; Christiansen and Frederiksen, 1983; Vecchio and Tang, 1990). Hopkins (1969) for example, upon testing a 1/4th scale beam-slab model, finds that the ultimate strength attained by the 3x3 test slab is twice that predicted by YLT.

This enhancement in slab performance is attributed to membrane forces within the slab which develop at large vertical deformations, and can be further enhanced with any increased restrained provided to the slab. Figure 1 illustrates the compressive and tensile membrane action that occurs in plates.

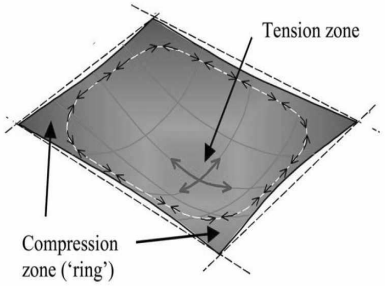

Figure 1. Membrane Forces in a Rectangular Panel (from Bailey 2004).

1.2 Scope of the Study

It is clear from previous research that it is important to include the effect of the slab when modeling a larger structure to improve accuracy of the system level response estimation. Herein, we focus on exercising potential modeling strategies related to modeling the slab itself, utilizing a pair of well-documented experimental datasets.

2. TEST PROGRAMS SELECTED FOR MODELING

2.1 Specific Details

Of the experiments conducted on slabs and beam-slab-column sub-assemblies, two notable and well documented experiments were selected. The first test program was conducted by Hung and Nawy (1971) and involved 29 isotropically reinforced, single panel slabs loaded under uniform loading. In the second test by Park (1971), a 2-panel slab with beams was loaded vertically. The effect of restraint provided by adjacent panels is mimicked in the test program by thickening the edge beams.

In the experiments conducted by Hung and Nawy (1971), all slabs are isotropically reinforced, top and bottom, using either deformed welded wire fabric or Grade 40 #3 bars (f_y = 287 MPa, 9.52 mm diameter). Of the 29 tests performed, two slabs are selected herein. These two slabs are selected for the study, as they only differ in boundary condition on one edge. Both slabs have a 1.524 m × 1.524 m clear span with a total depth of 63.5 mm. The average effective depth, i.e. the distance from the exterior concrete face to the center of the reinforcing steel, is 50.8 mm. One of the slabs has all four edges restrained against translation and rotation. The second slab considered for this study is fully restrained on three edges and hinged on one edge. The loading configuration adopted in these tests is shown in Figure 2. Both of the slabs are constructed with normal strength concrete with a mean compressive strength of 39 MPa and reinforced with #3 bars top and bottom, resulting in a reinforcing ratio of 0.58%. The slabs are able to carry 67% and 122%, respectively, more than predicted by YLT and this additional capacity is attributed to development of membrane action (Hung and Nawy, 1971).

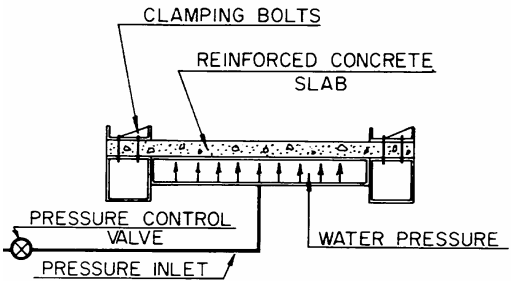

Figure 2 Test Setup of Hung and Nawy (1971), Single Panel Slab Experiment.

In the experiment conducted by Park (1971), a 1/4th scale slab-beam system is designed adopting yield line theory for the slab and assuming a collapse mechanism for the beam. The test specimen is 3.05 m × 3.12 m in plan dimension and simulates two slab panels with beams on each side. The effect of adjacent panels is simulated in the experiment by stiffening the beams in one direction. Figure 3 shows the general layout and dimensions of the beam-panel system. The slab model is restrained vertically at twelve locations, spaced 1.524 m from each other.

Slab panels are reinforced using 3.18 mm bars top and bottom resulting in a reinforcing ratio of approximately 0.2%. The beams are 7.6 cm × 11.2 cm in cross-sectional dimension, reinforced with 6.4 and 9.5 mm bars, resulting in a reinforcement ratio of approximately 0.3%. Stirrups are provided in the beam adjacent to the panels using 3.18 mm bars, with the stirrup spacing ranging from 34.0 to 76.2 mm.

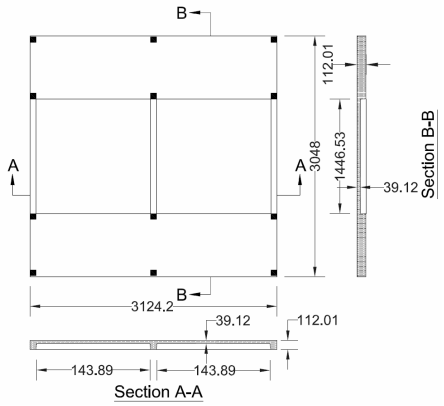

Figure 3 Dimensions of the beam-slab system tested by Park (1971), dimensions in mm, supports are shown in black

The load is applied in on the slab panel in two phases. In the first phase, a load amplitude slightly greater than the service load of the designed panel is applied and subsequently it is unloaded. In the second phase, the load continually increased until the panel fails. Deflections are recorded at the beam mid-span and at the center of the panels. The author concludes that the slab is able to take 64% to 88% greater load than the ultimate load as estimated with YLT.

2.2 Estimation of ultimate load for the Hung and Nawy slab Using YLT

Yield line theory assumes that the deformation in the slab is concentrated along *yield lines*, that is lines along which hinging occurs, while the remainder of the slab behaves as rigid body. As the load is increased, new yield lines will form, resulting to a plastic mechanism, until the slab can no longer carry additional load, yet will only continue to deform. Using the method of virtual work, YLT provides a strategy for predicting the ultimate load carrying capacity for different edge and loading conditions for slabs.

McGregor (1988) shows that for an orthogonally reinforced slab, if the yield line forms at an angle θ with the 'x' direction reinforcing bars, the bending and the twisting moment per unit length of the yield line can be calculated using Equations 1 and 2.

$$m_b = m_x \sin^2\theta + m_y \cos^2\theta \quad (1)$$

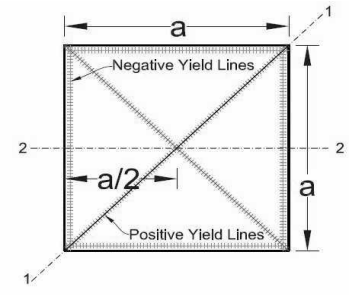
$$m_t = \left(\frac{m_x - m_y}{2} \right) \sin 2\theta \quad (2)$$

where m_x and m_y are the flexure capacity in the X and Y direction, m_b is the flexure capacity along the yield line, and m_t is the twisting moment. For isotropically reinforced slabs,

$$m_X = m_y \tag{3}$$

$$m_b = m_x = m_y \text{; therefore } m_t = 0 \tag{4}$$

Using the yield lines suggested by Johansen (1972) for rectangular slabs, and considering the symmetry for a square slab with all edge restrained the yield lines are shown in Figure 4. Assuming a unit deflection at the center of the slab, to calculate the internal work done along the hinge lines, the rotation of each hinge line needs to be calculated. Figure 5 articulates the deformation for each yield line.



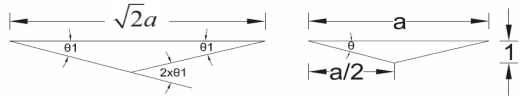


Figure 4 Location of yield lines in a square slab restrained on all sides

(a) (b)

Figure 5 Deflection and plastic hinge rotation along the yield lines, (a) Section 1-1 and (b) Section 2-2

Under a unit deflection, the external work done by a uniform surface load *q* is given by Equation 6.

$$W_{Ext} = q \times \frac{1}{3} a^2 \times 1 \tag{5}$$

One may also calculate the rotation along the positive and negative yield lines for the assumed deflection as:

$$2 \times \theta_1 = 2 \times \frac{\sqrt{2}}{a}, \quad \theta = 1 \times \frac{2}{a} \tag{6}$$

Therefore, the internal work along the yield lines is:

$$W_{Int} = 4 \times \left(m_{+ve} \times \frac{a}{\sqrt{2}} \times 2 \times \theta_1 + m_{-ve} \times a \times \theta \right) \tag{7}$$

where m_{+ve} and m_{-ve} are the yield moments in the positive and negative directions. From Equations 7 and 8 and substituting the values of $2\theta_1$ and θ:

$$W_{Int} = 4 \times \left(m_{+ve} \times \frac{a}{\sqrt{2}} \times 2 \frac{\sqrt{2}}{a} + m_{-ve} \times a \times \frac{2}{a} \right) \tag{8}$$

$$W_{Int} = 4 \times \left(m_{+ve} \times 2 + m_{-ve} \times 2 \right) \tag{9}$$

$$q \times \frac{1}{3} a^2 \times 1 = 4 \times \left(m_{+ve} \times 2 + m_{-ve} \times 2 \right) \tag{10}$$

For the square slab tested by Hung and Nawy (1971), $m_{+ve} = m_{-ve}$. Figure 6 presents the idealized and actual moment-curvature response for the 1m section of the slab (Hung and Nawy 1971), as obtained from an OpenSees (Mazzoni et al. 2005) analysis. The idealized yield moment of a unit of the slab section is calculated as 4.57 kN-m/m. Using Equation 10, the ultimate load carrying capacity of the slab is calculated as 94.4 kPa. This calculated load is 2% less than the ultimate load calculation done by Hung and Nawy (1971) using YLT.

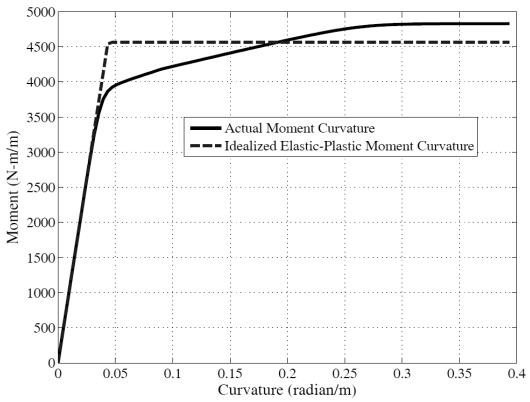

Figure 6 Moment curvature analysis of a unit cross section of the slab tested by – Hung and Nawy (1971) – actual estimated using OpenSees and idealized estimated using YLT.

3. NUMERICAL MODELING: HUNG AND NAWY SPECIMENS

3.1 Grillage model in OpenSees

Grillage models have been widely used in bridge deck analysis (e.g. O'Brien and Keogh,1999). A grillage model decouples the slab system into a grid of beam elements placed in orthogonal directions. In this fashion a 3-dimensional analysis can be undertaken using simple beam elements. In work done by Elghazouli et al. (2000), for example, a grillage model is used for the analysis of a slab deck under thermal loading. Figure 7 shows a simple grillage developed for modeling the slab system tested by Hung and Nawy (1971). In this model, each element is defined as a non-linear beam-column element with its cross

section defined by fibers made of uni-axial concrete and steel material. Each element has 6 degrees of freedom per each node, 3 translational and 3 rotational.

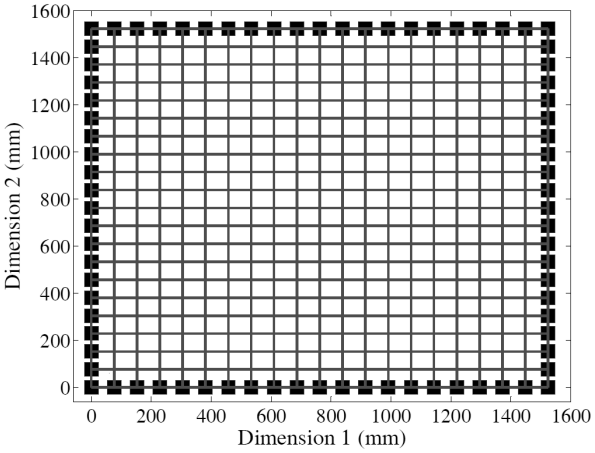

Figure 7. Grillage model (developed in OpenSees) of the slab tested by Hung and Nawy (1971) - grid size of 76.3 mm. Fixed boundary condition is shown in black square.

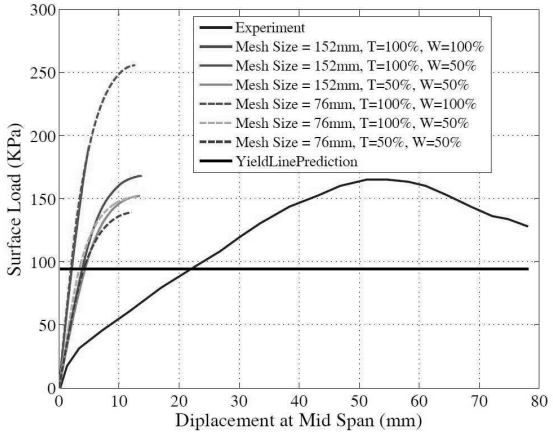
Concrete is modeled using the backbone for compression as proposed by Popovics (1973), with degraded linear unloading and reloading stiffness according to the work of Karsan and Jirsa (1969). Tension is assumed to following a linear secant stiffness path (*Concrete04*). The reinforcing steel is modeled using the *reinforcingSteel* material built in OpenSees. This material exhibits elastic behavior until yield, followed by a plateau region and eventually strain hardening.

A parametric study is undertaken to compare the numerical results from the OpenSees grillage model to the experimental results obtained by Hung and Nawy (1971). The parameters studied include (i) the effective width of the concrete section in flexure, (ii) the mesh size, and (iii) the torsional stiffness of the section. The effective width of the concrete section is a manifestation of the assumption inherent in grillage models, namely, since the response in two orthogonal directions is decoupled and represented by separate elements, an effective width to account for this decoupling of flexure must be defined. With regard to the torsional stiffness, it should be noted that OpenSees does not calculate the torsional properties of the section automatically. Torsional properties of the cross-section are defined by the analyst within the flexural properties of the section using *section-aggregate* command. Herein, the section is assumed to have elastic-perfectly plastic torsional behavior. For a section with no shear reinforcement, it is assumed that the section behaves elastically until cracking occurs. The cracking torsional resistance is estimated using the recommendations of ACI-318 (2008). The torsion properties are calculated assuming a rectangular concrete section as shown in Equations 11 - 13:

$$T_{cr} = 4\lambda\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right) \tag{11}$$

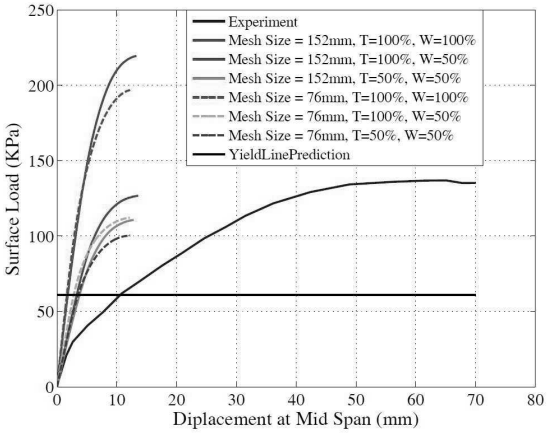
$$K_T = \frac{CG}{L} \tag{12}$$

$$C = \beta a b^3 \tag{13}$$



where T_{cr} is the cracking torsional strength, f'_c is the compressive strength of concrete, A_{cp} is the area of the concrete section, p_{cp} is the perimeter of the section, K_T is the torsional stiffness, G is the shear modulus, L is the length of the element, C is the torsional constant of the section of size a × b (a>b) and β is a constant depending on the ratio a/b.

In the grillage model, concentrated loads are applied at the node locations, equal to, the uniform load × tributary area of each node. A non-linear, iterative, implicit analysis is performed to go from one load step to another.



3.2 Numerical-experimental response comparison

Figure 8 presents the load versus displacement response of the two slabs modeled in OpenSees, considering variations in mesh size, effective width (W) and torsional stiffness (T). As observed in Figure 8, for all analyses, the grillage model appears to respond in a much stiffer fashion than the experimental specimen. However, concentrating on the effects of parameter variation, one may observe that varying the mesh size from 76.2 mm to 152 mm results in a difference of 10-15% in ultimate load, when other parameters are fixed. For both specimens (part a and b) it is clear that the width and torsional stiffness must be reduced, as 100% of initial estimates grossly overestimate the strength and stiffness of the section. When the effectiveness factor in flexure is decreased to 50%, the numerical simulation predicts the ultimate load with some degree of accuracy, though the low deformation stiffness is still overestimated. With 50% torsional stiffness of the original cross section, the calculated ultimate load decreases by approximately 10% for both the slabs. From these analyses, it appears reasonable, when seeking to capture the ultimate load, to use 50% of the effective width for flexure and 100% for torsion.

In all cases, the initial stiffness of the slab under vertical load is greater than that measured during the experiment. One reason for the larger stiffness is the assumption of perfect bond between the steel and the concrete, as adopted in the numerical simulation. A secondary reason may be the inability to accurately model the boundary conditions of such an experiment. Currently in the model, a perfect fixed boundary condition is applied at the individual nodes on the edge, while in the experiment this fixity at the boundary is applied via clamping a portion of the slab with through bolts. The boundary applied during the experiment may allow for small deformations, unlike the simulation, which assumes the boundaries to be perfectly fixed.

(a)

(b)

Figure 8 Load-displacement response comparison between the numerical grillage model in OpenSees and the experiments of Hung and Nawy, specimen with: (a) all edges fixed, (b) one hinged edge.

Figure 9 shows the location of yielding, when the ultimate load is achieved in the OpenSees model, for the slab restrained on all edges. In comparison with visual and measured strain data obtained during the experiment, OpenSees correctly predicts the yielding at the fixed edges in negative moment (shown in blue) and in positive moment at the center (shown in red). Although perfect agreement between the experiment and numerical model is not achieved throughout the deformation history of the specimen, the simple grillage model is shown to be effective in capturing salient features such as ultimate strength and strain distribution.

4. NUMERICAL MODELING: PARK SPECIMEN

This section describes the Park (1971) slab numerical modeling. This test specimen is modeled using similar grillage model concepts previously described, as well as adaptation of a 3-dimensional model in the platform LS-DYNA. Observations from the prior analyses indicate an effectiveness factor of 50% and 100%, for effective width in flexure and torsion respectively, are reasonable when adopting the grillage model concept, therefore these values are implemented in the analysis of the Park specimen.

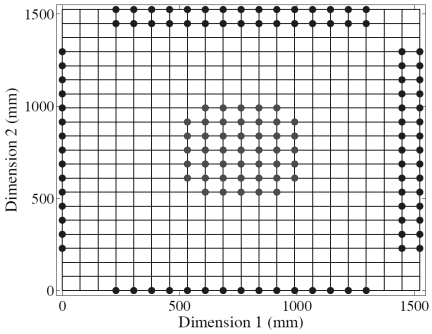


Figure 9 Location of yielding as predicted by the OpenSees grillage model; *Red* - yielding in positive direction and *Blue* - yielding in negative direction – Hung and Nawy slab specimen fixed on all edges.

4.1 Grillage model in OpenSees

A grid size of 152 mm is chosen for this analysis (span/10), based on the suggestion of Hambly (1999), who recommends at-least 10-12 elements along the span. The supports are fixed in the vertical direction using single point constraints. Figure 10 shows the grid and the support locations for the simulation in OpenSees.

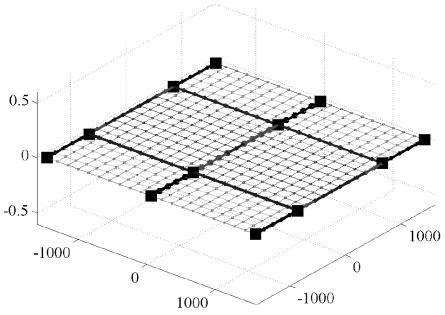

Figure 10 Grillage model of the Park (1971) experiment. The twelve supports are shown by the black squares. The color of the grillage elements represent different beam cross section

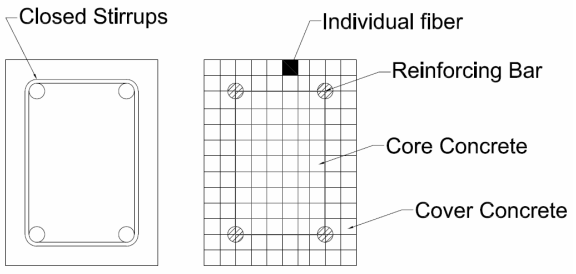

Figure 11 Reinforced concrete cross section of the beam model for the Park specimen, including its representation in OpenSees.

Due to presence of stirrups in the beam along the center span of the specimen, the beams in this region are modeled considering the effect of confining pressure. The method proposed by Mander et al. (1988) is used to calculate the effective confining pressure and the increase in the concrete compressive strength due to this confinement. A typical beam cross section used in the OpenSees analysis is shown in Figure 11. In this figure, the core and cover concrete materials are denoted.

4.2 3-Dimensional model in LS-DYNA

LS-DYNA is a commercial 3-dimensional, finite element software, developed by Livermore Software Technology Corporation (LSTC), widely used in the automobile industry for simulating automobile crash (Hallquist, 2006). It has a built-in material library for concrete materials, most of which are defined for solid elements. Select concrete materials are also defined for 4-noded shell and 2-noded beam elements. For the purpose of this study, the shell element material (MAT_172), is used to model the reinforced concrete slab and the 8 node solid element material (MAT_159) is used when modeling the reinforced beams.

The material 159 (Continuous Surface Cap Model) uses three failure surfaces to define the behavior of concrete. This material has the option of defining all the parameters effecting concrete behavior or the user can use a parameter generation option which only requires the concrete compressive strength and size of aggregate. Extensive tests have been done using this material and evaluated against experimental results (Murray, 2007; Murray et al., 2007).

For reinforcing steel, modeled by 2-node beam elements, a piecewise elastic-plastic material is used. To define this material, an analyst must define the steel elastic modulus, yield strength, Poisson's ratio and hardening modulus.

For beam and solid elements to work as a system, they need to be coupled. Sharing the solid nodes with beam nodes, wherever present is a straight forward way of coupling the two elements together. However, this does not account for slip between the concrete and rebar. Alternatively, coupling the beam and solid element can be incorporated in LS-DYNA using a 1-D contact algorithm. This algorithm requires the beam and solid element nodes to be along the same line, however, they do not need to be co-incident. The bond-slip relationship is defined using the radius of the rebar, the strength of concrete and the bond shear modulus between the rebar and concrete. Both of these methods require alignment between the beam and solid nodes, which is not always feasible. The third option available in LS-DYNA does not require the beam nodes to be aligned with the solid element nodes and constrains the beam nodes to move relative to the solid elements. Due to its simplicity and ease of input this later method is used herein to couple beam and solid elements.

Since a slab resembles a thin walled structure, with one dimension small compared to its span, shell elements are used to model the slab in LS-DYNA using material 172. Material 172 (MAT_CONCRETE_EC2) can be used to model plain concrete, plain steel or a mix of the two by defining a steel ratio for each case in both directions. When using this material, concrete is treated as a composite material formed by layer(s) of steel sandwiched between concrete. The exact position of steel and concrete is defined by specifying an integration rule for the shell elements. When defining the integration rule, the depth of each layer is defined in the iso-parametric coordinate system (i.e. $-1 \leq \xi \leq 1$) with the weight of each layer equal to the ratio of the thickness of the layer to the total thickness of the composite. For example, if a 2mm steel layer is present in a composite of total thickness 20mm, the weight corresponding to the steel layer is 2/20 = 0.1.

Material 172, used to model the slab panels, is not capable of accounting for vertical reinforcement and its effect on beam behavior in shear and torsion. To include the confined concrete behavior in LS-DYNA, the beams are modeled with 8-noded solid elements, while the beam reinforcement is modeled using 2-noded beam elements. The stiffened slab and the center slab panel are modeled using shell elements as they do not have any shear reinforcement present in them.

The average mesh size for this model is 17mm. This number is derived from the fact that at-least 4 elements are required in any direction to model beam bending with acceptable accuracy when using reduced integration solid elements. The 8-node single point integration solid elements do not have any rotational degrees of freedom. For moment transfer it is necessary that the slab rotates with the beam as a single system. Shell nodes are therefore constrained with the adjacent solid nodes for rotational compatibility. Figure 12 presents the wire-frame mesh of LS-DYNA model.

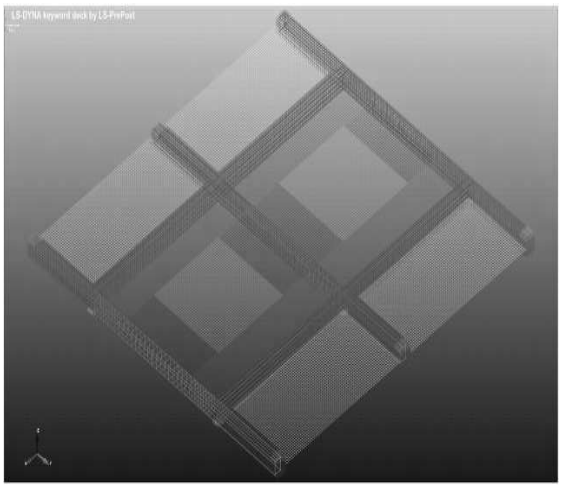

Figure 12 Wire-frame view of the Park (1972) LS-Dyna model.

Supports are modeled using rigid elements, which are restrained in the vertical direction only. To avoid local failure at the contact between the support and concrete beams, some elements are defined as elastic elements, with Young's Modulus and density of concrete.

A constant surface load is applied on the shell elements depicting dead load of the slab. A surface load is then applied to the center slab panel representing the load applied during the experiment.

4.3 Numerical-experimental response comparison

Figure 13 presents the load versus deflection response comparison between the numerical grillage and LS-Dyna models to the experiments. As can be seen, the numerical analysis with OpenSees is able to predict the ultimate load however, fails to predict the deflections correctly. It should be noted however that these analyses are performed under load control, therefore attainment of displacement response up to ultimate load, and not beyond, is anticipated. In this case the grillage model results in a slightly softer response when compared to the experimental results. Figure 14 shows the deflection profile of the beam-slab assembly as predicted by the grillage model at ultimate load. The deflected profile clearly articulates the extra restraint provided by the exterior and interior beams. The stiffened section of the slab, simulating adjacent slabs, do not deform considerably, compared to the center of the slab panel.

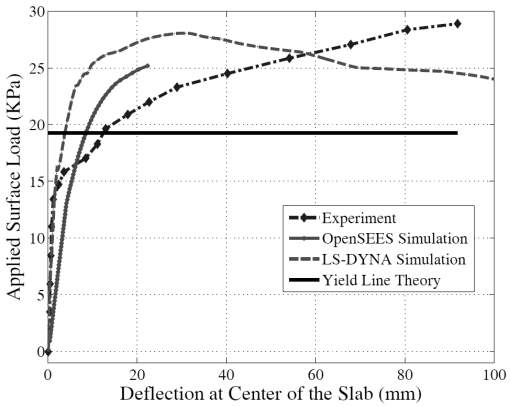

Figure 13 Comparison of slab center deflection as measured during the experiment to the grillage and 3-D modeling approaches.

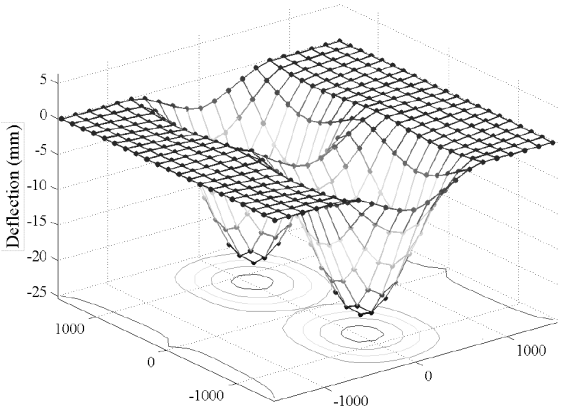

Figure 14 Deflection profile of the system under uniform loading as predicted with the OpenSees grillage model.

Comparing the numerical results from LS-DYNA with the experimental data, LS-DYNA is able to capture the initial stiffness of the system with reasonable accuracy. The results differ from the experimental data once the deflection is greater than 3-4 mm as shown in Figure 13, however overall the load versus deflection behavior is quite reasonably captured with LS-Dyna. Figure 15 presents the plastic strain development just prior to slab failure. The 'X – shaped' yield lines form in the slab where as the RC beams, modeled using solid and beam elements, articulate plastic regions at the supports and mid-span of the beam. These strain distributions are consistent with observations during the experiment.

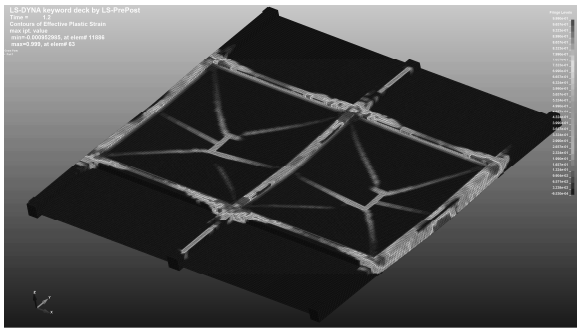

Figure 15 Plastic strains in the slab at ultimate load.

5. CONCLUSIONS

Numerical modeling of a series of slab test specimens is undertaken to investigate strategies for capturing membrane action in slab subsystems. Two finite element approaches are endeavored, namely, a simplified grillage model and a more complex 3-dimensional model using the platforms of OpenSees and LS-DYNA, respectively. The grillage model uncouples the behavior of the slab in two orthogonal directions. Though not accurate through a deformation history, this model does present reasonable results when comparing ultimate load and strain distribution at ultimate, thus it can be used to include the inelastic response of a slab into larger structural models. A grid dimension of clear-span/10 is recommended when using this method in bridge deck analysis (Hambly, 1991) and is shown to be reasonable for the numerical analyses cases discussed in this paper. This study also shows that since the response in two orthogonal directions are decoupled, it is advisable to decrease the flexural effectiveness of the section in each direction by reducing the width of each section by 50%. In the numerical analyses discussed in this paper the grillage model in OpenSees is capable of providing better results at low levels of inelastic behavior, and unfortunately at high levels convergence issues are observed.

LS-DYNA performs better when compared with the OpenSees grillage model. Moreover, an analyst has more liberty with materials and element types available to model reinforced concrete structures. LS-DYNA is able to model complex boundary conditions with ease. An analyst can

choose to model the structure using solid or shell elements depending on the expected behavior.

Both methods discussed herein do have their drawbacks. The grillage model analysis, though easier to perform and less computationally demanding, does not perform very well in predicting the vertical stiffness of the slab subsystem. The 3-D model on other hand, although it presents better results is much more computationally intensive. Depending on the complexity of the problem and level of inelasticity expected in the slab, either of the two numerical methods could be suitable for analysis.

Abstract: When subjected to seismic action, beam-column joints designed without seismic provisions (i.e. based on gravity load only) have been proved to be the vulnerable component in the moment resisting frames. The situation is particular devastating in old buildings with possible deterioration of concrete and reinforcements. The above urges for immediate attention and repair. In this study, a strengthening method using ferrocement and diagonal reinforcements is proposed to reduce the seismic risk and to possibly extend the life span of old buildings. Two specimens, including a control specimen and a specimen strengthened by the proposed strengthening method, were constructed and tested under cyclic loading. The specimens were designed to represent non-ductile beam-column joints. Horizontal cyclic displacement was applied at the upper column after high axial load was imposed on the column. Seismic performance of the specimens was evaluated in terms of strength, stiffness, energy dissipation and ductility. The test results have indicated that the proposed strengthening method is effective for enhancing the shear capacity of the joint. In addition, condition of the joint is significantly improved due to the reduction of joint shear force. The main parameters considered in further studies are mechanical properties of ferrocement and bonding behavior between ferrocement and the joint.

1. INTRODUCTION

In Hong Kong, more than 18,000 buildings were constructed in over 30 years ago, and pressingly, most of them are facing different degrees of degradation. For instance, Buildings Department of the HKSAR Government received roughly 7,300 dangerous building reports annually during the past decade (Law et al. 2010). In the next ten years, more than 500 buildings will reach their design life. As deign life of a building is around 50 years, proper maintenance and repair is necessary if we want to extend the usable life of buildings in particular those constructed in or before 1960s. The collapse of a 55 years old 5-story building on 29th January 2010 in Hong Kong, has raised further concern by the public urging proper repair/restoration of the old buildings. In addition, Hong Kong has been recognized as an area with moderate seismic risk but buildings in Hong Kong have been traditionally designed without seismic provisions (Lam et al. 2002). Thus, strengthening of old buildings is necessary and it requires means both to extend the life span and to improve the seismic behavior.

In terms of strengthening a reinforced concrete framed structures, beam-column joint has been recognized as a key member that affects the overall behavior of buildings under seismic action. Evidence from previous earthquakes has shown that failure of beam-column joints may cause the collapse of buildings (EERI 1999, Huo et al. 2009, EERI 2010). Figure 1 shows some damaged beam-column joints in Wenchuan earthquake. As a result, particular attentions have been paid on strengthening beam-column joints in the last forty years. Hakuto et al. (2000) and Pampanin et al. (2002) illustrated poor performance of typical interior beam-column joints designed without transverse reinforcement in the joint core (i.e. designed to gravity action only similar to those commonly found in Hong Kong). As such, strengthening of beam-column joints in existing buildings is inevitable.

Figure 1 Damaged beam-column joints in Wenchuan earthquake (Huo et al. 2009)

There exist various existing methods for strengthening beam-column joints. Concrete jacketing, one of the earliest and common methods, has been used for strengthening beam-column joints for many years. Hakuto et al. (2000) strengthened the interior and exterior beam-column joints by concrete jacketing of which was identified as an effective method for enhancing stiffness, strength and ductility. Recently, reinforced concrete jacketing with no joint shear hoops and no anchors installed into the joints was successfully applied to strengthen non-ductile interior beam-column joints (Wang and Hsu 2009). Unfortunately, concrete jacketing is labor intensive and space limitative.

Alternatively, steel jacketing was applied. Ghobarah et al. (1997) conducted experimental studies and verified the effectiveness of using steel jacketing for upgrading strength and ductility. Apart from potentially vulnerable to corrosion, steel jacketing is difficult to install and has poor performance under fire. Ghobarah and Said (2002), Pantelides et al. (2008) and Lee et al. (2010) proposed strengthening beam-column joint subassemblages with FRP. Enhancement on strength and ductility was observed; even through in some cases, debonding of FRP occurred at final stage of the tests. However, similar deficiency under fire condition has also been found in FRP. Bisby et al. (2005) illustrated that mechanical properties of FRP were substantially reduced during fire, with or without proper fire insulation. This has undermined its excellent performance in easy application, high ratio of strength to weight, corrosion resistance, etc. With the limitations on high cost and poor fire resistance of the above-mentioned methods, researchers have strived to develop alternative materials for strengthening. For example, Izi (2008) proposed steel-reinforced polymer composites for strengthening shear-deficient exterior joints. In the study, a new approach using ferrocement and diagonal reinforcement was proposed to strengthen beam-column joints. In previous research, Ho and Lam (2010) strengthened full-scale columns using high performance ferrocement. Effect of variation of mesh density and mortar strength to confinement action was investigated. Test results have shown that ferrocement is effective to enhance the axial load carrying capacity of columns.

Aim of this study is to investigate the behavior of beam-column joints strengthened by the proposed method. Main parameters affecting efficiency of the proposed method are discussed, such as mechanical properties of ferrocement and bonding conditions of interface between ferrocement and the joint.

2. FERROCEMENT FOR STRENGTHENING

Ferrocement is defined by ACI committee 549 in the report on ferrocement as “a type of thin wall reinforced concrete commonly constructed of hydraulic cement mortar reinforced with closely spaced layers of continuous and relatively small size wire mesh. The mesh may be made of metallic or other suitable materials” (ACI 1997). Ferrocement exhibits a number of mechanical characteristics different from concrete, such as high strength to weight ratio, crack resistance, durability, impact resistance and ductility. Furthermore, ferrocement is able to achieve these properties through a thin panel reinforced in two directions to protect the reinforcements. Thus, ferrocement is an ideal material for strengthening structural members. In addition, it has favorable fire resistance as compared with steel or FRP jacketing. Eltegaway (2009) illustrated that ferrocement panel, when subjected to 700℃ for 30 minutes, can still resist fire and reduce crack propagation. Nedwell (2010) indicated ductility and shock resistance of ferrocement have not been fully utilized. Kumer and Rao (2006) revealed large energy absorption capacity of ferrocement. Other advantages include ease of construction and requiring no special technique making it user friendly.

On the basis of the excellent behavior of ferrocement, it has been successfully used for strengthening various types of structural members. Shannag (2009) strengthened plain concrete cylinders by high strength ferrocement laminates and considered it a promising material for structural strengthening. Abdullah and Takiguchi (2003) investigated the behavior of column strengthened with ferrocement jacketing for confinement action. Lim et al. (2000) strengthened flexural strength of beams by incorporating ferrocement reinforced with longitude bars onto the soffits. Cao et al. (2008) strengthened beam-column joints by mortar reinforced with high strength wire. In the application field of ferrocement for strengthening, Wang et al. (2006) strengthened Zheng Chenggong memorial by ferrocement in Xiamen. The above have demonstrated ferrocement is a promising alterative material for strengthening structural members.

3. EXPERIMENTAL PRGRAM

3.1 Specimens

Two 2/3 scale interior beam-column joints were constructed and tested under cyclic loading. The first one is the control specimen, namely C1, which is based on typical reinforcement detail used in the existing buildings in Hong Kong. The other is the strengthened specimen, namely S1, which is strengthened by ferrocement and diagonal reinforcements. Both specimens have the same dimension and reinforcement arrangement as shown in Figure 2.

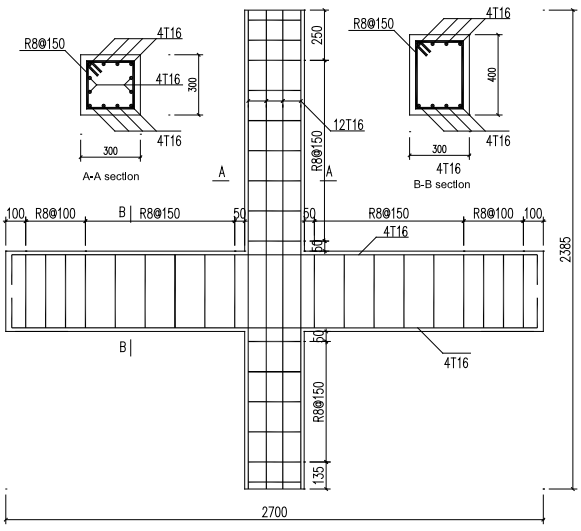

Figure 2 Details of specimen

Both specimens replicate lower stories of a building. Ends of the specimens coincide with the mid-span and mid-height of the actual frame structure. Columns are 2,385mm height and 300mm by 300mm in cross-section.

Main reinforcements comprise 12T16 (or 2.7% main reinforcement ratio). Beams are 2,700mm long and 300mm by 400mm in cross-section. Transverse reinforcements comprise R8 rectangular ties at 150mm spacing. Same reinforcements (4T16) are provided as top and bottom steel (or 1.35% main reinforcement ratio). The joints have no transverse reinforcements and are prone to shear failure when subjected to cyclic loading.

As stated in the above, the ratio of column depth to diameter of main reinforcements in beams is h_c/d_b=300/16=18.75, which does not satisfy the ratio of 20 as recommended by ACI-ASCE 352. Moreover, the beams have larger moment capacity as compared with the columns, which is also not in accordance with the current code of practice. The above are typical joint details in frame structures in Hong Kong. In addition, the concrete used in the specimens had measured cube strength on the day of test of 46.1MPa. Mix proportion of concrete is shown in Table 1. Measured yield strength of main reinforcement and transverse reinforcement are 540MPa and 410MPa respectively.

Table 1 Mix proportion of concrete

Component	Content
Cement (kg/m^3)	340
Coarse aggregate (kg/m^3)	880
Fine aggregate (kg/m^3)	875
Water (kg/m^3)	226
Super plasticizer (kg/m^3)	3.06

3.2 Test Setup and Loading Routine

The test setup is shown in Figure 3. The specimens are tested by a displacement control multi-purpose testing system with a maximum loading capacity of 10,000kN. The bottom column is fixed by a hinge, so that the bottom column is constrained in lateral displacement but allowed to rotate. Both ends of the beam are supported by rollers to enable ends of the beams free to move horizontally but not vertically.

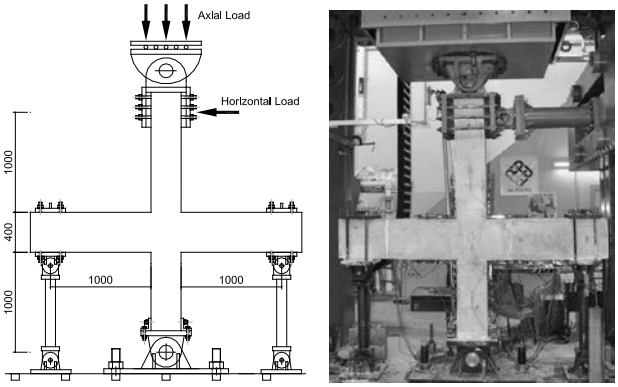

Figure 3 Test setup for beam-column joint

Axial load is applied at top of the top column and is kept constant throughout the loading test. Afterwards, cycles of horizontal displacement are applied from the top of the upper column based on displacement control. First of all, the yield displacement Δ_y is determinate as follows. The specimen is subjected to progressive increase in the horizontal load up to 75% of the nominal moment capacity of the columns. The corresponding tip displacement at the top is recorded and extrapolated to determine the yield displacement of column Δ_y. Afterwards, displacement ductility factor μ (ratio of actual displacement to yielding displacement) is used to control the loading cycles.

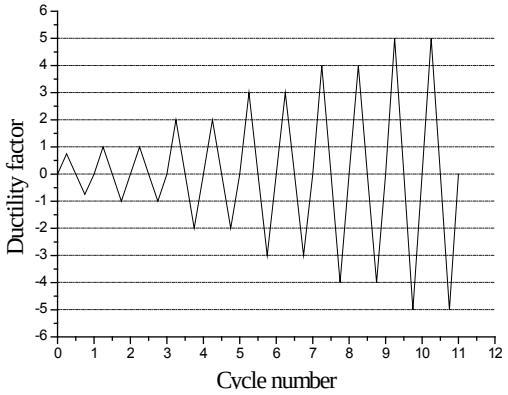

Figure 4 Loading routine

Each loading cycle is repeated twice until the horizontal load dropped to 85% of its maximum value. Loading routine is shown in Figure 4. It is to be noted that axial load reaches $0.6f_c'A_g$ which is consistent with the common range of axial load from 0.5 to 0.7 due to high main reinforcement ratio in the columns (Lam et al. 2000).

3.3 Strengthening Scheme

Strengthening of a beam-column joint is achieved by ferrocement and diagonal reinforcements as shown in Figure 5. The proposed strengthening scheme can be divided in two parts. Firstly, ferrocement with the wire mesh properly folded along the dotted lines and cut along solid lines is installed to replace the concrete cover in the beam-column joint region (Figure 5(a)). It enhances shear capacity and provides confinement. In this study, two layers of wire mesh were installed in the joint region. Welded square mesh is adopted in this study. The mesh has averaged wire diameter of 1.45mm and width of spacing at 13.23mm in both directions. Cement-based mortar of averaged 7-day cube strength of 33MPa is used. The ratio of binder over sand is 1:2.5 by weight, and 15% of cement was replaced by PFA. Although PFA retards the early strength, it improves workability. Secondly, two diagonal reinforcements of 10mm diameter are installed in the joint and effectively anchored to the main reinforcements of the beams to reduce the force transferred to the joint. Its yield stress is about 800MPa.

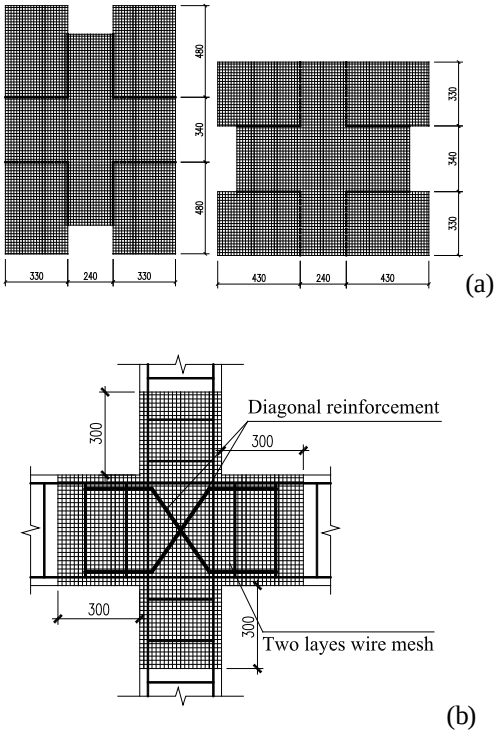

Figure 5 Strengthening scheme

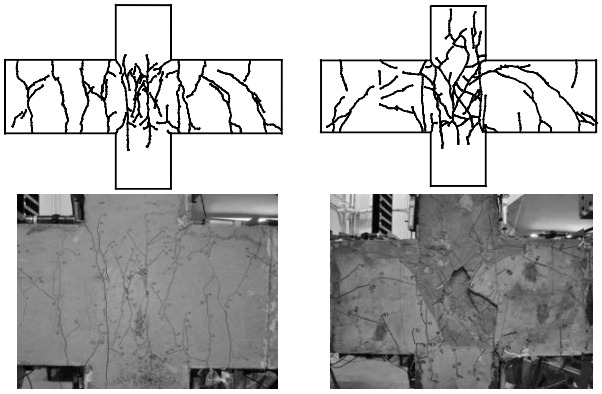
Strengthening process is consisted of four steps. Firstly, concrete cover is removed and surface of the joint region is roughed. Secondly, holes are drilled for installation of diagonal reinforcements. Diagonal reinforcements are welded to main reinforcements of the beams and the holes are subsequently grouted with mortar. Thirdly, wire mesh is installed to beam-column joints. Wire mesh is cut to size and folded to warp around beams and columns. Lapping between wire mesh is at least 100mm. Lastly, mortar is applied to specified thickness of 30mm after bonding agency is brushed. Main procedures of the strengthening process are as shown in Figure 6.

Unstrengthened specimen | Prepare surface & Drill hole | Weld diagonal reinforcements



Install wire mesh | Apply of bond & rendering material | Strengthened specimen

Figure 6 Strengthening procedure

4. EXPERIMENTAL RESULTS

4.1 General Behavior and Failure Modes

For the control specimen C1, one vertical crack in the joint and several flexural cracks in the beams were observed after applying the axial load. When the displacement at the column tip reached 17.4mm, second vertical crack was observed. Occurrence of vertical cracks in the joint is attributed to the deformation of the main reinforcements of the column without shear hoops under high level of axial load. This is also supported by phenomenon of bulging in the joint. Meanwhile, diagonal cracks appeared at the corner of the joint at the same displacement of 17.4mm. As the horizontal displacement increased, diagonal cracks propagated due to diagonal tension. Moreover, obvious diagonal cracks were observed on both sides of the joint. With opening and closing of diagonal cracks under the cyclic loading, spalling of concrete in the joint along the diagonal direction occurred. Although moment capacity of the columns is smaller than that of the beams, crack was not observed on the column. This is attributed to the high level of axial load in the columns that reduces tensile strain in the columns. Final crack pattern was consisted of two vertical cracks along the main reinforcements of the columns, diagonal cracks in the joint and flexural cracks in the beams as shown in Figure 7.

(a) (b)

Figure 7 Crack patterns of (a) specimen C1, and (b) specimen S1

Formation of cracks in strengthened specimen S1 was improved due to better ability on crack control offered by ferrocement. However, once the ultimate tensile strain of ferrocement was attained, cracks propagated. When horizontal displacement reached its fourth cycle of 8.7mm, an obvious diagonal crack was observed. In the next cycle of 17.4mm, diagonal cracks formed in the other diagonal direction, and several inclined cracks occurred in the column. Subsequently, the cracks propagated to the overall joint region. At the displacement of 26.1mm, spalling of mortar was observed outside the wire mesh in the upper column. This was probably caused by inconsistent deformation between the parent substrate and ferrocement under high

axial load. Diagonal cracks of strengthened specimen also appeared earlier than that of the control specimen. This may be attributed to the low strength of mortar. It is worth noticing that delamination of ferrocement and bulging of the main reinforcements of column occurred as shown in Figure 8. Main reinforcement buckled due to inadequate confinement. Nevertheless, ferrocement offers some degree of confinement to the joint, though ferrocement in the joint region spalled off at the advanced stage of loading. Another apparent observation is that cracks were distributed more uniformly in the case of specimen S1 and serves to demonstrate that ferrocement has good ability of crack control.

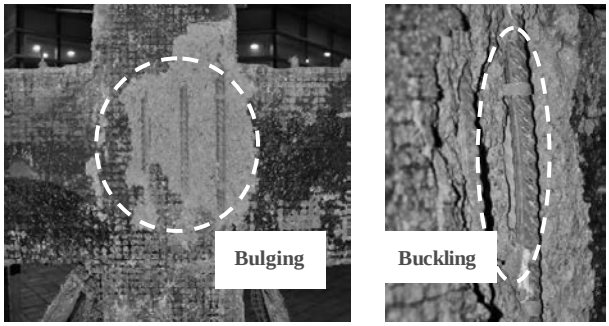


Figure 8 Failure of beam-column joints

Failure modes of both specimens are generally similar and are due to insufficient shear strength in the joint and buckling of main reinforcement of the columns. For specimen S1, delamination of ferrocement occurred at the joint.

4.2 Hysteretic Behavior

The horizontal load-displacement relationship of the column tip for control specimen C1 and strengthened specimen S1 are shown in Figure 9. It is noticed that the ultimate load of specimen S1 is higher than that of control specimen C1. Specimen S1 reaches its ultimate load of 92.4kN at the displacement of 23.20mm and -90.1kN at the displacement of -17.40mm, while specimen C1 attained its ultimate load of 84.3kN at the displacement of 25.4mm and -84.7kN at the displacement of -25.35mm. Here positive and negative displacement represent pull and push direction respectively. Ultimate strength is enhanced by 9.6% in pull direction and 6.4% in push direction. This is attributed to the strengthening scheme, which enhanced the capacity of the joint. Obviously, the enhanced strength is limited due to the spalling of mortar during the tests. Furthermore, comparison of drift capacity between control specimen and strengthened specimen indicates that the proposed strengthening method may increase the drift capacity.

Envelopes of lateral load-displacements for control specimen and strengthened specimen are shown in Figure 10. Horizontal load of specimen C1 is smaller than that of specimen S1 except at horizontal displacement of -26.4mm (a minus represents push direction). This is due to failure of ferrocement at this loading stage.

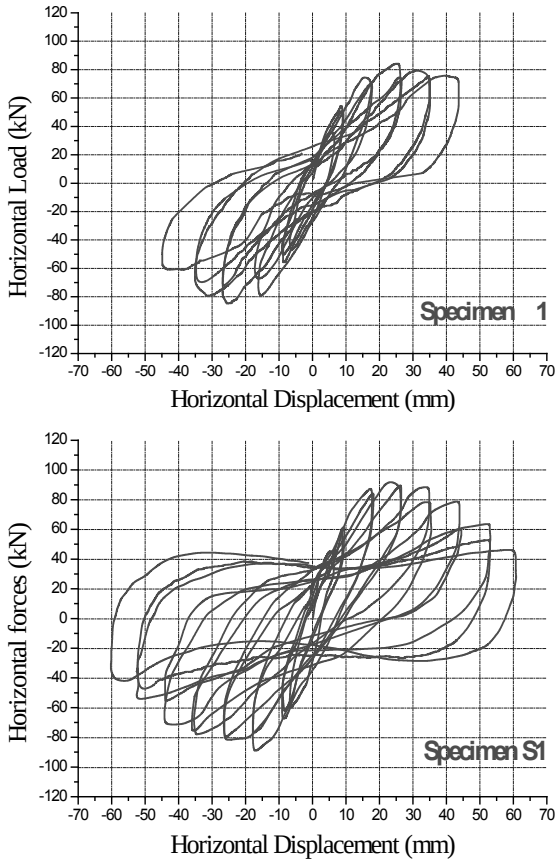

Figure 9 Column tip load-displacement relationship

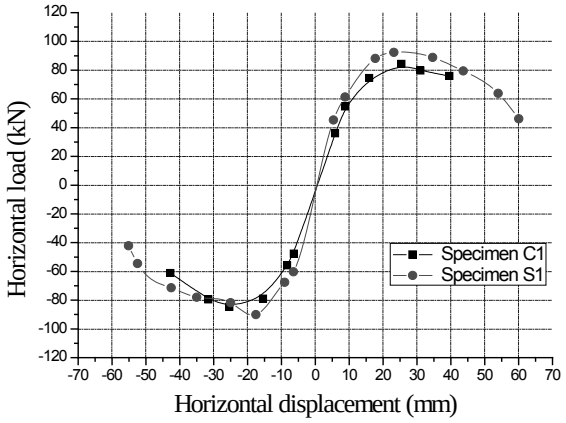

Figure 10 Relationship between envelope of horizontal load and horizontal displacement

4.3 Energy Dissipation

Energy dissipation of both specimens under cyclic loading is calculated from the area of lateral load-displacement loops at different cycles of horizontal displacement. Energy dissipated at each cycle and cumulative energy dissipation are shown in Figure 11(a) and Figure 11(b) respectively. Energy dissipation capacity is enhanced at higher loading stage. In other words, if the same energy dissipation is required during an earthquake, specimen S1 will have smaller horizontal displacement as compared with specimen C1. At higher loading, energy

dissipation of specimen S1 is larger than that of specimen C1. Specimen S1 sustains a larger increase in energy dissipation as the horizontal displacement cycle increases. At horizontal displacement cycle of 10, energy dissipation and cumulative energy dissipation for specimen S1 are enhanced by 14.7% and 19.6% respectively as compared with specimen C1.

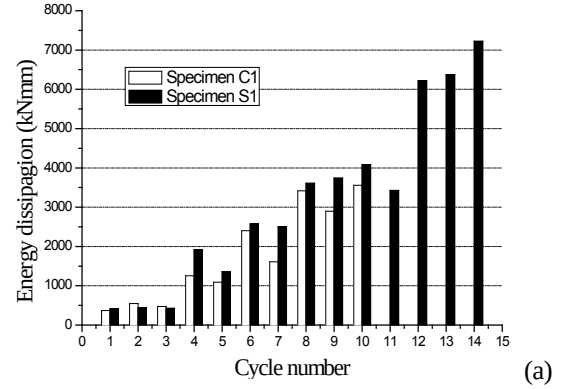

Figure 11 Energy dissipation of (a) Each cycle, and (b) Cumulative at each cycle

4.4 Stiffness Degradation

Stiffness of a specimen is determined by secant slope of line passes origin to the point interested at each loading cycle. It represents resistance of structural member to deformation. The results are plotted in Figure 12. Initial stiffness of specimen S1 is significantly higher than that of control specimen C1. This can be attributed to the use of ferrocement and diagonal reinforcements in the joint region. However, stiffness of specimen S1 decreases rapidly as the horizontal displacement increases due to delamination of ferrocement. In addition, at the later stage of loading, stiffnesses of both specimens degenerate similarly. In general, stiffness of specimen S1 is greater than that of specimen C1.

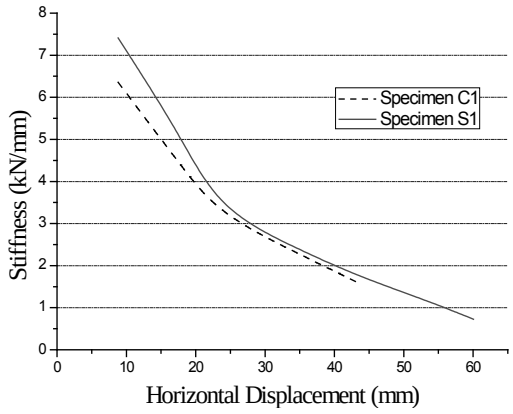

Figure 12 Relationship between stiffness degradation and horizontal displacement

4.5 Curvature

Curvatures are calculated from measured values obtained from a pair of LVTDs installed at both sides of a beam (as shown in Figure 13). The averaged curvature at each cross section can be calculated as follows:

$$\frac{1}{\rho} = \frac{\Delta_{Li} - \Delta'_{Li}}{L_i h} \quad (1)$$

Where Δ_{Li} and Δ'_{Li} are the readings of the ith pair of LVDTs installed at the top and bottom of beam respectively, L_i is the length between the measurements and h is the center-to-center distance between top and bottom LVDTs. In this study, L_i=100mm and h=430mm.

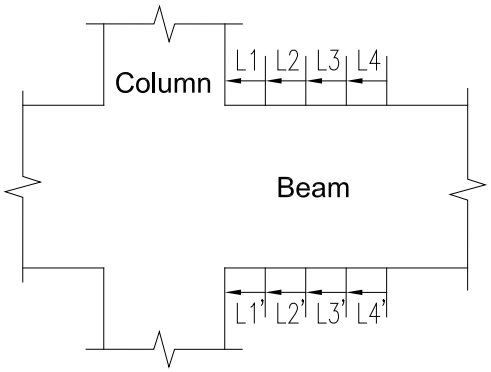

Figure 13 Arrangement of LVDTs on beam

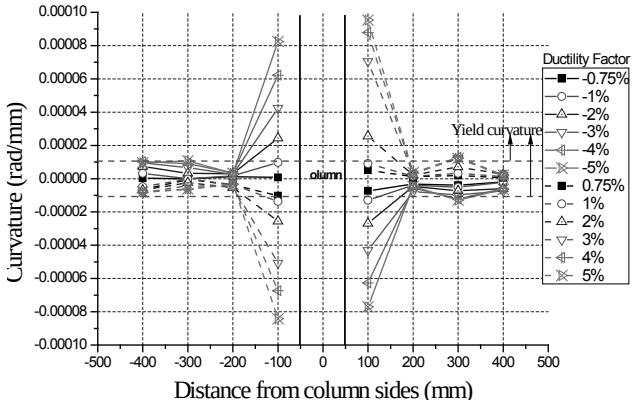

Figure 14(a) and Figure 14(b) show the beam curvature profiles of specimens at each displacement ductility factor. Both specimens show high curvature values within the distance of 100mm from the column face. This is attributed to the large bending moment in this region and wider crack width as observed during the test. With the contribution of the ferrocement applied at the sides of beams, curvature of specimen S1 at the same displacement ductility was smaller than that of specimen C1. As the displacement ductility increased, curvature increased. Since deformation ability was weakened by deterioration of mortar. It is apparent that ferrocement is effective to strengthen beams close to the column face if high strength ferrocement is applied.

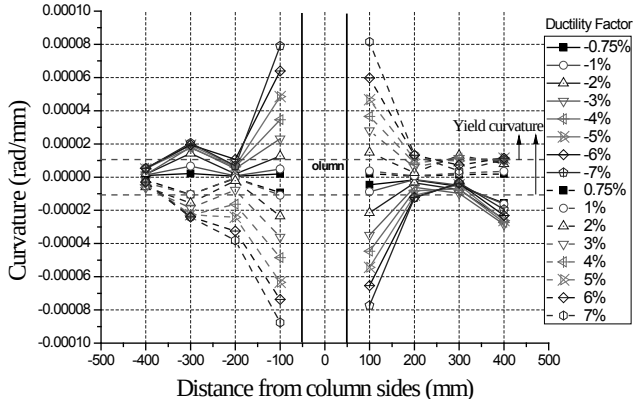
Theoretically, curvature can be calculated by equation (2) based on linear elastic method.



$$\frac{1}{\rho} = \frac{M}{EI} \quad (2)$$

Where ρ is radius of curvature, E is elastic modulus, I is moment of inertia of cross section, and M is bending moment. Reinforced concrete members exhibit nonlinear relationship between bending moment and curvature as stiffness EI changes. In the initial stage, reinforced concrete showed almost elastic behavior before cracking. Due to cracking of members, the increase in curvature was caused by yielding of reinforcements in the beams. Curvatures of reinforced concrete members were taken into account through using equivalent cross section according to ACI 318.

Beam curvature is at or above 1.1×10^{-5}mm^{-1} when the reinforcement yields. The yield curvature is shown in Figure 14 in dotted lines. For specimen C1, yielding of beam began at the interface of 100mm away from column face when the horizontal ductility factor reached 1. As the horizontal displacement increased, yielding was extended away from interface at final stage of loading. For specimen S1, yielding was first observed in the cross section away from column face of 400mm. The plastic hinge zone of specimen S1 was larger than that of specimen C1.

(a)

(b)

Figure 14 Curvature profile of beam for (a) Specimen C1, and (b) Specimen S1

4.6 Joint Shear Stress

Joint shear stress is estimated by shear force V_{jh} divided by effective joint area A_j. The shear force acted on the joint is calculated using equation (3) (Pauley and Priestly 1992) in the form of,

$$V_{jh} = T + C_c + C_s - V_{col} \tag{3}$$

By approximating $T'=C_c+C_s$, the joint shear force is simplified to

$$V_{jh} = T + T' - V_{col} \tag{4}$$

Where T and T' are tension force acting at opposite column faces, C_c and C_s are compression forces acting on the joint by concrete and reinforcements respectively, and V_{col} is the column joint shear force. Thus, joint shear force is obtained based on the tensile force of reinforcements acting at both column faces and shear force of the column. Tensile force of reinforcement is estimated from measured strains of reinforcement at column faces, which represents the force transferred to joint core. Shear force of column is the applied horizontal force. The effective joint area is calculated by considering $A_j=b_jh_c$ (ACI-ASCE 352). Where b_j is the effective joint width and is whichever the smallest of $(b_b+b_c)/2$, $b_b+\Sigma mh_c/2$ and b_c (h_c is the depth of column). Based on the above, joint shear stresses are 11.45MPa and 8.10MPa for specimen C1 and Specimen S1 respectively as shown in Table 2.

Joint shear stress has significant effect on the performance of the joint, especially the bonding condition and stiffness of the joint. Thus, several design codes have specified that the nominal shear stress of joint depends on the strength of concrete and other parameters. ACI code suggests a nominal shear stress of $\sqrt{f_c'}$MPa. New Zealand Standard specifies $0.2f_c'$ as the lower limit of joint shear strength. EN code restrains the joint shear strength through the following equation,

$$v_{jh} \le \eta f_c' \sqrt{1 - v_d / \eta} \tag{5}$$

Where $\eta=0.6(1-f_c'/250)$ denotes the reduction factor on compressive strength of concrete due to tensile strain in the transverse direction. v_d is normalized axial force ratio on column. Different from the other two codes, EN code incorporates the effect of axial load ratio on shear stress. The limiting shear stress decreases as the axial load ratio increases. Shear stresses suggested by ACI, NZS and EN codes and measured shear stress of specimens are shown in Table 2.

From the table, it is obvious that both specimens do not satisfy the limiting value of joint shear stress, though the joint shear stress in specimen S1 is reduced by 30%. One reason for reduction on shear stress is due to the use of diagonal reinforcements that can effectively reduce the forces transferred to the joint from the beams. The other contributor for reduction of shear stress is due to ferrocement in the joint that resists part of the shear stress.

Table 2 Joint shear stresses suggested by ACI, NZS and EN codes and measured values obtained from specimen C1 and specimen S1

	ACI	NZS	EN code*	Specimen C1	Specimen S1
Shear stress# (MPa)	5.88	6.92	N/A	11.45	8.10

Based on the averaged value of maximum shear stress in both loading directions.
* High axial load ratio is not included in EN code for shear stress in interior joint.

5. FURTHER STUDIES

It is necessary to improve performance of the proposed strengthening method. Firstly, mode of failure of specimen S1 is primarily due to shear and this is not desirable. Secondly, there is limited enhancement on strength. Based on the observations and experimental results, high performance mortar will be used and varying layers of wire mesh will be applied in further studies. Moreover, bonding behavior between ferrocement and the joint will be improved by incorporating shear studs.

In a previous study, Lam et al. (2009) demonstrated that fiber reinforced concrete is a sustainable construction material. Adding fibers to the mortar have the advantage of crack control at the stage of hardening and avoidance of spalling under fire condition. Moreover, as fiber reinforced mortar possesses higher tensile strength due to bridging of fibers, ferrocement can contribute more shear resistance in the joint. Hence, mortar mixed with fibers will be used in further studies. To achieve the above, mechanical properties of ferrocement and bonding conditions will be estimated. Direct tensile test at room temperature and elevated temperature as well as direct shear test will be conducting on high performance ferrocement. Direct tensile test will be used to determine the ultimate strength and modulus at differential temperatures. Direct shear test will be used to assess shear behavior at ideal pure shear state. Figure 15 shows the test setup of direct tensile test and shear test.

Figure 15 Test setup for (a) direct tensile test, and (b) direct shear test

6. CONCLUSIONS

An experimental program was conducted to evaluate the effectiveness of revitalizing interior beam-column joint subassemblages using ferrocement and diagonal reinforcements. Based on the observations and experimental results of two interior beam-column joint subassemblages, the following are concluded.

(I). Seismic performance of interior beam-column subassemblages is improved by the proposed strengthening method with enhancement on ultimate strength, energy dissipation, stiffness and drift.

(II). Significant reduction on joint shear stress was obtained in the strengthened specimen. This is attributed to diagonal reinforcements which balance part of force and ferrocement which resists part of the shear stress.

(III). Modes of failure of both specimens are due to buckling of main reinforcements in the columns accompanied by shear failure in the beam-column joint subassemblages. Improved confinement to main reinforcements in the joint will have to be provided.

(IV). Although both specimens fail in unexpected modes, strengthened specimen S1 is able to sustain its load carrying capacity after cracking due to confinement action provided by ferrocement. Improvement on the proposed strengthening method will be carried out through using high performance mortar, applying varying layers of wire mesh and improving the bond behavior between ferrocement and the joint.

Abstract: The most common structural system used in the design of mid- to high-rise residential buildings in Chile is shear wall construction. The 2010 Chilean Earthquake, Magnitude 8.8 created a unique opportunity for the evaluation of the performance of wall and frame wall buildings designed according to modern building codes that are similar to those used in the USA and Japan. Due to the extent of the rupture area during the earthquake, many large cities of Chile were affected with different levels of intensity and PGA. In effect, it created a full-scale laboratory that can be used to study the interrelation of the different elements in a wall system during strong ground motions, and also the design provisions for wall buildings that are currently in buildings codes of seismically active countries. A study of the damage observed in a typical building is conducted, and an elastic 3D model of the building is used to study the distribution of the stress in the different resistant axis and their influence in the damages observed.

1. INTRODUCTION

The most common structural system used in the design of mid- to high-rise residential buildings (over 3 stories) in Chile is shear wall construction with a story height around 2.5 [m] with typically wall thicknesses of 15 [cm], 20 [cm] 25 [cm]. The structural walls are located in the interior and on the perimeter of the building for the two principal direction of the building.

Guendelman et al. (1997) used mainly two parameters to characterize the Chilean buildings; the first parameter is the ratio of the building height, H, to the fundamental period of the building, T, or H/T. In a recent study also made by Guendelman et al. (2000) results gave an average value for H/T of around 40 to 70 meters/second for buildings in Chile. Using this parameter, a lower value would indicate a more flexible building and a higher value would indicate a more stiff building. The second parameter used by Guendelman et al. (1997) is the density of walls in the buildings. The density of wall is calculated as the wall area in one direction divided by the total area of the floor. The value of this parameter has remained relatively constant, around 3%, in the last few years. However, it is important to note that this parameter does not reflect the fact that the heights of the buildings in Chile have been increasing in the past few years.

The Chilean's buildings are designed under the code and standards created by the National Institute of Normalization (INN) and approved by the authorities of the country (Ministry of Housing). Typically, the Chilean codes are based in the International Codes and the national codes used in other seismically active countries like USA, Japan and New Zealand. The Official Seismic Chilean Code is the NCh433 Of. 96 on Earthquake Resistant Design of Building, this code was written and developed by the Asociación Chilena de Sismología e Ingeniería Antisísmica (ACHISINA).

The basic objectives and principles used for the seismic design of buildings in Chile are established in the Section 5, which in the subsection 5.5.1 (NCh433of96) states "*..this code applied together with the specific design code for each of the materials named in paragraph 5.3, aims to produce structures that:*

- *Resist moderate intensity seismic actions without damages*
- *Limit damage to non-structural elements during earthquakes of regular intensity*
- *Prevent collapse during earthquakes of exceptionally severe intensity, even though they show some damage"*

These principles are very similar to the philosophy that is described in the Recommended Lateral Force Requirements and Commentary of the Structural Engineers Association of California (2009) known as the "SEAOC Blue Book." (Rojas et al. 2010a)

In addition, the Chile Earthquake, February 27, 2010 provided a unique opportunity to study the behavior of all kind of structures and, in particular, the behavior of mid- to high-rise buildings that were designed with a recent building code and subjected to strong and long duration ground motions. The most common type of damage experienced by the buildings in Chile during the earthquake are located at or near the ground level due to compression and tension

effects in the walls. This caused the crushing of the concrete due to heavy compression at the end of the elements and the buckling and fracture of the steel bars in the boundaries of the walls. The long duration of the ground motions apparently caused cyclical fatigue during the strong shaking, and the buckling of the vertical reinforcing steel was almost ubiquitous, as was reported by the Reconnaissance Team of Los Angeles Tall Building Structural Design Council (Naeim et al. 2010, Carpenter et al. 2010, Rojas et al. 2010b} and other teams (Moehle et al 2010). The lack of confinement of the boundary elements in the walls, seismic hooks and cross ties were also observed, this happened because the Chilean code (Nch433 OF 96 - Section B.2.2) allows the requirements for boundary elements in structural walls from the ACI 318-95 to be disregarded.

In this paper a preliminary study of a 20 story building located in the Concepcion Area that suffered severe damage during the Magnitude 8.8 Chile Earthquake will be discussed. First, the building and the damages observed during the earthquake are described in detail, and following an elastic 3D model of the building using Etabs software (CSI) is analyzed the behavior that the structures suffered during the earthquake.

2. CASE OF STUDY

2.1 Description of Building

The building study is a 20-story reinforced concrete wall building for residential used with one basement. It is located between Concepcion and Coronel in Concepcion Province, Octava Region (Figure 1). This is the second building of a complex of eight buildings that is under development in the same location, until now only two building have been built. The studied building has a rectangular shape in plan view, with the long direction oriented in the north-south direction, and the narrow direction pointing east-west, view Figure 1. The design was finished in 2006, and the construction was finished in 2008.

Figure 1: Location of the Building (Google Map, 2010)

(a) (b)

Figure 2 Exterior view of the Building:
(a) Front (Facing Inland) (b) Back (Facing Ocean)

The main lateral resisting system is a wall system, with wall placed in the interior and on the perimeter of the building as shown in Figure 3 and Figure 4. The typical size of the wall used is 20 [cm]. The main walls for the long direction are located along axis K, L, Figure 3, in the corridor area, and for the short direction the walls that take the lateral loads are distributed over all the length of the building at difference of the long direction. The story heights are presented in the Table 1. The Building is regular and constant between floors 2nd and 18th, with some small differences in the 15th, 16th and 17th floors. The 19 and 20 floors correspond to a reduced floor where the Gym, swimming pool and the elevator mechanical room are located. In the first floor are presented some modifications in main direction to close the building in the first floor and also to make room for the entrance. The basement is only under the center portion of the building. The slab thickness is 15 [cm], which provided the rigid diaphragm at each floor, the slab only has large openings at the elevator location and stairs. The stairs are connected directly to the walls. Most of the beams are located in the perimeter of the building to create the balcony, and support for the slab, with typical dimension of 20 [cm] wide and depths of 29.5, 67.5, 112.5 and 152.5 [cm]. The vertical load is carried by the slab to the same walls that form the resisting lateral system and from there to the foundations.

Table 1 Story Height Building

Floor	Height [cm]
Basement	255
1st Floor	320
2nd to 19th Floor	255
Gym Floor	350

The Concrete used for all elements of the building had a compressive stress of fc' = 250 [kg/cm^2] (H-30), and an

A63-42H steel was used for the steel bars used for the reinforcement of the concrete, which had a fy = 4200 [kg/cm^2]. The longitudinal steel used in the walls varies between a minimum of 8 [mm] diameter bars with a spacing of 20 [cm] (steel ratio of 0.625%) to 22 [mm] diameter bars with a spacing of 20 [cm] (steel ratio of 2.37%), and the transversal reinforcement used in the building varies between a minimum of 8 [mm] diameter bars with a spacing of 20 [cm] (steel ratio of 0.625%) to a 16 [mm] diameter bars with a spacing of 13 [cm] (steel ratio of 1.93%). At the edges of the wall only the last two lines of reinforcement at each face of the wall are confined with typically 12 [mm] diameter bars at 20 [cm] spacing (Youssef et al. 2010).

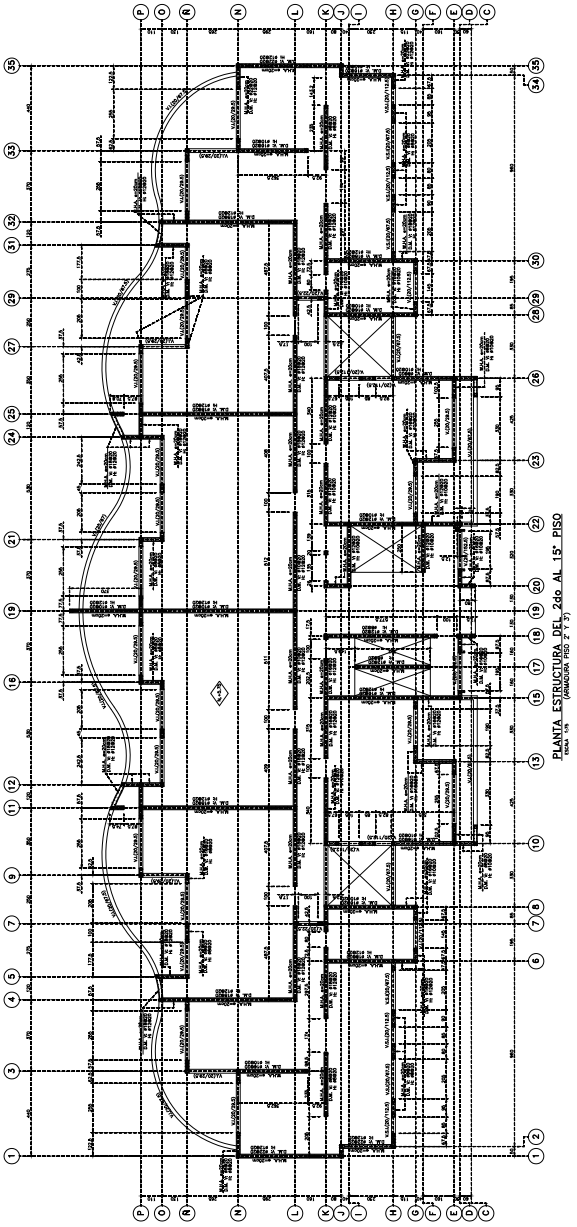

Figure 3: Typical Floor Plan of the Building

The Region of Concepcion, where the building is located, has a variable ground condition, as was reported by Rojas et al (2010b), because the influence of the Bio - Bio River in the North - West Side of the location of the Building, which has produced a large area of the soil of San Pedro city is formed with unconsolidated recent deposits, which come from unconsolidated sand from fluvial origin, clays and fine sediment from the water in swamps, and river deltas (Galli et al. 1963). However, in the east side of the building we have the influence of the marine deposition. In conclusion, the area of the building can be described as a main thick layer of sand with areas with superficial thin layer of artificial deposit (unconsolidated clays, silts and sands). This type of soil when the sand is dense is classified as Soil Type III under the NCh433 OF 96, which is the case of the building studied. The foundation used for the building consists in a mat foundation with a thickness of 120 [cm].

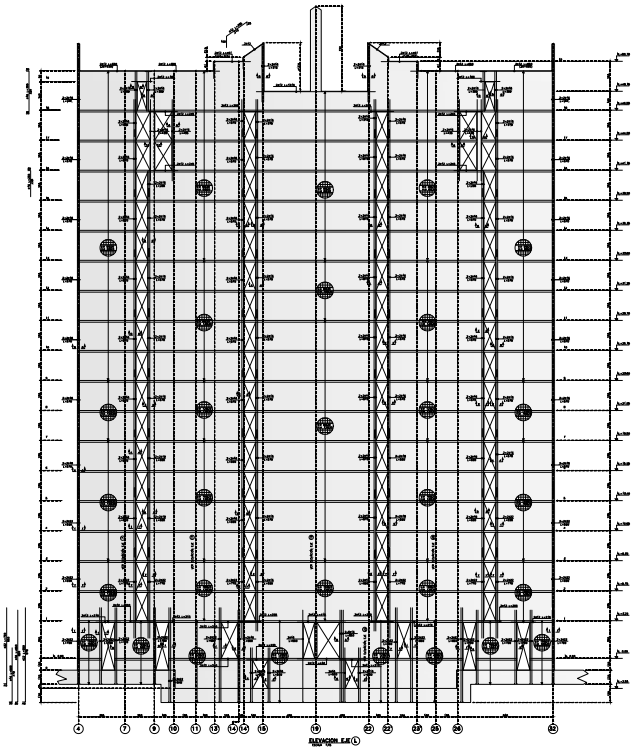

Figure 4: Elevation L

The Building was designed according to the Chile codes and standards, using the load shown in the Table 2, and a soil capacity of σ_{adm}=2.5 [kg/cm^2] in the static case and of σ_{adm}=3.0 [kg/cm^2] for the seismic case, this was informed by the designers, and because the structure is located in a seismic zone 3, with a soil type III, the elastic response spectra used for the modal analysis is shown in Figure 6. For more information of the code requirements and equations used for the construction of the response spectra, the reader is reference to Rojas et al. (2010a).

Table 2 Load used in the design of the Building

Load Case	[kg/m^2]
Additional Dead Load	50
Live Load	200
Live Load Roof	100

2.2 February 27, 2010 Magnitude 8.8 Chile Earthquake

The Magnitude 8.8 Chile earthquake occurred at 3:34 am local time in the central area of Chile, the rupture started at 36° 12' 28" S and 72° 57' 46" W at a depth estimated of 47 [Km], the area of the total rupture was 450 [Km] of length by 130 [km] wide. Concepcion is located 105 [Km] from the epicenter of the earthquake (Seismological Service, Univ. of Chile 2010). An effect of cascade due to the length of the rupture produced a buildup of pulses that created strong ground motion that was felt over all the center and south part of Chile, in San Pedro city the total shaking time was roughly 3 min.

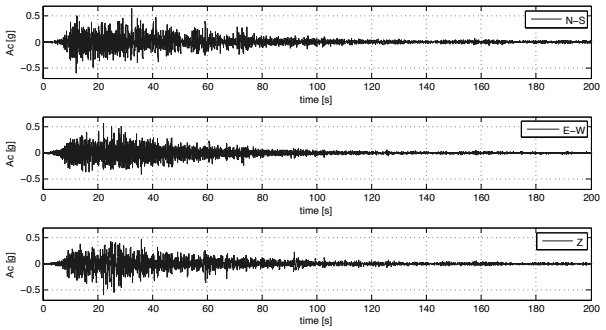

Figure 5 Acceleration Record at San Pedro High School, Concepction (02/27/2010 – Recorded by Seismological Service, Univ. of Chile)

Two accelerometers were working at the moment of the earthquake in the area of Concepcion, each instrument recorded 3 components (N-S, E-W and Vertical). One instrument was located in the downtown of Concepcion, however, this record has not been yet released to the public domain. The other instrument was in San Pedro High School , located in the San Pedro City , at roughly 3 miles from the Downtown of Concepcion and on the other side of the Bio-Bio River (S.S. Univ. of Chile, 2010). The second instrument, shown in the Figure 1, measured an acceleration of 0.65g in the N-S direction, 0.58 g in the E-W direction and 0.6 g in the vertical direction (S.S. Univ. of Chile 2010), and the duration of the record is approximately 3 min with almost 60 second of strong ground motion. This is the nearest recorded data available for the Building studied, which is around 3 miles away.

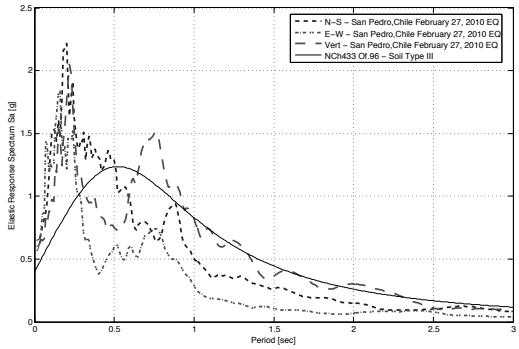

Figure 6 Comparison Elastic Response Spectra Seismic Zone 3 - Soil Type III vs recorded Acc obtained in San Pedro HS during the February 17, 2010 Chile Earthquake

In addition, A GPS station located in the Transportable Integrated Geodesic Observatory (TIGO) at the University of Concepcion, about 8 [km] from building studied, measure and recorded the event showing a displacement at Concepcion of roughly 3 [m] in the west direction (GEO's Chile Event Supersite Website, 2010).

2.3 Damage Observed

The principal type of damage detected in the reinforced concrete wall buildings in Chile after the February 27, 2010 Chile Earthquake are located in the ground level, due to compression and tension effects in the walls, causing the crushing of the concrete due to a heavy compression at the end of the elements and the buckling and fracture of the steel bars in the boundary elements of the walls due to cyclic fatigue during the shaking. Also, in some cases, buckling of the bars in the vertical reinforced steel bars through the wall was observed. Also, at other areas in Chile, the confinement of the boundary zone of the walls was not observed in the construction that suffer failure; this is consequence that the Chilean code (Nch433 of 96 - Section B.2.2) allows one to ignore these requirements that are present in the ACI318. Also a lack of seismic hooks and cross ties in the wall elements was observed. This was reported by the Reconnaissance Team of Los Angeles Tall Building Structural Design Council (Naeim et al. 2010, Carpenter et al. 2010, Rojas et al. 2010b} and other teams (Moehle et al 2010).

A continuation is detailed the damage observed in the building during the two visit done by the author of this paper when participated as a member of the Reconnaissance Team of Los Angeles Tall Building Structural Design Council (LATBSDC) for the February 27, 2010 Chile Earthquake. In addition, also are shown part of the study of the building done by the team after the earthquake (Youssef et al. 2010) and additional remarks.

As is shown in the areal view Figure 1, two building are presented in the site, rectangular shape building, which is the studied building that suffer considerable damage, and a V shape building. This second structure, a 13-story Building, suffered only minor damage. The difference of response could be attributed to the shape and orientation of the building with respect to the ground motion, assuming that do to the proximity of the two building, they have similar soil condition, and felt similar ground motions, this may indicate a important role of the directionality of the earthquake in the behavior of the building, as it was also noted by Youssef et al. (2010)

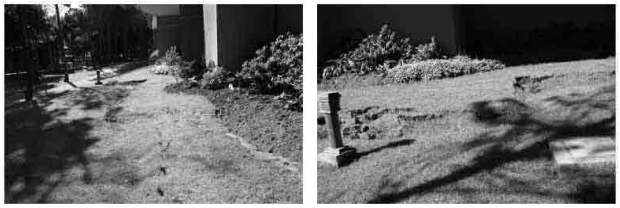

Figure 7 Damage in the soil around the Building

In an inspection of the exterior of the building different

types of damages were detected. In the soil around the building, and specially in the back of the building, large settlement of the ground Figure 7, which can be attributed to poor backfill compaction of the soil after construction, because no indication of foundation or settlement of the foundation were observed. In the structure, some short column failures, Figure 8a, shear failure of short beam; Figure 8b, shear wall failure, Figure 8c, crushing of the concrete, Figure 8c, and flexural-compression crushing of concrete and the steel in walls Figure 8d were observed. All the severe damage observed in the exterior is located at the first floor level.

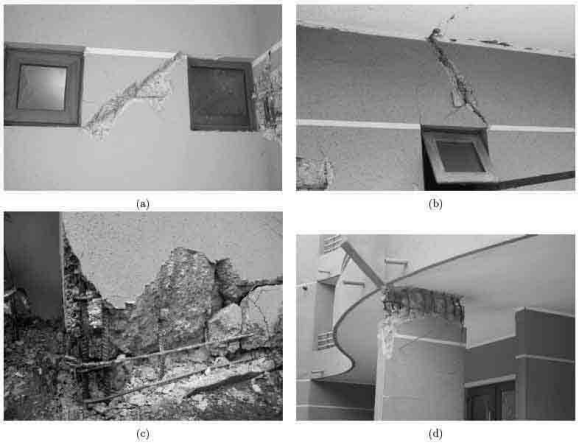

Figure 8 Damage in the Exterior of the Building: (a) Short Column Failure; (b) Shear Beam Failure; (c) Concrete Crush; (d) Compression - Tension Failure

The two main shear wall failures in the exterior of the building are concentrated in the two walls that are in the entrance of the building. These walls spans along the 15 and 22 gridline between the gridline K and D Figure 3, above the first floor, in the first floor theses walls are extended out of the building to form the entrance, which create a vertical discontinuity and an outrigger effect. In the elevation of the gridline 15 shown a opening just under the diagonal cracking, and also is noted that one side under the opening is connected to the mat foundation, and the other side is founded on another. In conclusion, the opening produced an extended part of the first floor that attracted large demand; there was not enough area at the end of the opening for the load to travel producing a crushing at the end of the diagonal Figure 9, as it was also reported by Youssef et al. (2010).

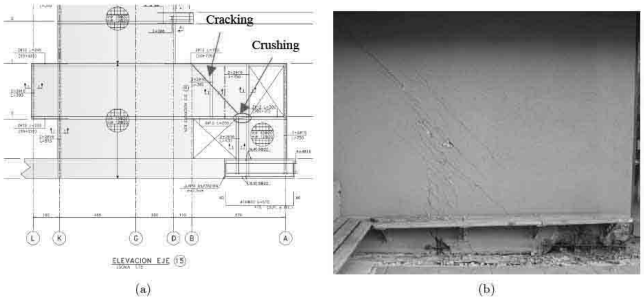

Figure 9 Damage in the Elevation 15: (a) Elevation 15 (Youssef et al 2010); (b)Shear Damage and Concrete Crushing

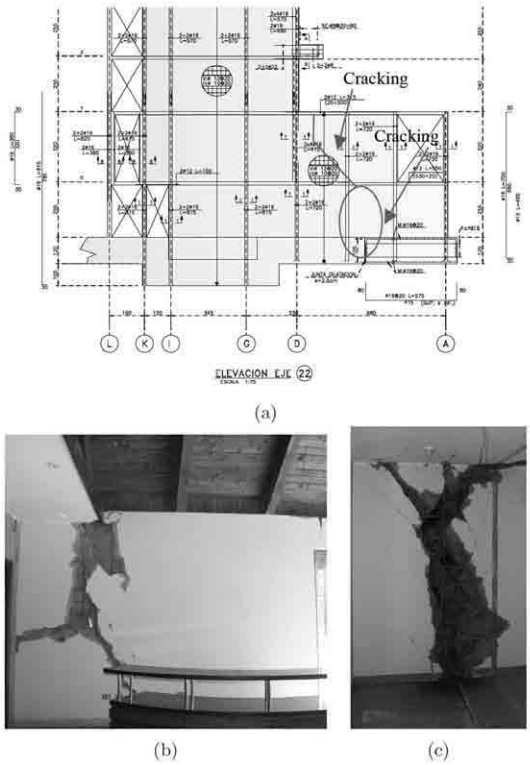

Figure 10 Damage in the Elevation 22: (a) Elevation 22; (b) Crack 1st Floor; (c) Cracked Basement

Instead, in the gridline 22, the wall is extended even more in the basement. No opening is observed at the first floor, Figure 10. However the wall is founded one part over the mat foundation, and the other portion over a different foundation, which could have produced some differential deformation in the wall due to the overturning moment of the building which produce a failure in the wall at the level of the basement Figure 10.

The damage of the thin walls produced by the coupling of flexural and compression demand that caused the crushing of the poorly confined or even unconfined boundary element part of the walls, which crack and propagate through the section, it was reported almost in all the building review and visited by the different Reconnaissance teams (Youssef et al 2010, Naeim et al. 2010, Carpenter et al. 2010, Rojas et al. 2010b, Moehle et al. 2010), and was mainly observed what happened in the walls that presented vertical discontinuities at the first floor and form the so call ``Flag Wall''. In the ocean facing exterior of the Building studied is observed the failure of a wall due to flexural crushing, in the wall at the end of the gridline 19. The wall in this gridline span between the balconies beams and the gridline L Figure 3 without openings between the 2nd and 19th floor, and only at first floor two openings appear, the smaller for architectural reasons, and the other to locate the door for a room at the entrance level Figure 11. In addition, the exterior edge of the wall is set back a few inches in the first floor. This could have caused the end wall to be submitted to large compression and tension demand for the overturning moment due to the wall in the above floors.

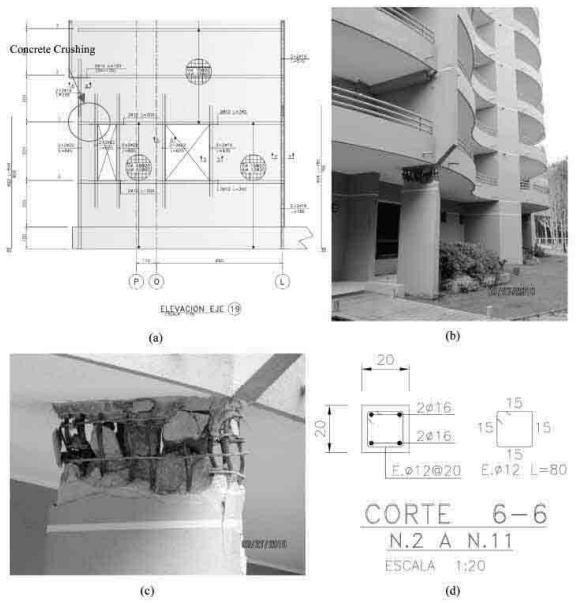

Figure 11 (a) Elevation of lower floors along line 19; (b) concrete crushing along line 19; (c) closer view of crushing at top of wall; (d) boundary confinement details at line 19 (Youssef et al 2010)

In the Interior of the building the damage is concentrated mainly in the center part of the building along gridline L. In the first Floor the damage in gridline L is centered around gridline 22 Figure 12, the large crack turns horizontal at the end of the wall, with crushing of the concrete at the boundary element, and buckling and fracture of some of the longitudinal steel bars. Looking the elevation of the gridline L at that position is observed that the damage could be the result of the discontinuity of the wall above in combination of the thin wall and poor confinement of the boundary elements, Figure 12, and also the crushing in the top the wall at first floor could be caused by the flexural over turning of the two different walls from above (Youssef et al. 2010).

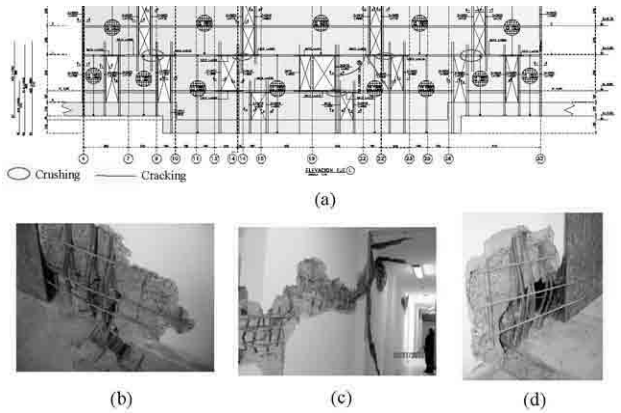

Figure 12 Damage in the elevation L in the interior of the Building at the 1st and 2nd Level: (a) Elevation with damage location (b) damage at left size; (c) damage at center of elevation (d) damage at right size

In addition, the elevation L presented some crushing of the wall at the end of the 2nd floor around gridlines 6 - 8 and 28 - 30 Figure 12a, these failures can also be attributed to the discontinuity in the walls. In this case two walls at each edge of the elevation, which are separate over all the height of the building, were connected at the first floor, and also included some openings, which produce a reduction of the section of the walls. Trying to compensate this reduction, an increase of the wall at the first floor is observed. However the area for the transition of the load at the second level was not enough to produce the crush of the concrete and the buckling of the steel bars Figure 12 b,d.

In the rest of the stories the damage is concentrated mainly in the floor, showing a severe damage of the floor when acted as a coupling beams along the walls in the gridline L and K Figure 13 (a) and (b), show the deterioration of the floors at the position of the door openings, because the crushing of the concrete, and diagonal crack between the doors openings in opposite side of the corridor. No special detailing for steel reinforcement is observed for the bars parallels to gridline L, K for the area of the slab located in the door openings that connect the walls along gridline L and K, it is typically found 8 [mm] diameter bars at 20 [cm] spacing (Youssef et al. 2010). In addition, it is interesting to note that the slab between the gridline L and K also acts as a coupling beam in the perpendicular direction to the corridor between the gridline L and K for the wall in the short direction of the building, this is shown for the parallels crack observed in the celling along the the wall in the gridline L and K Figure 13 (c) and (d). This type of damage was observed almost in all the building visited by the different by the different Reconnaissance teams (Naeim et al. 2010, Carpenter et al. 2010, Rojas et al. 2010b, Moehle et al. 2010)

Figure 13 Damage observed in the slabs at different levels: (a) and (b) damage of the slab between walls; (c) and (d) parallels cracks to walls in the slabs at the corridor area

The final severe damage observed in a wall in the building is located in the top of the building in the gymnasium area, and is a shear wall failure. This failure also happened for a vertical discontinuity of the wall in the gridline 15, which caused the connection in the last floor of

the wall along K and L, producing a large shearing demand over that section of the wall. This is traduced in the failure observed, which was also noted by Youssef et al. (2010).

2.4 3D Elastic Model

A 3D elastic model of the building is developed using Etabs software V9.7 (CSI, 2010), Figure 14, as an initial approach to study the behavior of the building during of the Magnitude 8.8 Chile Earthquake February, 27 2010. The modal analysis of the model indicates that the 1st and 3rd modes are a coupling of the longitudinal direction and torsional, which is expected due to the distribution of the resistant walls in the x direction (See Figure 3), and the 2nd mode is in the transversal direction.

Table 3 Modal Participation Factor of the Building

Mode	Period [sec]	Mxx	Myy	Mzz
1	0.71	27.90	0.37	41.02
2	0.69	0.14	67.42	0.26
3	0.57	43.95	0.00	26.93

Figure 14 3D Elastic Model

In the Table 4 is presented the weight for square meter used in the model for each floor, that come from account for the 100% of the dead load and a 25% of the live load. The other parameter shown is the density of wall area in each direction for each floor. The values obtain for this building are typical for residential Chilean building, which are 1 Ton/m^2 and above 3 % of wall area for each direction. However, the H/T ratio gave 79.9 m/sec for the longitudinal direction, and 96.8 m/sec in the transversal direction, which indicates a more stiff building.

A response spectra analysis is used to analyze the distribution of stresses inside the building. The elastic response spectra with 5% damping used is obtained from the accelerograms recorded during the earthquake (Figure 6). The N-S record is applied to the longitudinal direction (Long direction) and the W-E record is applied to the transversal direction (short direction).

Table 4 Properties for Floor

Story	H	Weight/Area Floor [Ton/m^2]	% Density of Wall in X	% Density of Wall in Y
19	2.55	1	3.46	4.76
18	2.55	1.18	3.19	4.85
17	2.55	0.99	2.67	4.12
16	2.55	0.97	2.72	3.44
2 - 15	2.55	0.97	2.7	3.31
1	3.2	1.11	3.34	3.59

To account for the inelastic behavior of the structure in the response spectrum is used the reduction factor defined in the Chilean Seismic Code (NCh433 of 96) (Figure 15) for Wall system building

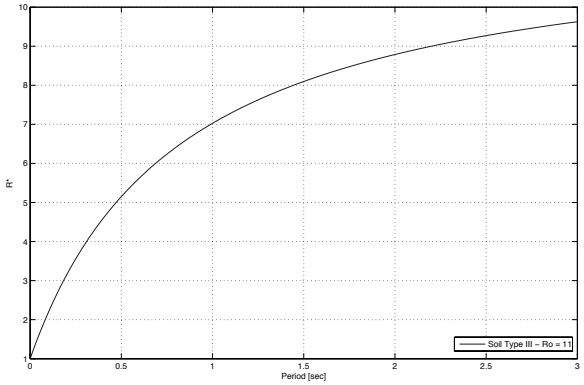

Figure 15 Reduction Factor

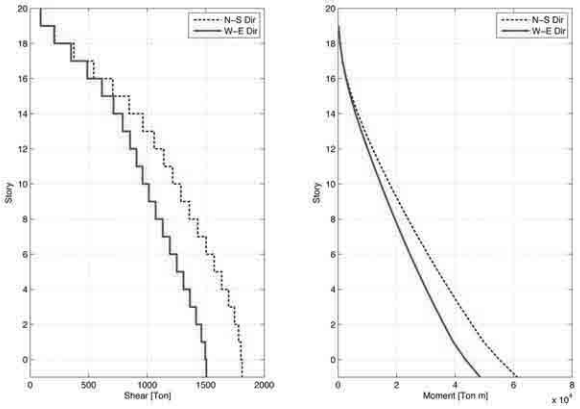
The Shear and Moment over the structure in the two principal directions are shown in Figure 16. The shear in the N-S direction corresponds to an 11.3 % of the total weight of the building and a 9.4 % of the total weight in the W-E direction (Short Direction)



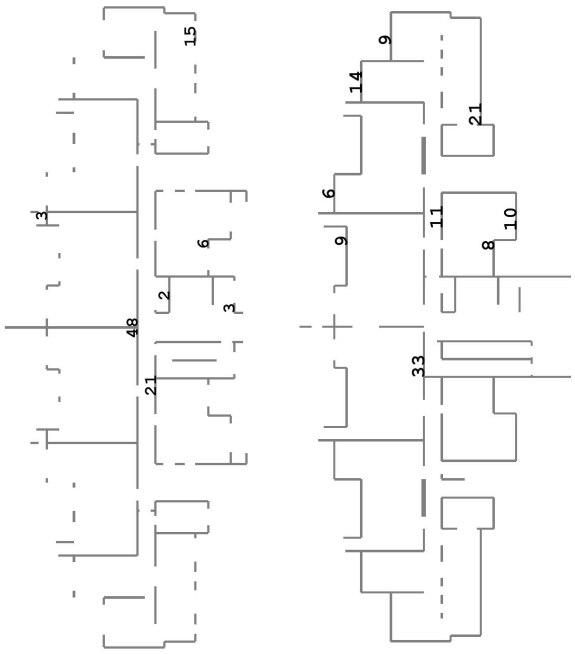


Figure 16 Reduction Factor

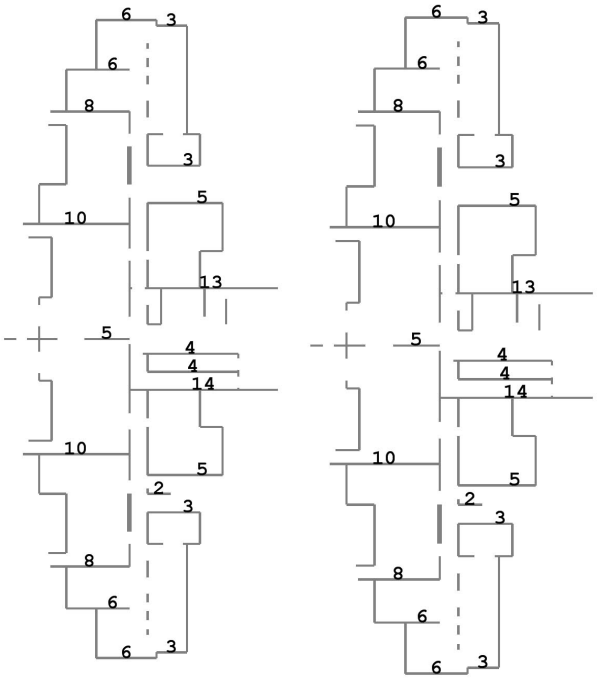
In addition, it is studied the distribution of shear in each direction inside of the building. It is observed that for the long direction between the 2nd and 16th floor the axis L and K take around a 70 % of the total shear of the floor (Figure



17a), and at level of the first floor some of this shear is released to the exterior wall that appears only at that floor (Figure 17b), which can cause the failure of the short column and short beam in the first floor at this new walls (Figure 8)

(a) (b)

Figure 17 Distribution of % Shear in the Long Direction
(a) Typical Floor (b)1st Floor

In the other direction the shear is distributed more uniformly over the different resistant axis (Figure 18). In addition this axis help to resist the torsion form for the separation between the center of gravity and the center of rigidity in the short direction.

(a) (b)

Figure 18 Distribution of % of Shear in Short Direction
(a) Typical Floor (b)1st Floor

The damage in line 19, it is attributed to the action of the overturning and the combination of the axial load when the wall is divided to accommodate a door and an architectural feature, that cause an over compression stress of the head of the wall at the first level. This type of failure was very common in the all the Chilean building. Also the damage in the slab at the level of the corridor it is observed in the model for a concentration of stress at zone of the perpendicular wall that corroborate the assumption that the slab is acting as a coupling beam in the structure. The damage in line 15 and 22 are corroborate for the model to observed a increase in the shear demand at that lines at the level of the first floor (Figure 18)

The internal damage observed in the axis L, like in the Figure 12a and 12b, are attributed by a excessive compression stress due to the transference of forces at that strangulation, that produce an increase in the shear and compression demand, which is shown in the result of the model. In addition the overturning along that resistant axis produce an additional component that contribute to the failure.

3. CONCLUSIONS

The Chile Earthquake provided a unique opportunity to study the behavior of reinforced concrete wall buildings. The Building study is one of the examples available to study and compare analytical model with real response. In fact, these buildings are real laboratory test cases, that need large studies to understand better the interrelation of the different elements of the structures when are subjected to strong ground motion, and use these studies to improve the codes and stander available for seismic design.

This particular building was selected because of the amount of data that is available on hand, such us recorded accelerogram of near field, drawings, building specifications, and damage information. Also, this building has the characteristic of having severe damage and many different types of damage. An initial study of the damage and comparison of the damage and elastic model was presented in this paper to evaluate the damage of a shear wall building during a Magnitude 8.8 earthquake. Even if an elastic model is used for analysis of the structure, the model is able to represent where the concentration of stresses were during the earthquake and evaluate theses critical points in the structure. A more comprehensive model it is need to study in more depth the actual value in each area and study how was the evolution of the damage in the structure and how the interrelation of the different components of the structure, such as wall, slab and beam, interacted during the earthquake.

Abstract: Reinforced concrete shear wall buildings are by far the most common lateral force resisting system used to resist ground shaking that occurs in the frequent large earthquakes that occur in Chile. Since the Chilean building code is based on ACI 318-95, with only a few exceptions, the performance of buildings in Chile to the very strong shaking that occurred in the Mw = 8.8 February 27, 2010 earthquake provides an excellent opportunity to evaluate the behavior of taller RC buildings (>10 stories). The 15-story, residential, Torre Alto Rio building was one of the few, modern RC buildings over ten stories to collapse. Studies of reasons for the collapse were conducted using post-earthquake observed damage, structural drawings, and preliminary analyses (e.g., section analyses and two-dimensional nonlinear analyses). The preliminary studies indicate that collapse was likely influenced by discontinuous walls on the east side of the building, wall layout and configuration, and the location of splices of wall vertical reinforcement.

1. INTRODUCTION

Reinforced concrete shear wall buildings are the predominant lateral force resisting systems used to resist ground shaking that occurs in the frequent large earthquakes that occur in Chile. Detailed studies of a number of Chilean buildings were conducted following the March 3, 1985 M7.8 earthquake (Wallace and Moehle, 1989; 1993; Wood, 1991). These studies indicated that the overall good performance of the modern RC buildings in Chile resulted due to the use of a large percentage of wall area to floor plan area, as well as limited wall axial stress.

The building codes in Chile are similar to building codes used in the United States. Chile's reinforced concrete design specifications are based on ACI 318 Building Code requirements. An important variation between ACI 318 in the Chilean code (NCh 433.Of96) involves an exception which allows shear walls in Chile to be constructed without special boundary elements and significant boundary transverse reinforcement. Preliminary reports (EERI, June 2010; Wallace, 2011) indicate that the lack of boundary transverse reinforcement, thin walls, and relatively high levels of axial stress likely led to greater damage to buildings in 2010 than was observed in 1985.

The recent and past earthquakes in Chile provide an excellent opportunity to evaluate the behavior of taller (more than 10 stories) reinforced concrete buildings subjected to strong, long duration, ground motions. Moreover, it is noted that the subduction zone in Chile is similar to that in the US Pacific Northwest, where the Juan de Fuca plate subducts under the North American plate (Figure 1-1).

Figure 1-1 Subduction zones

1.1 The February 27, 2010 Chile Earthquake- A Brief Overview

The 2010 Chilean earthquake occurred off the coast of the Maule Region of Chile on February 27, 2010, with Mw = 8.8 for shaking lasting about two minutes. The epicenter of the earthquake was located at 335 km (210 miles) SW of Chile's capital city, Santiago, and 105 km (65 miles) NNE of Chile's second largest city, Concepcion. Displacement spectra with 5% damping is shown in Figure 1-2.

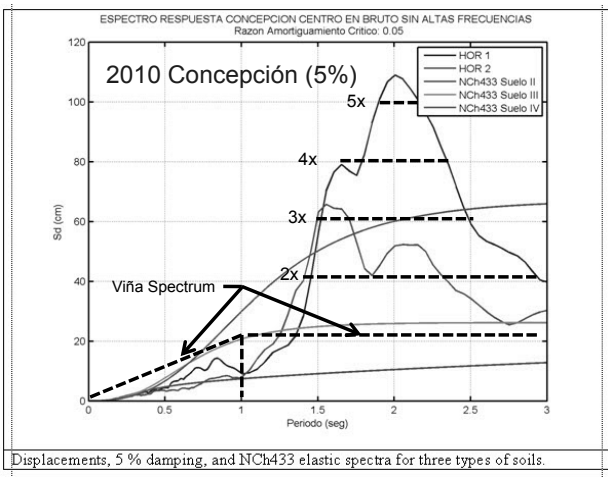

Figure 1-2 Displacement Spectra with 5% damping

2. OBSERVED DAMAGE

The 15-story residential building Torre Alto Rio, constructed in 2008, collapsed in the main shock and led to the majority of deaths reported in modern reinforced concrete buildings (EERI Newsletter, June 2010). Photos of the collapsed building are provided in Figures 2-1 and 2-2.

Figure 2-1 Collapsed building: Torre Alto Rio [The Associated Press]

Figure 2-2 Collapsed building view from the base

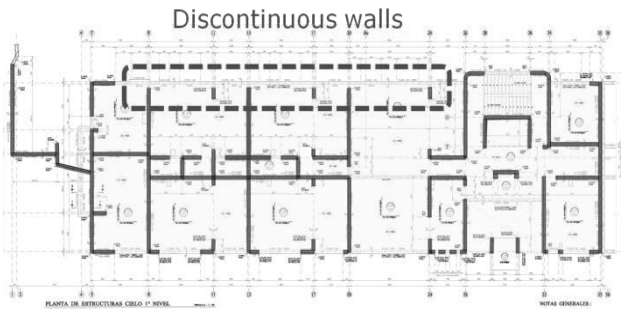

Figure 2-3 Plan view [Moehle,9th US NCEE, Toronto]

Shear wall layout can be clearly seen in the plan view (Figure 2-3), with primary lateral strength direction provided by walls with T-shaped cross sections, with flanges formed by the corridor walls (Figure 2-4). Therefore, when loaded, one of the T-shaped walls has flange in compression (Figure 2-5 (a)), the other one (Figure 2-5 (b)) has flange in tension.

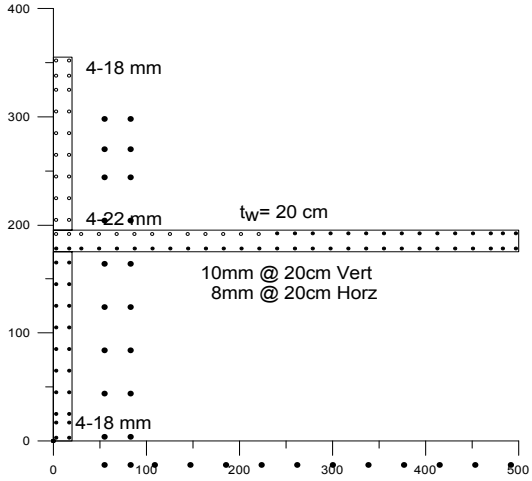

Figure 2-4 Cross-sectional view of the T-shaped wall highlighted in Figure 2-4

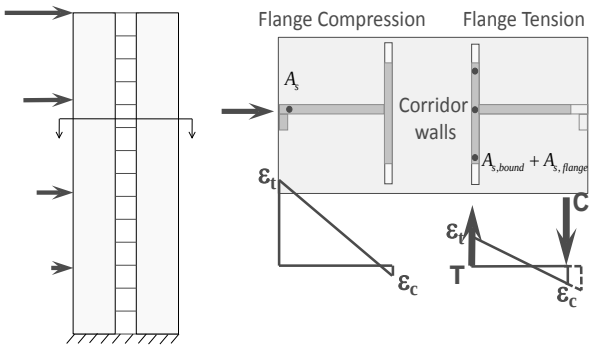

Figure 2-5 Schematic plan view

In case (a), large tensile strains are developed at the wall boundaries at the building edge (east and west faces).

The very wide compression zone formed by the corridor wall results in a very small depth of the compression zone due to the small quantity of tension reinforcement used at the east edge of the wall. The large tensile strains make the boundary longitudinal reinforcement susceptible to fracture. Some of the wall vertical reinforcement fractured at the building edge and rebar splice failures were observed along the tension web. [EERI Special Earthquake Report- June 2010] (Figure 2-6). On the other hand, in case (b), large web-compression forces occur in T-shaped walls (corridor walls in tension) and results in buckling of the vertical reinforcement and concrete crushing at the building edges. The latter case can be clearly seen in Figure 2-7 which presents the behavior of a T-shaped wall with flange under tension, from an experimental study of reinforced concrete structural walls with rectangular and T-shaped cross-sections (Thomsen and Wallace, 1995; 2004). These issues are discussed in more detail and similar post-earthquake and experimental damage photos are presented by Wallace (2011).

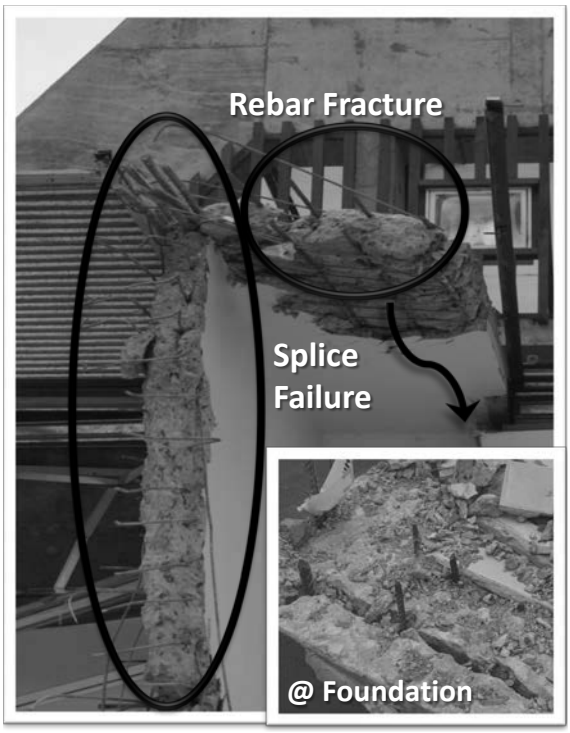

Figure 2-6 Splice failure and rebar fracture

To understand the reasons for collapse, curvature demand is compared with curvature capacity of the T-shaped wall. Curvature demand is calculated as 0.00012/cm using displacement-based design methodology (Eq. (1)), where spectral displacement is obtained from Figure 1-2 as 12 cm by estimating fundamental period of the building as 1 sec. In the equation, plastic hinge length is taken as two times the wall thickness (i.e., α=2) based on results presented by Wallace (2011). Curvature capacity is obtained using moment-curvature analysis and compared with curvature demand in Figure 2-8. The red solid line represents the behavior with axial load based on tributary gravity load, whereas the blue dashed lines display the curvature demand and indicate that concrete crushing is expected (along with rebar buckling). Once the wall web crushes/buckles, (type (b)), the wall shortens and causing the building to rotate/lean. Post-earthquake observations indicate that crushing/buckling of wall webs was very common for T-shaped walls, particularly when there is setback at the web boundary (Figures 2-9, 2-10). Rotation in the building is likely to produce large tension on the opposite wall (type (a)). Due to the large tensile force, longitudinal reinforcement fracture and splice failure are likely. This sequence is illustrated in Figure 2-11.

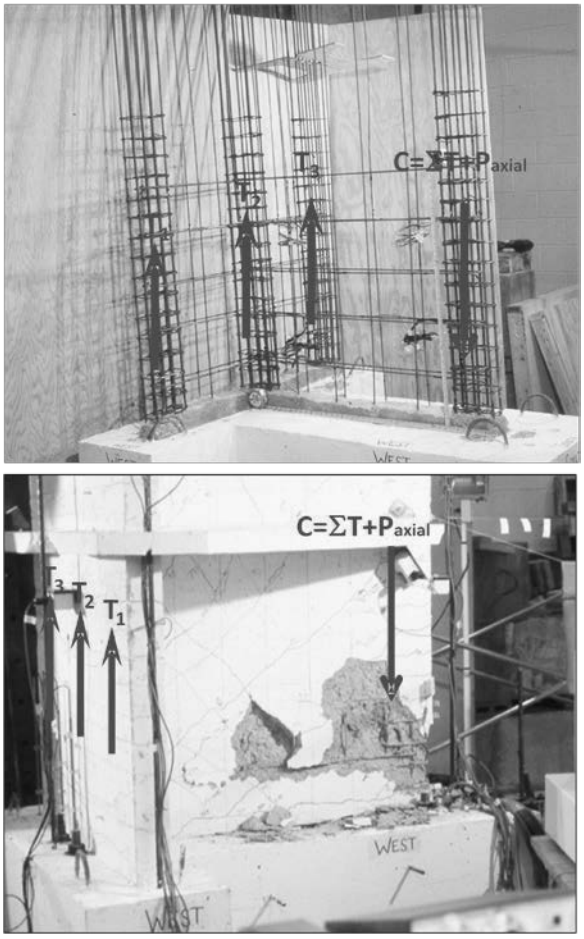

Figure 2.7 Specimen TW1 [Thomsen and Wallace, 2004]

$$
\begin{aligned}
S_d(T = N/15 = 1\text{sec}) &= 12cm \\
\frac{\delta_u}{h_w} &= \frac{1.5S_d}{39m} = 0.0046 \\
\phi_{demand} &= \left(\frac{\delta_u}{h_w}\right)\left(\frac{1}{l_p = \alpha t_w}\right) \\
\phi_{demand} &= (0.0046)(1/2*20cm) \\
\phi_{demand} &= 0.00012/cm
\end{aligned}
\tag{1}
$$

Figure 2.9 Example for wall crushing (Macul, Santiago) [Wallace, 2010]

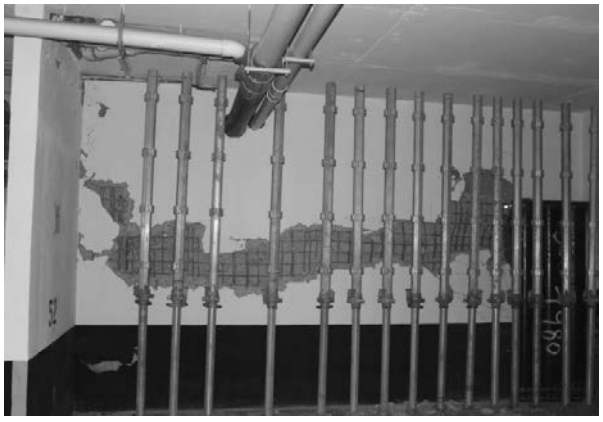

Figure 2.10 Example for wall crushing (Santiago) [Moehle, 2010]

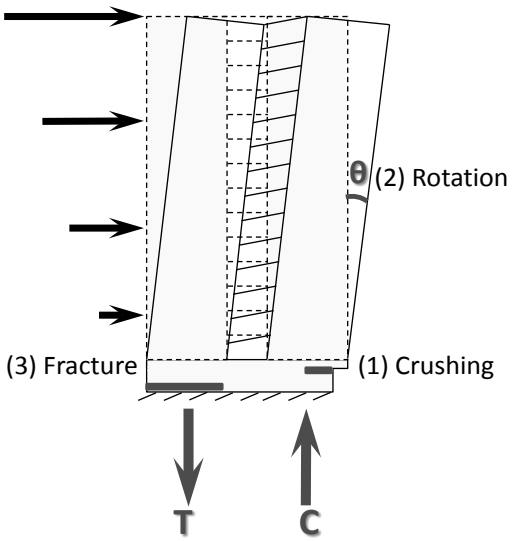

Figure 2.11 Assumed collapse mechanism

Vertical wall discontinuity, on the other hand, can be clearly seen in the schematic elevation view of the building (Figure 2-12). Shear walls below the ground level were setback to provide for parking spaces. As discussed above, when the corridor wall (flange) is in tension, larger wall shear and web-boundary compression forces develop. The large compression, along with the vertical wall discontinuities, were important factors leading to the observed building performance (collapse).

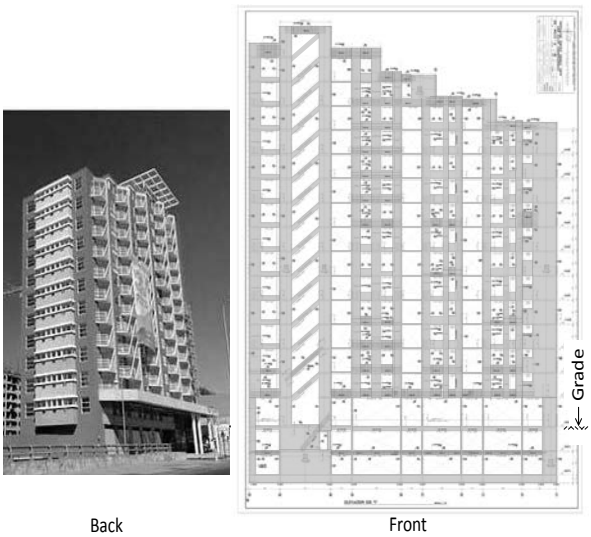

Figure 2.12 Elevation view of the building [Moehle, 9th US NCEE, Toronto]

3. CONCLUSIONS

Reinforced concrete shear wall buildings are the predominant lateral force resisting systems used to resist ground shaking that occurs in the frequent large earthquakes that occur in Chile. Since the building code in Chile is based on ACI 318-95 and the subduction zone in Chile is similar to that in the US Pacific Northwest, the performance of buildings in Chile that are subjected to the very strong shaking in the February 27, 2010 earthquake provides an excellent opportunity to evaluate the behavior of taller reinforced concrete buildings. The Torre Alto Rio; a 15 story, residential, modern reinforced concrete building collapsed in February 27, 2010 earthquake. Reasons for the collapse were studied using post-earthquake observed damage, structural drawings, and moment-curvature analysis. The preliminary studies show that collapse was most likely affected by:

- wall layout (T-shaped walls),
- discontinuity and setback in the east-side basement walls to provide space for parking, and
- lack of sufficient transverse reinforcement at wall web boundaries.

Abstract: In design of ductile RC moment frames, more hoops than needed for shear resistance are required at ends of beams and columns both to confine the concrete and restrain the buckling of longitudinal reinforcement. However, disadvantages of using hoops for confinement are inherent. Hoops can only confine the concrete core, which usually results in the spalling off of concrete cover during large inelastic deformation reversals. Amount of hoops for yield regions is usually dictated by code specified maximum spacing instead of by a rational design. In addition, closely spaced hoops and supplementary bars at yield regions require more construction time and efforts, not to mention the miscellaneous stringent detailing requirements. In order to achieve improved constructability, better confining effect and better post-earthquake reparability, new types of ductile RC moment frames were proposed where yield regions of columns are wrapped with external tube confinement instead of using extra transverse reinforcement. This paper focuses on the development of a rational design procedure that aims to relate the characteristics of tube confined concrete to the overall system behavior.

1. INTRODUCTION

The ductile reinforced concrete moment frames have been widely constructed in regions of highest seismicity in most of the world. According to the seismic design method used in many countries, the ductile inelastic response of a RC frame during strong earthquake ground shaking can be achieved if the following design goals are satisfactorily met: 1) strong column-weak beam mechanism; 2) adequate shear strength; 3) sufficient transverse confinement at yield regions of members; and 4) avoidance of anchorage and/or splice failure. It can be seen that the transverse hoops plays a significant role in ensuring the expected ductile inelastic response in traditional RC frames. In current seismic design codes transverse hoops have three main functions: 1) provide shear strength; 2) prevent buckling of longitudinal rebars; and 3) confine the core concrete of yield regions for better deformability. The current transverse hoop design is based on the work of Richart et al. (1929) and was developed so that the compressive strength of the confined core of a column after spalling should be equal to the strength of the gross section of the column before spalling. However, the disadvantages of using transverse hoops for confinement are inherent. Firstly, transverse hoops can only confine the core concrete and leave the concrete covet neither confined nor reinforced. Under large inelastic deformation reversals, the concrete cover will spall off, causing bond stress loss of longitudinal reinforcement and loss of stiffness and strength of the member due to the reduction of sectional area. Secondly, the current confinement reinforcement design leads to extra construction cost and efforts in that closely spaced hoops will concentrate within the lengths of yield regions and thus increase the construction time of steel cage and the difficulty in pouring and vibrating concrete, not to mention the stringent detailing requirements for the supplementary cross ties. Thirdly, although the strong column and weak beam mechanism is intended to restrain the local damage at beam ends and then to avoid the story mechanism due to the existence of weak columns, as shown in Figure 1(a), column yielding is inevitable due to the limiting column-beam strength ratios. Kuntz and Browning have suggested that only when column-to-beam strength ratio is relatively high (on the order of four) can the most preferred full structural mechanism, as shown in Figure 1(b), be developed. ACI 318 adopted a relatively low while very practical value of 1.2 as the column-to-beam strength ratio, leading to the intermediate mechanism as shown in Figure 1(c). This intermediate mechanism is associated with stringent detailing requirements on hoops at yield regions, resulting increased construction cost.

(a) (b) (c)

Figure 1 Failure patterns of ductile RC frames (a) story mechanism (b) beam mechanism and (c) intermediate mechanism

It is believed by the authors that the traditional way of using transverse hoops as confinement reinforcement in ductile RC moment frame is inherently inefficient to ensure the strong column-weak beam mechanism and to provide confinement at yield regions of members. Using hoops at yield regions for confinement requires extra construction efforts in steel cage fabrication, concrete pouring and vibrating, and quality control. In order to enhance the confinement effect at yield regions and improve the constructability of ductile RC frames, a new type of ductile RC frame where transverse hoops are only for shear resistance and the yields regions are confined with steel tubes is proposed in this paper.

2. REARCH BACKGROUND

A great deal of research work has been carried out to investigate the behavior of retrofitted deficient RC bridge columns. Those existing RC bridge columns designed following old codes needed retrofitting in that previous earthquakes had revealed their inherent deficiencies in strength, ductility and energy dissipation capacity (Fung et al, 1971; Priestley, 1988; Lew, 1990). Various retrofitting methods were developed by researchers around the world, mainly in U.S. and Japan. It has been widely accepted that using steel jacket to encase the potential plastic hinge regions of circular and rectangular bridge columns can result in the increase in ultimate compressive strain, strength and ductility (Sakino and Ishibashi, 1985; Tomii et al, 1987; Xiao, 2001; Zelinski, 1990; Priestley et al, 1992; Priestley, et al. 1994a and b). Carbon fiber reinforced plastic has attracted a great deal of attention from researchers due to its superior mechanical properties. Using CFRP wrap to enhance the flexural strength and ductility of deficient bridge columns has been accepted as an effective way of retrofitting. Using post-tensioning straps for strengthening was different from the above-mentioned methods in that the straps actively prestressed the column laterally. Therefore, it was more efficient in terms of material use and confining effect. Hassan et al. has conducted experimental studies on the behavior of columns confined by external prestressed metal straps and obtained satisfactory results.

One of the most interesting conclusions drawn from previous research was that the confinement could reach best effects on circular column section while for square or rectangular column section the confinement would be less effective compared with circular columns. However, it is obvious that if this issue could not be resolved satisfactorily, the use of externally confined concrete in new building structures would be very limited since most of the columns in building structures are square or rectangular. Therefore, it is worthwhile to further investigate the external confining methods for non-circular columns.

Although a lot of research programs have been carried out on the behavior and modeling of confined concrete, only few of them focused on the confined concrete for new buildings. Thus the design method of the confinement steel, especially the external confinement was empirical instead of rational. Furthermore, previous research only focused on the behavior of a structural member while rarely studied the confined concrete at the system level. This lack of systematic study on confined concrete has limited its application in newly built structures. This research aims to conduct some preliminary studies on the externally confined concrete as part of a structural system.

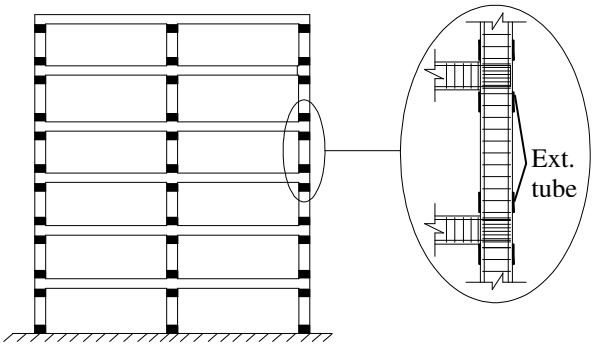
3. PROPOSED PARTIALLY TUBE-CONFINED RC DUCTILE FRAME

In order to improve the constructability and meanwhile enhance the seismic performance, several partially external tube-confined structural columns were conceived by the authors. It is proposed herein to develop new types of RC ductile frames with partially tube-confined columns where yield regions are confined using external encasement instead of transverse reinforcement.

The proposed partially tube-confined ductile RC moment frame is depicted in Figure 2. Deviating from the conventional ductile RC moment frames, transverse hoops in partially tube-confined ductile RC frames are only for shear resistance, resulting in the uniform distribution of hoops along the full height of the column except for the joint regions. At the ends of columns, tubes are provided to confine the entire column sections of potential yield lengths. The construction procedure of the partially tube-confined RC frame is very similar to that of traditional RC frame. The only difference is that the confining tube is installed after the column concrete has been cured. The confining tube can be fabricated by welding steel shells that form an enclosure to the column sections at potential yield regions. The external encasement is terminated slightly short of the connecting member or footing (e.g. 5 mm gap) to ensure that the tube provides confinement only.

2.1. Type-1: RC Columns Partially Confined by Steel Tubes

The use of rectilinear steel tubes for confining square or rectangular columns has been proved experimentally to be very effective provided that the steel shell has sufficient out of plane flexural stiffness. The beam action will be relied on to develop efficient lateral confinement to the concrete sections. The construction of the steel tube is depicted in Figure 3(a). The steel shells can be field welded to form the encasement of the column section. A thin layer of cement grout is filled between the column surface and the steel encasement.



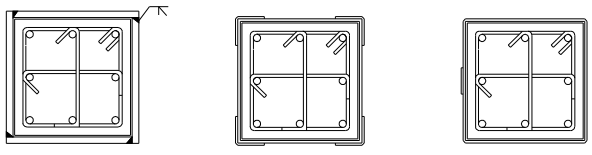


Figure 2 Partially tube-confined RC frame

2.2. Type-2: RC Columns Partially Confined by Carbon Fiber Reinforced Plastic (CFRP) tubes

Figure 3(b) illustrates the proposed CFRP tube details. The corners of the CFRP tube are strengthened by adding extra layers locally. Due to the substantially varied distribution of the confining pressure for square and rectangular column sections, much higher pressures are developed at corners as compared to the pressure developed at the midpoints between corners. Therefore, without special strengthening measures taken, the CFRP confining tubes will most likely fracture at the corners, resulting in relatively poor confinement effects compared with circular columns. Therefore local strengthening at corners of the CFRP confining tube can enhance the confining effect.

2.3. Type-3: RC Columns Partially Confined by Post-tensioning Metal Straps

Post-tensioning metal straps

4. RESEARCH OBJECTIVES AND SCOPE

This research program is to investigate the seismic performance and to develop guidelines for design of RC ductile moment frames where yield regions of columns are confined using external tube encasement instead of traditional transverse reinforcement. The followings are the detailed objectives of this program:

i. To define and to provide constructable details of the external tube confinement at column ends using different materials;

ii. To develop and to evaluate design methods for the partially tube-confined RC columns;

iii. To develop and evaluate the design method for the RC ductile frame system consisting of partially tube-confined columns and regular beams;

iv. To evaluate the effectiveness of the currently available constitutive models for confined concrete;

v. To compare the effectiveness of different partial confinement schemes using different materials.

5. PROPOSED DESIGN APPROACH FOR PARTIALLY TUBE-CONFINED COLUMN

A performance design approach is proposed to design the partially tube-confined RC ductile frame. The approach includes the following major steps:

i) Select a controlling sway mechanism of the preliminary proportioned frame using limit analysis;

ii) Estimate the required column-girder flexural strength ratios from the results of step i;

iii) Estimate the required drift demand;

iv) Design column and confinement to satisfy strength and deformation demand obtained from steps ii and iii;

v. Conduct a refined analysis and check the strength and deformation adequacy.

Four possible failure patterns of the partially tube-confined column were identified, including shear failure, flexural failure at critical confined section at column ends, flexural failure at critical section of unconfined column section and failure of confining steel tube. In order to ensure the ductile inelastic response of the column, shear failure should be avoided before the development of the flexural mechanism strength at selected locations. As shown in Figure 3, section A represents the critical section of the confined yield regions. Section B is the critical section of the unconfined segment of the column. Although the flexural failures of the critical sections of both confined and unconfined column segments are ductile, more benefits can be expected if choosing the external confining steel tube as the structural component where ductile failure occurs first. Since the confining tube exists externally, it would be very convenient to remove the failed tube and replace with a new one after experiencing rare earthquake events. In other words, choosing the yielding of the external confinement as the failure mechanism of the system can result in superior reparability compared to other mechanisms. Furthermore, the strengths of the column would be sustained even if the external confinement fails. Thus the collapse of building can be

prevented.

5.1 Confining Tube Design

In design of the confining tube, the equivalent confinement pressure is estimated first corresponding to the moment when the nominal flexural strength of the confined section. A simple way of estimating such an equivalent confinement pressure can be established based on the ACI 318 code (2008). To ensure the rotational deformability of the potential plastic hinges near column ends, ACIT 318 code requires the transverse reinforcement be

$$A_{sh} \geq 0.3 \frac{sh_c f_c^{'}}{f_{yh}} (\frac{A_g}{A_{ch}} - 1) \quad (1)$$

$$A_{sh} \geq 0.09 sh_c \frac{f_c^{'}}{f_{yh}} \quad (2)$$

Where A_{sh} is the total transverse steel cross-sectional area within spacing s; h_c is the cross-sectional dimension of column core measured center-to-center of the outermost peripheral hoops; f_c' is the specified compressive strength of concrete; f_{yh} is the specified yield strength of the transverse reinforcement; A_g is the gross area of section; and A_{ch} is the cross-sectional area of the column measured out-to-out of transverse reinforcement. Eqs. (1) and (2) can be used to define an equivalent lateral pressure f_{eq}. Since f_{eq} is corresponding to the development of nominal flexural strength of the confined section, the concrete compressive strength f_c' can be substituted by the compressive strength of confined concrete f_{cc}'. Thus, f_{eq} can be expressed as

$$f_{eq} = \frac{A_{sh} f_{yh}}{sh_c} \geq 0.3 f_{cc}^{'} (\frac{A_g}{A_{ch}} - 1) \quad (3)$$

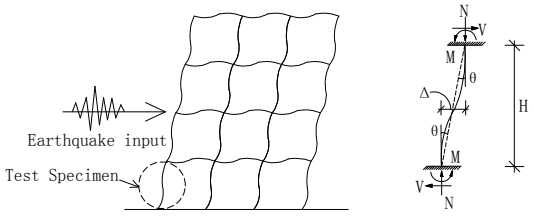
$$f_{eq} = \frac{A_{sh} f_{yh}}{sh_c} \geq 0.09 f_{cc}^{'} \quad (4)$$

It can be seen that for externally confined column sections Eqs. (1) and (3) are automatically satisfied. Thus Eqs. (2) and (4) govern the design. The design of the confining tube is based on a limit state where an appropriate yield mechanism is formed. For steel tube confinement, the limit state can be the beam action with plastic hinges formed at middle and corner sections along each side. For CFRP tube, the mechanism can be the failure at corners. For post-tensioning straps, the mechanism can be the yielding at corners. The length of the tube encasement is chosen to ensure that the moment demand immediately beyond the tube will not exceed 75% of the original flexural capacity.

5.2 Flexural Strength Check at Critical Column Sections

The required flexural strength for the critical section at the confined segment is determined based on the mechanism flexural strength at beam end multiplied by a column-to-beam strength ratio. Since the confined concrete effect is considered, a moment-curvature sectional analysis may be necessary to estimate the flexural strength of the critical confined section based on the stress-strain relationship of confined concrete. The flexural strength demand at the critical unconfined concrete can be estimated by assuming the inflection point is located at the mid height.

5.2 Shear Design



The shear demands of the columns should be calculated based on the plastic moments at column ends considering confined concrete effect. The transverse reinforcement can then be determined based on the shear demand following relevant shear design provisions in ACI 318 code. The spacing of transverse reinforcement is uniform along the clear column height.

5.3 Joint Check

Due to the consideration of confined concrete effect at column ends, the shear demand may increase and result in the development of shear cracks. The joint reinforcement is then of great significance to ensure the strong column-weak beam mechanism.

6. EXPERIMENTAL PROGRAM

A comprehensive experimental program is under development at the structural laboratory of Chongqing University. The experimental program consists of two phases of testing. At phase one, short square columns with proposed external confinement will be tested under axial compression to examine the effectiveness of the additional measures that aim to compensate for the reduction of confining effect due to non-circular column section. The stress-strain relationships of confined concrete as well as the stress state of the confining tube will also be studied.

(a (b)

Figure 4 (a) Prototype structure; (b) loading condition

At phase two, the model column specimens simulating the behavior of frame columns will be tested subjected to cyclic lateral loading under constant axial load. The prototype building and the loading conditions of the specimens are depicted in Figure 4. by assuming the infinity of the floor slab stiffness, the column ends are treated as fixed. Under constant axial load N and cyclic lateral shear force V, the specimen will deform as shown in Figure 4(b) with double curvature. It is

believed this loading condition can satisfactorily simulate the frame column behavior during earthquake event.

7. SUMMARY

Partially external tube-confined RC ductile moment frames are proposed along with three different confining schemes. Using external confinement can overcome the inherent disadvantages of traditional transverse reinforcement and provide additional benefits such as the improved reparability after earthquake. A design procedure is also suggested to design the system including the partially confined column. The forthcoming experimental program was briefly outlined.

Abstract: This paper reports the results of the numerical investigation of reinforced concrete (RC) columns subjected to impact loads from tsunami water-borne shipping containers. High-fidelity numerical simulation of the shipping container-column impact is carried out using the nonlinear finite element code LS-DYNA. A series of RC columns with square and circular cross-sections is considered to investigate effects of transverse reinforcement ratio, longitudinal reinforcement ratio, column section size, and axial load ratio on peak impact force. Based on the numerical results, formulae to estimate peak impact force on RC columns are obtained in terms of column cross-section size and kinetic energy of the container.

1. INTRODUCTION

Indian Ocean tsunami of December 2004 resulted in massive destruction to coastal communities particularly with a higher death toll compared to all other tsunamis that have occurred in the past. Post tsunami reconnaissance surveys have reported that light-framed wood and unreinforced masonry residential buildings were severely damaged or completely collapsed due to impact of water-borne massive objects such as boats and heavy vehicles (Ghobarah et al. 2006, Inoue et al. 2007, Kaushik and Jain 2007). Similar damage was reported due to recent tsunamis of September 2009 in Samoa and February 2010 in Chile, where many water-borne shipping containers impacted on buildings and port facilities as the area became inundated (Robertson et al. 2010ab). An example of damage to an RC building due to impact of a shipping container during the Samoa tsunami is shown in Fig. 1. Several RC columns collapsed and beams in the impacted region sustained severe damage due to the container impact.

Madurapperuma and Wijeyewickrema (2011) considered the impact of a water-borne shipping container on an RC building, where the impact force-time histories were first obtained from a high-fidelity finite element analysis using LS-DYNA (2007) and next the impact analysis of the entire building was carried out using OpenSees (2009), an analysis framework that uses beam-column elements with fiber-based descretization. In the present study, the numerical simulation carried out using detailed finite element models facilitates a more comprehensive analysis of the shipping container-column impact scenario. The impact analysis is carried out using the nonlinear finite element code LS-DYNA (2007). Prior

to numerical simulation, formulae to estimate the peak impact force given in current design guidelines such as ASCE 7-10 (ASCE 2010) and FEMA P646 (FEMA 2008) are critically reviewed. Next, details of finite element models and numerical results for the container-column impact are presented. A series of RC columns with square and circular cross-sections is considered to investigate effects of transverse reinforcement ratio, longitudinal reinforcement ratio, column section size, and axial load ratio on peak impact force. Based on numerical results, formulae to estimate the peak impact force on RC columns are obtained. The present study can be considered as a very comprehensive investigation of container-column impact.

2. EXISTING METHODS TO ESTIMATE PEAK IMPACT FORCE

In this section the current design guidelines (ASCE 2010, FEMA 2008) which refer to impact force due to water-borne objects are reviewed.

The peak force F_p due to impact of a water-borne massive object given in ASCE 7-10 (ASCE 2010) is

$$F_p = \frac{\pi m v}{2\Delta t}, \tag{1}$$

where m is mass of the object, v is velocity of the object before impact, and Δt is time to decrease object velocity to zero in the compression phase. Equation (1) is based on the principle of impulse and momentum, and assumes a half-sine pulse for the impact force-time history where the force increases from zero to the peak value F_p in time Δt, then decreases to zero in the restitution phase. Although the value of Δt would vary with the stiffness characteristics of the impacting objects a single value of $\Delta t = 0.03$ has been recommended in ASCE 7-10 (ASCE 2010).

In the case of FEMA P646 (FEMA 2008) the peak impact force is given by

$$F_p = C_m v \sqrt{k_{eff} m}, \tag{2}$$

where C_m is added mass coefficient and k_{eff} is effective contact stiffness i.e., $1/k_{eff} = 1/k_{obj} + 1/k_{str}$; in which k_{obj} and k_{str} are contact stiffness of the impacting object and the structural member, respectively. Equation (2) is based on an undamped single-degree-of-freedom (SDOF) system and can be obtained by considering energy conservation and a linear force-deformation relation i.e., $F(x) = k_{eff} x$ where x is deformation in the contact region. Although this approach is rational compared to the impulse-momentum consideration given in ASCE 7-10 (ASCE 2010) as it incorporates stiffness properties of impacting objects, the estimation of k_{eff} is not always straightforward in practical applications. The mass and effective stiffness values are provided in FEMA P646 for a few types of water-borne massive objects.

For example, consider a $20'$ shipping container with a tare weight of 2200 kg for velocities ranging from 0-10 m/s (Yeom et al. 2009) impacting on a structure. Using $k_{eff} = 1.5 \times 10^9$ N/m (FEMA 2008), the estimated peak impact forces obtained from Eqs. (1) and (2) are compared in Fig. 2. It is seen that, for instance, at a container velocity of 6 m/s the estimated peak impact force is 691 kN from ASCE 7-10 and 10,900 kN from FEMA P646 without considering added mass effect. This indicates that the above formulae are not consistent in the estimation of peak impact force and further investigations are warranted. In the present study, formulae to estimate peak forces on RC columns due to impact of shipping containers are obtained based on a series of numerical analyses.

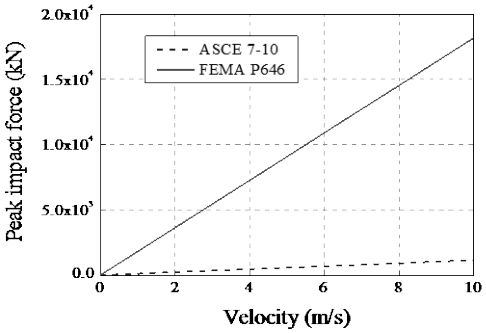

Fig. 2. Comparison of estimated peak impact force for $20'$ shipping container.

3. FINITE ELEMENT MODELING OF SHIPPING CONTAINER-COLUMN IMPACT

In the impact problem under consideration the finite element simulation takes into account the following critical modeling issues: (a) appropriate inelastic material models, (b) strain rate effects of the container and the RC column, (c) reinforcement slip in the column and (d) accurate modeling of contact. The explicit Lagrangian finite element code LS-DYNA (2007), used extensively for impact problems, is used in the present study.

3.1 Shipping Container

In the present study, A $20'$ (20 foot) standard shipping container which has a length of 6.06 m $(20')$, width of 2.44 m $(8')$, and height of 2.59 m $(8'6'')$ is considered (Maersk Line 2010, Magellan 2010). The different parts of the container which include corrugated panels, corner posts, top side rails, bottom side rails and cross members (see Fig. 3a) are modeled using 4-node Belytschko-Lin-Tsay shell elements (Belytschko et al. 2000). A finer mesh is used at

critical locations of the container which enhances the accuracy of the inelastic deformations of these parts. A coarse mesh is sufficient in non-critical locations where the container does not experience much of deformation during the impact (Figs. 3b and c). Hence, the 20′ container model consists of 64,608 nodes and 41,537 elements.

The material model MAT_PIECEWISE_LINEAR_PLASTICITY (MAT_024) with strain rate effects is used to represent material behavior of the container (LS-DYNA 2007). Previous studies have shown that this material model is computationally efficient for use with shell elements for impact simulations (Wu and Thomson 2007). The material properties density 7850 kg/m^3, Young's modulus 200 GPa, Poisson's ratio 0.3, yield strength 343 MPa, tensile strength 481 MPa and strain at fracture in tension 22%, and details of section sizes are given in container specifications (Maersk Line 2010, Magellan 2010).

3.2 RC Columns

Square and circular columns that are commonly used in buildings are considered for the impact simulation. The columns were designed and detailed only for gravity loads according to the requirement in ACI 318-08 (ACI 2008) considering a 3-story, 2-bay by 2-bay RC building, supporting $6\text{ m} \times 6\text{ m}$ slabs at each floor which carries uniformly distributed loads of 4.8 kN/m^2 representing live load on a typical office building, school or building for public assembly (ASCE 2010). The compressive strength of concrete f_c' is taken as 37 MPa. The axial load on the center column of the periphery which will be considered for the impact simulations is 340 kN. For comparison purposes, circular columns are chosen to have nearly the same cross-sectional area as the square columns.

The constant stress 8-node solid elements with one-point quadrature and the Hughes-Liu beam elements are used to represent concrete and reinforcing steel, respectively (Fig. 4a). Each concrete element in the square column is a 25 mm cube, and the element length of 25 mm is used in the circular column in axial direction. The longitudinal and transverse reinforcement are modeled using 25 mm long beam elements. The material models MAT_CONCRETE_DAMAGE_REL3 (MAT_072R3) and MAT_PLASTIC_KINEMATIC (MAT_003) are used for concrete and reinforcement, respectively (LS-DYNA 2007). More details of the RC column model which incorporates strain rate effect and bond slip and associated validation are given in Madurapperuma and Wijeyewickrema (2010).

The constraints provided by foundation and the upper end at the beam-column joint were included in the model as shown in Fig. 4(b).

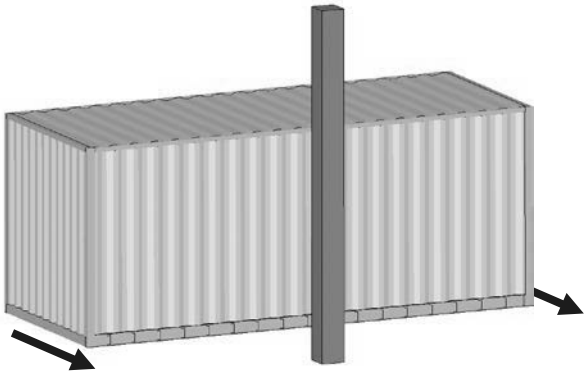
(a) (b)

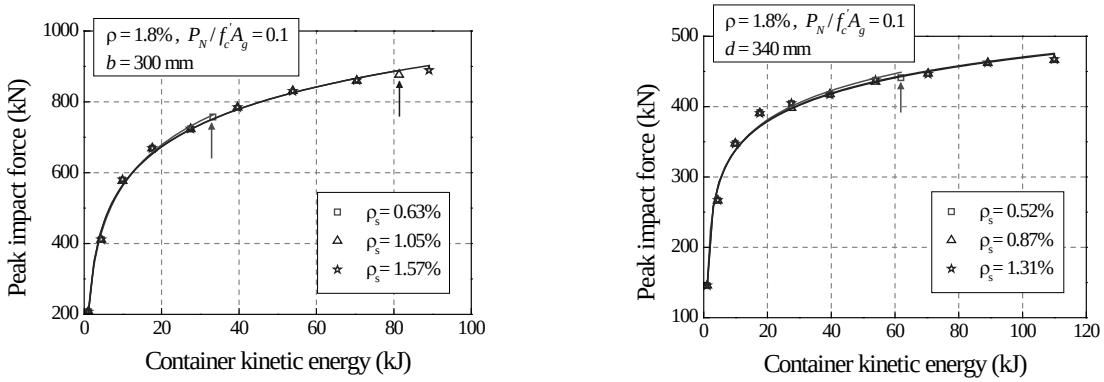
Fig. 4. (a) RC column models and (b) constraint conditions.

4. FORMULAE FOR PEAK IMPACT FORCE

Formulae to estimate peak impact forces on RC columns are obtained in terms of significant parameters using a series of container-column impact analyses. The parameters considered in the present study are transverse reinforcement ratio ρ_s, longitudinal reinforcement ratio ρ, column section size (width b or diameter d), and axial load ratio $P_N / f_c' A_g$ in which P_N is axial load, f_c' is compressive strength of concrete, and A_g is cross-sectional area of the column. In each analysis, the container height above ground level is 0.05 m and the container impacts with the column in the transverse direction (Fig. 5).

First, gravity loads acting on the column are applied as an axial load. This axial load is applied gradually to minimize inertia effects since the analysis is explicit dynamic. Next, container impacts the axially loaded column and the peak impact force on the column is obtained. The effect of each parameter on peak impact force is shown in Figs. 6-9. In these figures horizontal axis represent kinetic energy of the container before impact. The container mass is 2200 kg and the velocity varies from 1-10 m/s, and the corresponding kinetic energy varies from 1 to 110 kJ.





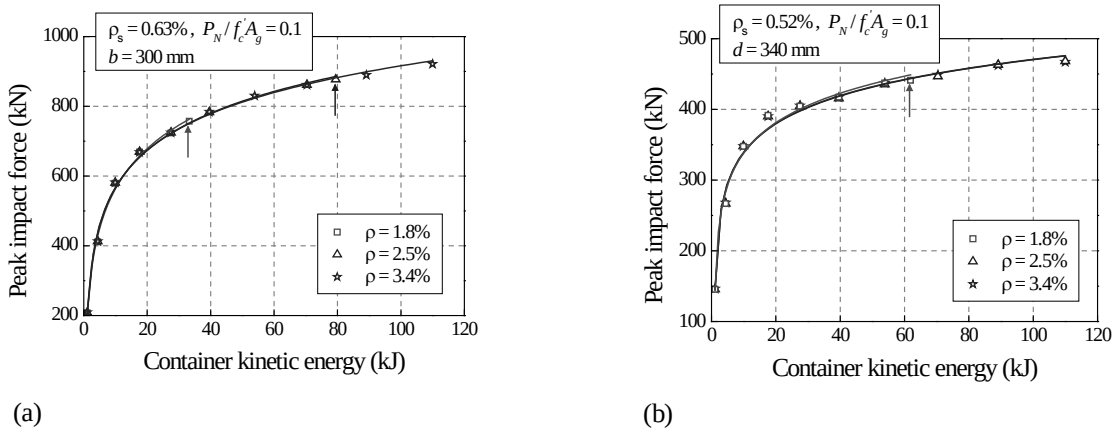


Fig. 5. Transverse impact configuration.

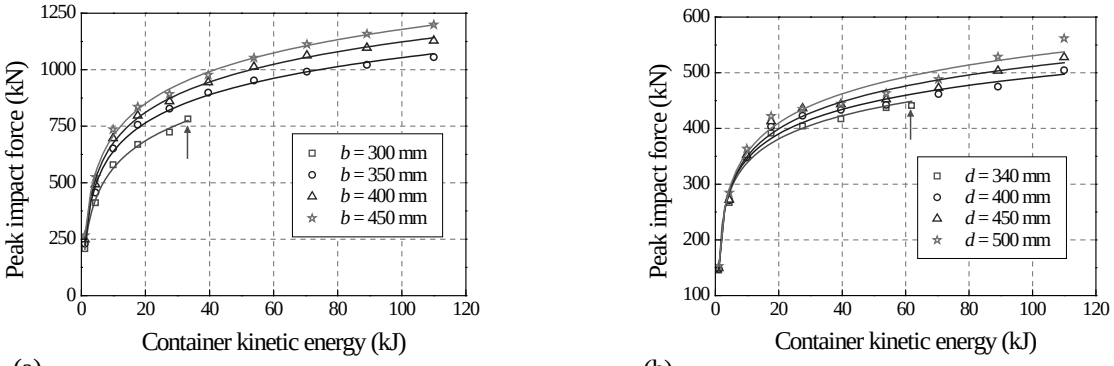
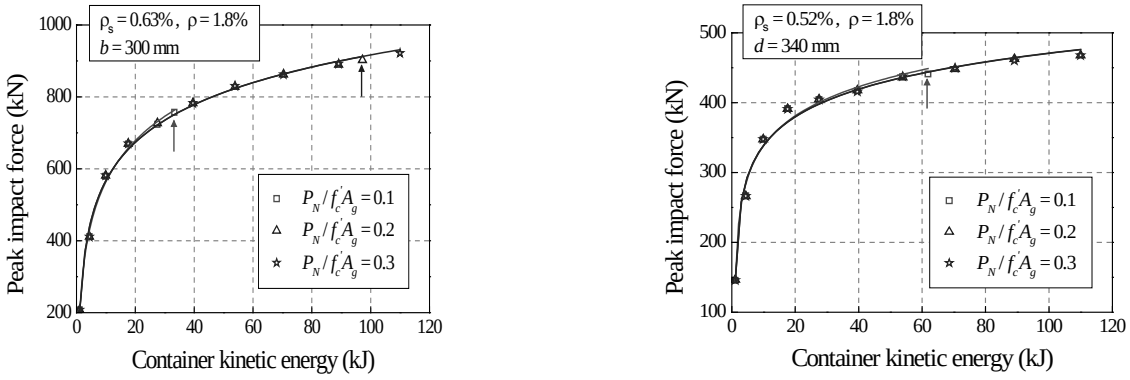


(a) (b)

Fig. 6. Effect of transverse reinforcement ratio on peak impact force: (a) square columns and (b) circular columns. The arrow indicates that for container kinetic energy beyond this that the column would collapse.



(a) (b)

Fig. 7. Effect of longitudinal reinforcement ratio on peak impact force: (a) square columns and (b) circular columns. The arrow indicates that for container kinetic energy beyond this that the column would collapse.

(a) (b)

Fig. 8. Effect of column section size (width or diameter) on peak impact force: (a) square columns and (b) circular columns. The arrow indicates that for container kinetic energy beyond this that the column would collapse.

(a) (b)

Fig. 9. Effect of axial load ratio on peak impact force: (a) square columns and (b) circular columns. The arrow indicates that for container kinetic energy beyond this that the column would collapse.

As shown in Figs. 6-9, the peak impact force increases with container kinetic energy but its rate of increase tends to decrease due to rapid degradation of container stiffness in the vicinity of contact. The numerical results revealed that the most significant parameter that affects the peak impact force is the column section size (width or diameter). The increase in the width (or diameter) of a column increases the number of cross members that simultaneously resist deformation, hence characterizing the sensitivity of force magnitude to column width (or diameter) as shown in Fig. 8.

Since, the peak force usually occurs early during an impact event and the column has no time to respond to the rapid change of loading, the effects of either reinforcement ratio or axial load ratio on the peak impact force are not significant. It is noted that several columns tend to collapse when the container kinetic energy is less than 110 kJ, i.e., equivalent to the kinetic energy of a container with mass of 2200 kg and velocity of 10 m/s, and indicated by an arrow in these figures.

Formulae to estimate the peak impact force are obtained in terms of column section size (width or diameter) and container kinetic energy using nonlinear regression analysis. For square columns, the corresponding formula is

$$F_p^{sq} = 117.8 + 261.6\, b + (70.6 + 306.9\, b)\ln(E_i), \quad (3)$$

where b is column width and E_i is kinetic energy of the container before impact. For circular columns, the formula is

$$F_p^{cir} = 175.9 - 27.9\, d + (40.9 + 79.8\, d)\ln(E_i), \quad (4)$$

where d is column diameter. In Eqs. (3) and (4) F_p^{sq} and F_p^{cir} are in kN, b and d are in m, and E_i is in kJ. It is noted that the proposed formulae are obtained by considering a container mass of 2200 kg and velocities ranging from 1 to 10 m/s, and the corresponding kinetic energy varies from 1 to 110 kJ. In the case of fully loaded container with a mass of 30,480 kg, the impacting kinetic energy typically varies within the considered range as the velocity of a water-borne container tends to decrease significantly with the increase of container mass (FEMA 2008). Hence, the range of kinetic energy considered is typical for impact of a tsunami water-borne shipping container.

The comparison of estimated peak forces from the proposed formulae with the numerical results is shown in Figs. 10 and 11. The solid lines in each plot denote curves obtained from the proposed formulae, and the dashed line denotes the curve obtained from the formula given by ASCE 7-10. The curves obtained from the above formulae for different column widths and diameters correlate very well with the numerical results. As shown in Fig. 10, for the square columns, ASCE 7-10 underestimates the peak impact force for kinetic energy $E_i < 60$ kJ. For the circular columns (see Fig. 11), the peak impact forces estimated by the proposed formula are less than those estimated by ASCE 7-10 when the kinetic energy $E_i > 8$ kJ. As noted in Section 2, the peak impact forces estimated by FEMA P646 are extremely conservative and differ by an order of magnitude and are not shown in Figs. 10 and 11.

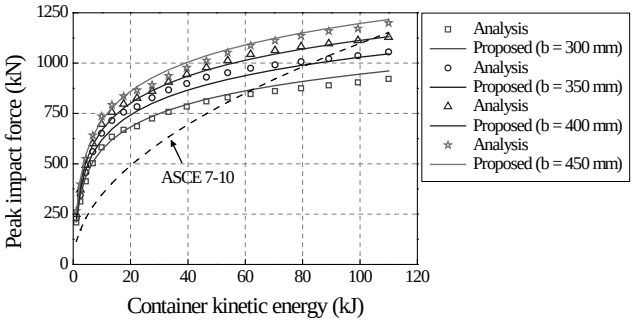


Fig. 10. Comparison of numerical results, proposed curves, and ASCE 7-10 estimate for peak impact force for square columns.

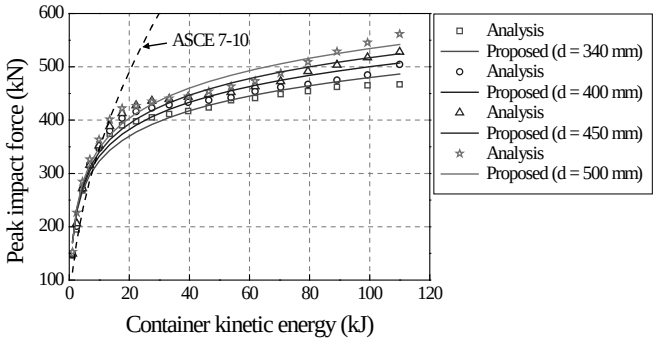

Fig. 11. Comparison of numerical results, proposed curves, and ASCE 7-10 estimate for peak impact force for circular columns.

5. CONCLUSIONS

Impact of tsunami water-borne shipping containers on RC columns was investigated using a detailed finite element model of the 20′ container which is a general purpose standard shipping container and a series of RC columns with square and circular cross-sections.

Formulae to estimate peak impact forces on RC columns are obtained in terms of column cross-section size and kinetic energy of the shipping container. The peak impact forces obtained from the proposed formulae compare well with the numerical results.

For the square columns, ASCE 7-10 underestimates the peak impact force when the kinetic energy is less than 60 kJ. For the circular columns, the peak impact forces estimated by the proposed formula are significantly less than those estimated by ASCE 7-10 when the kinetic energy is greater than 8 kJ. On the other hand, the peak impact forces estimated by FEMA P646 are extremely conservative and differ by an order of magnitude for both square and circular columns.

Abstract: A series of belled piles with high-strength longitudinal reinforcement were tested to investigate seismic performance focusing flexural behavior. In comparison with large diameter and small diameter piles with high-strength reinforcement, this paper presented that the flexural behavior of belled pile with high-strength longitudinal reinforcement was equivalent to the pile with normal-strength one; however, large splitting out of reinforcement and large rotation was occurred.

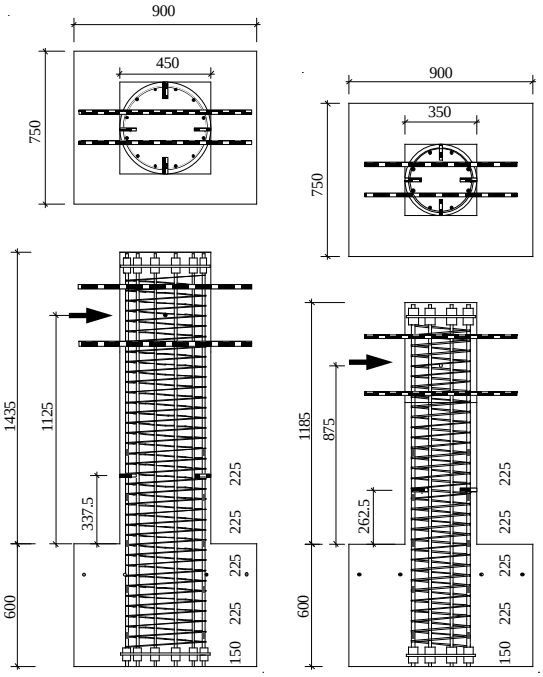
1. INTRODUCTION

The belled pile has been used for mid-rise or high-rise reinforced concrete buildings. Regarding design of the piles, the calculation of ultimate strength of belled pile is not required under AIJ guideline (1999) and ACI guideline (2008); however, the ultimate strength of belled pile after flexural yielding becomes major topic to ensure sufficient seismic capacity of buildings recently. To obtain enough capacity for large ductility, large flexural strength and shear strength is offered. Hence, large amount of reinforcement is offered, too.

Nagae et al. (2000) carried out experimental test of belled piles with high-strength transverse reinforcement and presented that the pile have large flexural capacity and longitudinal reinforcement tends to be overstuffed.

Then this paper presents flexural behavior of belled pile with high-strength longitudinal reinforcement to develop an ultimate strength design of that. The experimental tests were carried out to investigate the behavior of belled pile after flexural yielding.

2. EXPERIMENTAL TEST PROGRAM



2.1 Test Specimens

A series of piles with high-strength longitudinal reinforcement were tested to investigate seismic performance focusing flexural behavior. A summary of the main properties of the specimens is shown in Table 1. The specimens were fabricated as 1/5-scale pile assuming the pile in mid-story reinforced concrete building and different diameters and different strength of longitudinal reinforcements were used to compare effect of those on flexural capacity. The prototype pile, L1 presented in Fig. 1(a) has 450 mm diameter with normal-strength longitudinal reinforcements, otherwise, the pile L2 has 450 mm diameter with normal-strength longitudinal reinforcements. The S

series specimens have 350 mm diameter with high-strength longitudinal reinforcements. Fig. 1(b) shows the geometric properties of the pile S1. The amount of longitudinal reinforcements of each pile was determined by fiber analysis of section so that the flexural strengths of those were the same. The axial load was assumed as 407.4 kN considering dead load of mid-rise reinforced concrete building by the calculation provided by AIJ guideline (1999). The shear span-to-depth ratio, M/VD=2.5 was constant for all the specimens, which was assumed by Chang method whose N value is 3 in condition that a pile head was fixed. The compressive strengths of concrete were targeted as 25 MPa and 45 MPa. The 25 MPa was assumed as the same as generally used strength for belled pile and the 45 MPa was assumed to obtain fully yielding condition of longitudinal reinforcement (Suzuki et al., 1998). The material properties of steel, and concrete were shown in Table 2 and Table 3.

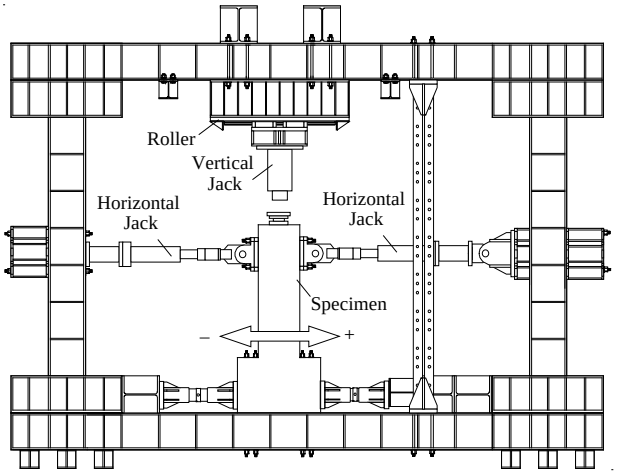

Fig. 2 Test setup

2.2 Test Setup

Bi-directional cyclic loading tests were conducted using the test rig shown in Fig. 2. The cyclic lateral load applied by cantilever system with two horizontal jacks who are installed on each side of the frame. A vertical jack is installed in the middle of the frame to apply a constant axial load at the top of the pile. A roller is placed between a vertical jack and the frame to free horizontal movement of the pile during lateral cycling loading while maintaining the vertical load. The plus and minus beside arrow symbol shows the loading direction. The tests were controlled by deflection angle, R obtained from the horizontal displacement divided by shear span length. The loading history was as follows: R=±1/400×1, R=±1/200×2, R=±1/100×2, R=±1/67×2, R=±1/50×2, R=±1/33×2 and R=±1/25×1.

2.3 Test Results

Comparisons between the measured lateral load versus deflection ratio for L1, L2, S1, S2, S3 and S4 are shown in Fig. 3(a) to (f), respectively. The broken-line on the figure indicates the predictions by AIJ guideline (1999). Square, diamond and circle symbols are drawn at the points where concrete crushing at the boundary surface, flexural yielding of longitudinal reinforcements and peak shear strength, respectively. The observed and predicted shear strength for the piles are summarized in Table 4.

The cyclic loading of all the specimens showed that large flexural capacity still after the deflection angle of 0.02 rad. Small strength degradation is observed when the defection angle was 0.04 rad. The prediction of the specimens S1 to S4 was a little smaller than the peak shear strength point, otherwise the predictions of the piles L1 and L2 are vice versa. The cyclic loading of the specimen with high-strength reinforcements shows larger stiffness while unloading, which makes hysteresis curves close to origin-oriented hysteresis. The effect of difference from diameter on flexural behaviors was not observed by comparing the pile between L2 and S1. The peak shear strength of the pile S2 and S4 were 20 % larger than that of the pile S1 and S3, respectively, which indicates that increasing of peak shear strength was attributed to the

Table 5 Comparison of post yielding stiffness

Specimen	R_y	V_y kN	Post yielding stiffness MPa	Ratio
L1	0.005	117	23000	1
L2	0.015	176	10700	0.47
S1	0.017	178	12200	0.53
S2	0.014	197	16600	0.72
S3	0.018	140	8780	0.38
S4	0.019	163	9940	0.43

concrete strength. Additionally, a fracture of reinforcement was observed only on the pile S4 where the point illustrated by x symbol on Fig. 3(f) with large strength degradation.

Comparison of obtained post yielding stiffness was shown in Table 5. The R_y and K_y represent the deflection angle at the flexural yielding and post yielding stiffness,

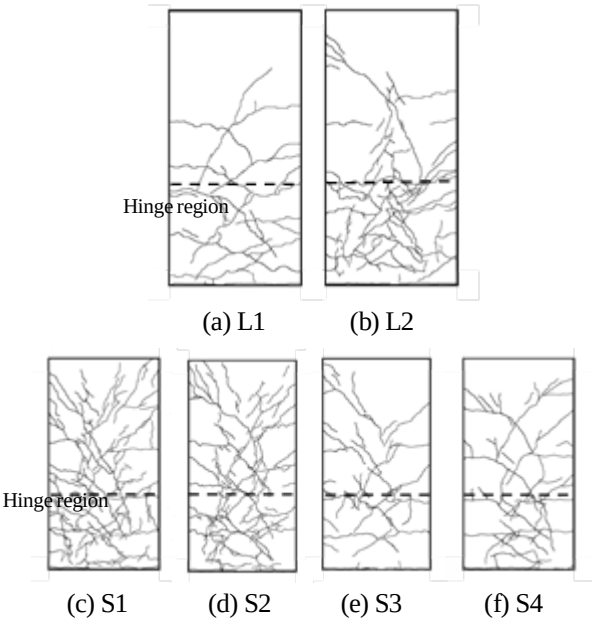

Fig. 4 Crack patterns of the piles after failure

respectively. The K_y was a stiffness obtained by a diagonal line connecting between origin and yielding point on relationship lateral load versus deflection.

The post yielding stiffnesses of the pile with high strength reinforcements were smaller than that of the pile L1; however, for the piles, S2 and S4, it was 10 % larger than that of the piles, S1 and S3, respectively.

The observed crack drawings are shown in Fig. 4. The blue, red and broken line represent the cracks at positive

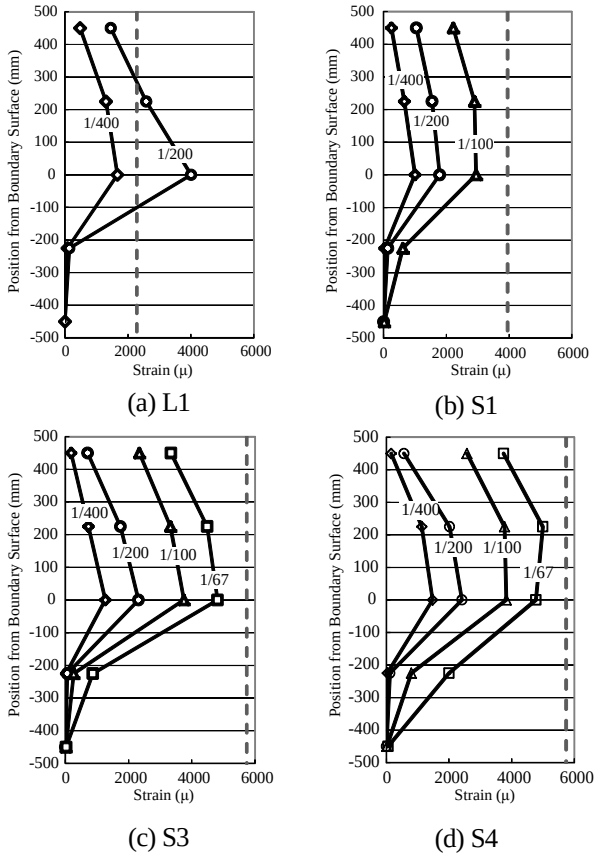

Fig. 5 Distribution of strain of longitudinal reinforcement

direction's loading, negative ones and height of the hinge region which was 0.85*D* height from the boundary surface, respectively.

The first bending cracks were observed at the boundary surface of pile. Then, the cracks were distributed toward to the top of piles as increasing shear force. After that, the shear cracks were observed as increasing the yielding of reinforcements. Distribution of shear cracks of the piles with normal-strength reinforcements was wider than that of the one with high-strength reinforcements, which indicates the rotation of the hinge region was distinguished.

2.4 Distribution of reinforcements' strain

Measured strain of longitudinal reinforcements for each cycle's loading: *R*=1/400, *R*=1/200 and *R*=1/100, is shown in Fig. 5 The y axis represents measured position from boundary surface. The positions of strain gage were illustrated in Fig. 1 with red rectangles. The broken line drawn in figure indicates the yield strain of reinforcements.

The strain of reinforcements at 0 mm was largest in all the piles till *R*=1/200; however, the strains of the piles S1, S3 and S4 were constantly increased after *R*=1/100 at the range between 0 mm and 225 mm where is inside of hinge region. The strain of the pile S4 is larger than that of the pile S3 when the deflection angle is *R*=1/67, which indicates that high-strength reinforcement of the piles with 45 MPa concrete is worked effectively for increasing flexural capacity.

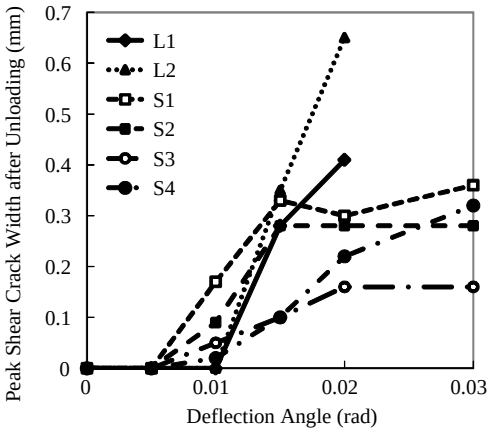

Fig. 6 Comparison of shear crack width and deflection angle

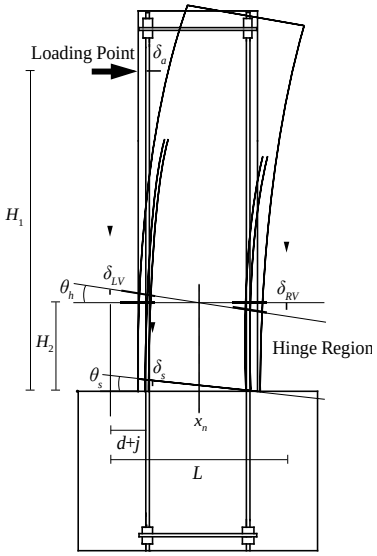

Fig. 7 Schematic of deflection measurement

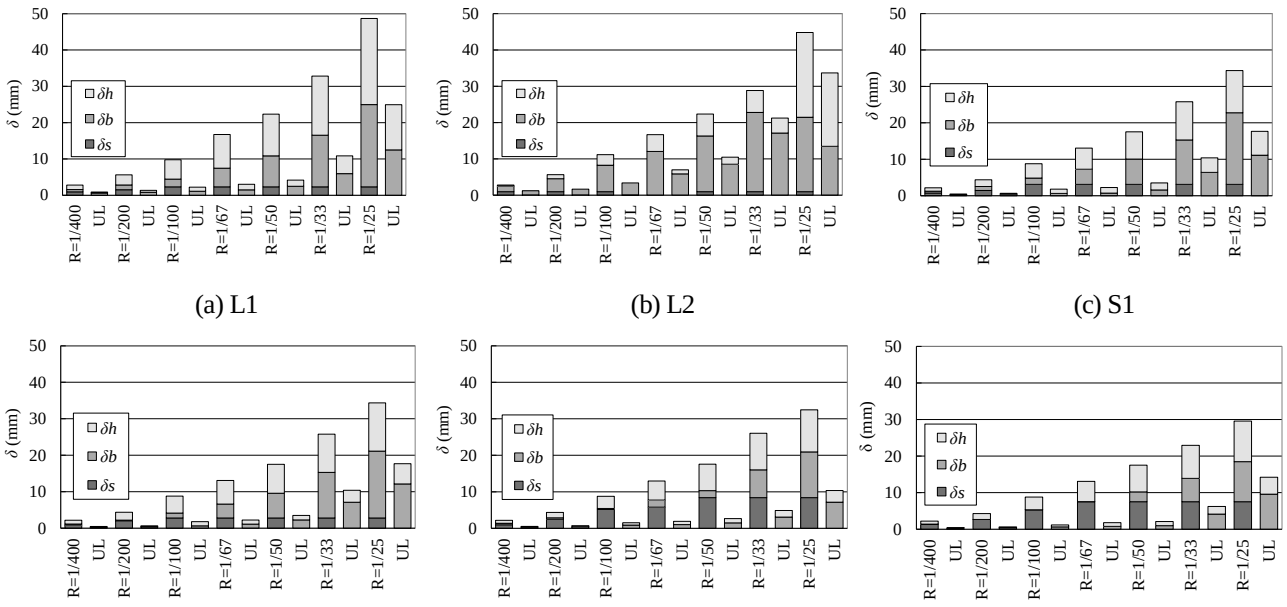
2.5 Comparison of shear crack width and deflection angle



Relationship between shear crack width and deflection angle is shown in Fig. 6. The shear crack width was measured in a direction perpendicular to a crack and the diagonal crack which was extended from a bending crack was taken into account too. A digital microscope which has 0.01 mm limit of resolution was used for measurement.

Fig. 6 shows that cracks are the smaller when deflection angle is *R*=1/100, the larger the reinforcements' strength and concrete strength are. The cracks of the S series piles caused smaller cracks in ultimate state than that of the L series piles because of large transverse reinforcement ratio and large axial force. The piles with high-strength longitudinal reinforcement are effective for large earthquake to minimize damage in ultimate state.

2.6 Ratio of amount of deflection

To study a damage contribution of parts of the pile for total deflection, a ratio of amount of parts' deflection was calculated using measured displacement the parts.

The total horizontal displacement, δ_a is measured

(a) L1 (b) L2 (c) S1

(d) S2 (e) S3 (f) S4

Fig. 8 Ratio of amount of deflection

deflection by strain gauge-type transduces at the loading position's height. The rotation angle at hinge position, θ_h was assumed by following equation using vertical displacement measured by transducers installed on both side of the specimen which is shown in Fig. 7.

$$\theta_h = \frac{\delta_{LV} - \delta_{RV}}{L} \tag{1}$$

where δ_{LV} and δ_{RV} are vertical displacement of left and right, respectively; L is distance between δ_{LV} and δ_{RV}.

Herein, deflection caused by the pile's rotation at hinge region, δ_h is given by following equation using θ_h.

$$\delta_h = \theta_h \left(H_1 - H_2 \right) \tag{2}$$

where H_1 is shear span length; H_2 is height of hinge region.

The rotation angle at boundary surface is given by following equation on assumption that a neutral axis position, x_n at boundary surface is the same as that at hinge height. Note that the x_n was calculated by δ_{LV} and δ_{RV}.

$$\theta_s = \frac{l_s}{x_n - \left(d + j \right)} \tag{3}$$

where l_s is calculated length of slipping out of longitudinal reinforcement by integrating of measured strain placed in foundation (see Fig. 1); d is distance between tensile edge and rebar's position; j is distance from vertical transducer's position to the pile surface (see Fig. 7).

The deflection due to the hinge region's rotation occurred by slipping out of longitudinal reinforcement, δ_s is obtained by Eq. (4) and deflection due to bending of the pile, δ_b is given by Eq. (5). The deflection, δ_s is considered till before a cycle when reinforcement is yielded and after the cycle, the displacement was assumed as constant. Note that if the deflection, δ_s is larger than the deflection, δ_h, the deflection, δ_s is assumed to be equal to δ_h.

$$\delta_s = \theta_s \cdot H_1 \tag{4}$$

$$\delta_b = \delta_a - \delta_h \tag{5}$$

The ratio of amount of deflection at each cycle's loading and unloading is shown in Fig. 8. The UL of x axis represents unloading.

The deflection, δ_s of the pile L1 are smaller than the others at each cycle and that of the pile L2 is much smaller because of lesser numbers of reinforcement (see Fig. 9(a), 9(b)). For the pile L2, large residual deflection was observed at every cycle which indicates that the rotation due to a splitting out of reinforcements was distinguished. The displacement, δ_b of the pile S1 is larger than that of the others till R=1/33 cycle when a stiffness degradation was occurred (see Fig. 9(c)). Regarding of comparison between Fig. 9(c) and (e), the deflection, δ_s is the larger, the larger the strength of reinforcement is. For the pile S3, the deflection, δ_s is constant between R=1/400 and R=1/50; and after R=1/50, the bending deflection, δ_b was increased whereas the deflection due to splitting out of reinforcement, δ_s was decreased (see Fig. 9(e)). Therefore, large splitting out of longitudinal reinforcement and large rotation were attributed to large stain and large stress of high-strength reinforcements which makes a hysteresis similar to origin-oriented hysteresis (see Fig. 3). The effect of difference of concrete strength on flexural behavior could not be observed from the comparison of amount of deflections.

3. CONCLUSIONS

This paper focuces on the flexural behavior of belled piles with high-strength reinforcement. The bi-directional experimental tests of specimens were carried out. In

comparison with large diameter and small diameter piles with high-strength reinforcement, the following conclusions were obtained:

1. The flexural behavior of the pile with small high-strength reinforcement is almost equivalent to the pile with large normal-strength reinforcement.
2. Large splitting out of reinforcement occurred in the pile with high-strength reinforcement which causes large rotation and low post yielding stiffness; however, small shear cracks occurred.
3. Increasing of concrete strength does not affect the ultimate deformation capacity and causes ductile failure due to a fracture of longitudinal reinforcement; however, increase the post yielding stiffness.

Abstract: Devastating earthquakes have shown the difficulty in preventing weak story failure in ductile moment resisting frames. Rather than relying on the strength hierarchy between columns and beams, it is attempted to handle this problem by providing additional continuous stiffness to the frame. The effect of continuous stiffness on the story drift concentration of frame structures is evaluated through nonlinear dynamic analysis. Preliminary equation of estimating the continuous stiffness demand is obtained. A rocking wall-frame system to implement continuous stiffness in concrete structures is then introduced. The effectiveness of rocking walls to control the deformation pattern of reinforced concrete frames is demonstrated through numerical simulations of an example rocking wall-frame structure.

1. INTRODUCTION

The difficulty in suppressing the unintended weak story failure in frame structures is evident from building damages in devastating earthquakes (Villeverda 1991; AIJ, 1991; Ye, 2009). As a well-known effort to control the failure mechanism of concrete structures, the capacity design methodology developed by Paulay and Priestley (1980, 1992) has lead to a widely accepted concept of strong column-weak beam for seismic design of ductile moment-resisting frames. Some amplification factor is applied to the flexural strength demands for columns as stipulated in major seismic codes in the world for decades in the hope of better ensuring the global failure mechanism (SNZ, 2004; ACI, 2005; GB50011, 2001). Such kind of design measures have, however, been frequently questioned by the professions in view of the many unintended weak story failures that actually happened in strong earthquakes (Bondy, 1996; Villaverde, 1997; Ye, 2009).

Strong column-weak beam type global failure mechanism should not be the ultimate goal of seismic design. Rather, it's only one of the ideas to control the deformation pattern in ductile frames and to prevent weak story failure. Rather than the strength hierarchy between beams and columns, MacRae *et al* (2004) revealed that continuous columns (e.g. gravity columns) in concentrically braced frames can reduce the story drift concentration. This effect was also examined by Ji *et al* (2010) in a more analytical manner. Tagawa (2005) extends this effort to moment-resisting steel frames. The appreciation of the global effect of continuous stiffness over the height of the structure may lead to another and more promising solution for the prevention of weak-story mechanism. In what follows, the relationship between continuous stiffness and inter-story drift concentration is examined. Rocking wall-frame system for multi-story reinforced concrete structure is introduced and its efficiency is demonstrated through numerical analysis.

2. EFFECT OF CONTINUOUS STIFFNESS

2.1 Numerical model

Lumped-mass shear model with continuous column is adopted herein to evaluate the effect of continuous stiffness on the story drift concentration, where the shear model represents the ductile moment-resisting frame. The continuous column is connected to the lumped mass by ideal horizontal links. The shear springs have peak-oriented hysteresis and continuous column is assumed linearly elastic and pinned at the bottom. Each lumped mass has only 1 DOF in the horizontal direction. The effect of vertical loads is not considered.

9, 6 and 3-story models are considered. It is assumed for all the models that the story stiffness and mass is identical for every story in the moment frame and the fundamental period of the frame is tuned to be 0.1*N*, where *N* is the number of story. The shear strengths of each story are proportioned in accordance with the Chinese seismic code (GB50011, 2001).

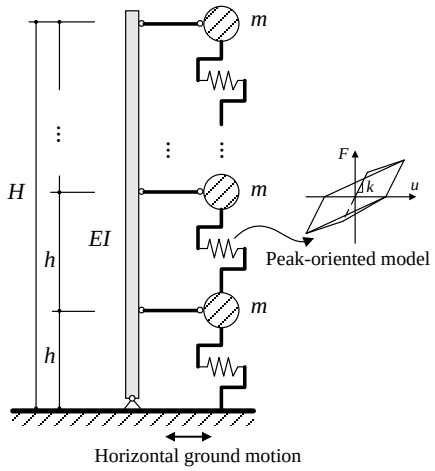

Figure 1 Lumped mass model with continuous column

As suggested by MacRae *et al* (2004), stiffness ratio α as defined in Equation 1 is used herein as a dimensionless measure of the continuous stiffness.

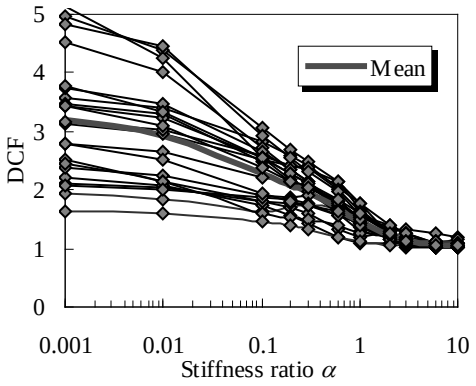
$$\alpha = \frac{EI}{kh^3} \tag{1}$$

where EI is the sectional bending stiffness of the continuous column, h is story height and k is story stiffness of the frame.

In the following discussion, α varies in the range of 0.001 to 10 by proportioning the cross section of the continuous column.

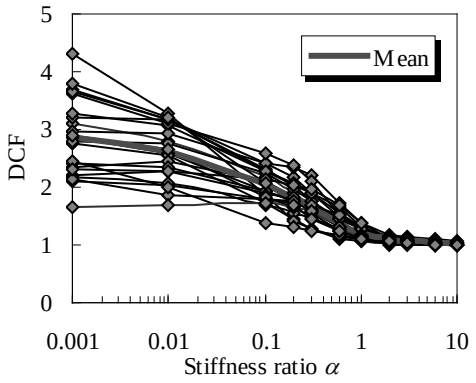
The models are subjected to a suite of 22 ground motion records selected from the PEER/NGA strong motion database as well as the China Strong Motion Network Center (CSMNC) database of the 2008 Wenchuan earthquake. All the ground motions are scaled so that the spectral acceleration at the structure's fundamental period $S_a(T_1)$ equals $\alpha_1 g$, where α_1 is the base shear coefficient in the seismic code and g is the acceleration of gravity.

2.2 Relationship of drift concentration-stiffness ratio



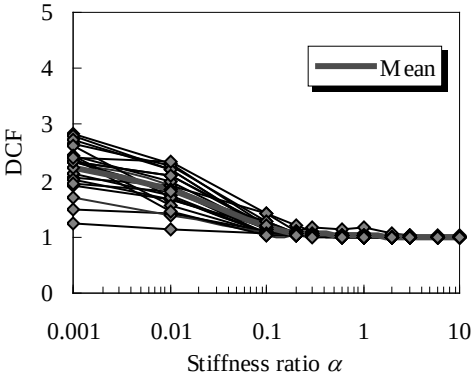
Nonlinear dynamic analysis is carried out and the drift concentration factor (DCF) results are shown in Figure 2. DCF is defined in Equation 2.

$$\mathrm{DCF} = \frac{\mathrm{IDR}_{\max}}{u_r / H} \tag{2}$$



where $\mathrm{IDR}_{\max}$ is the maximum inter-story drift ratio among stories. u_r is the roof displacement and H is the total height of the structure.

DCF is considered as a measure of uniformity of the deformation pattern over the height of the structure. It is observed that DCF decreases rapidly with the increase of stiffness ratio α, suggesting that the continuous stiffness is very effective in reducing the inter-story drift concentration.



Besides, DCFs in higher structures are larger until α is large enough to produce a unity DCF, in which cases the continuous columns behaves almost like a rigid body rotating around the base pin.

(a) 9 story

(b) 6 story

(c) 3 story

Figure 2 Relationship between drift concentration factor (DCF) and stiffness ratio α

2.3 Continuous stiffness demand

Controlling target of DCF needs to be carefully chosen so that it can ensure high probability that weak story failure mechanism can be suppressed. It's considered not practical and also not necessary to require the DCF to be unity since unreasonably large continuous

stiffness would be required. Here the DCF of the 1st mode vibration of the structure is simply selected as the controlling target. The required α (denoted as α_{dem}) can be collected from the average curve of the above results for structures with different numbers of stories (Figure 3a). When plotted against the number of stories, α_{dem} shows an almost linear relationship with the number of storiy (Figure 3b).

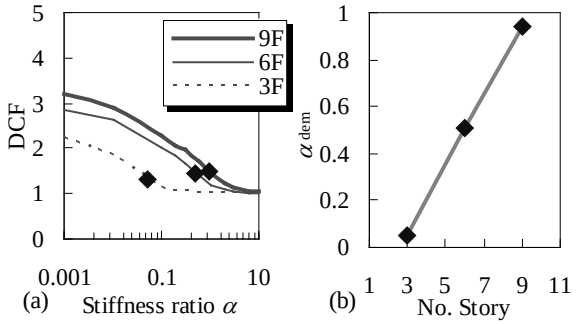


Figure 3 Relationship of number of story and demand stiffness ratio α_{dem}

Quantitative relation between α_{dem} and number of story N can then be found by linear regression as shown in Equation 3. With this equation, the required continuous stiffness can be readily estimated only from the number of story, based on which the cross sections of the continuous components can be checked and determined.

$$\alpha_{dem} = 0.148N - 0.368 \quad (3)$$

In what follows, this equation is used to estimate the required stiffness of rocking wall in order to prevent weak story failure in reinforced concrete moment frames.

3. CONTINUOUS STIFFNESS IN RC FRAME

3.1 Introduction to rocking walls

In steel frames, gravity columns serve as the continuous components that provide continuous stiffness to mitigate the risk of weak story collapse. In reinforced concrete frames, however, it's not easy to construct such gravity columns. Instead, concrete walls often provide strong resistance to weak story failure if shear failure in the wall can be successfully prevented. An innovative solution is provided and demonstrated by the retrofit project of G3 Building on the Suzukakedai campus of Tokyo Tech, in which post-tensioned continuous concrete walls with pin bearing at the bottom (so-called "rocking walls") are attached to the existing steel reinforced concrete frame (Wada *et al*, 2009).

To verify the effectiveness of rocking walls in controlling the deformation pattern, reinforced concrete (RC) moment frame as shown in Figure 4a is enhanced by replacing the middle column with a piece of rocking wall (Figure 4b). Their responses to strong ground motions are evaluated through nonlinear dynamic analysis.

The original RC frame is 8-story high and is seismically designed in accordance with the Chinese seismic code (GB50011, 2001). In the lower 4 stories, column cross section is 600❹800mm and beam cross section is 350❹700mm. In the upper 4 stories, the cross sections are reduced to 600❹600mm for columns and 300❹700mm for beams.

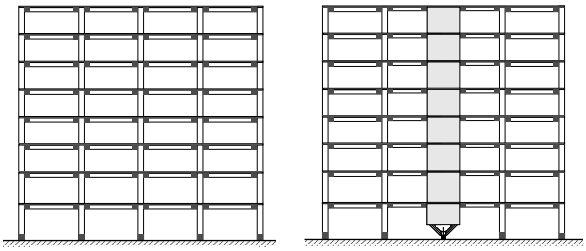

Figure 4 Pure frame and rocking wall-frame

In the rocking wall-frame structure (Figure 4b), the cross section dimensions of the rocking wall are determined based on the required continuous stiffness *EI* calculated from Equation 3. However, an amplification factor of 2.0 is imposed to consider the stiffness loss due to cracking of the rocking wall. The resulting cross section of the rocking wall is 3600❹300mm. The reinforcement of the rocking wall is shown in Figure 5. The rocking wall is supported by steel pin-bearing at the bottom which can resist large shear force while providing little rotational constraint.

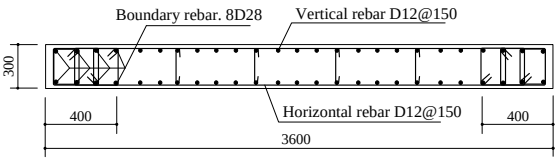

Figure 5 Reinforcement of rocking wall

3.2 Numerical assessment of damage mechanism

The above pure frame (F) and the rocking wall-frame (RWF) are modeled by fiber-based beam element in ABAQUS 6.8 with user-defined material models for concrete and steel fibers. Details of the user-defined material models can be found in Qu (2009). A set of 10 ground motion records are used as earthquake input, which is a subset of the above mentioned 22 ground motions used to evaluate the relationship between DCF and stiffness ratio α. In order to provide an identical earthquake scenario, the ground motions are scaled by non-structure-specific intensity measure PGV, rather than $S_a(T_1)$ as previously did. All the records are scaled to PGV=50cm/s.

3.3 Results and discussions

Inter-story drift ratio (IDR) responses of the rocking wall-frame (RWF) to the ground motion set are shown in Figure 6, where the mean and one deviation responses are compared with those of the pure frame (F). It is obvious that the maximum inter-story drift of the rocking wall-frame is much smaller than that of the pure frame. Most importantly, deformation in the rocking wall-frame is more uniformly distribution over the height of the structure compared to the pure frame. The drift concentration factors (DCF) of rocking wall-frame under various ground motions are much smaller than those of the pure frame (Figure 7).

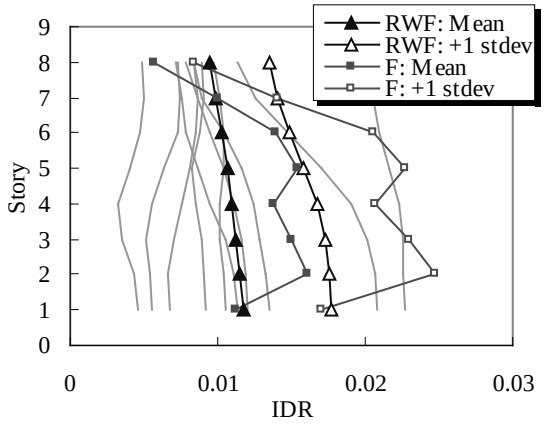

Figure 6 Inter-story drift ratios (IDR) of rocking wall-frame

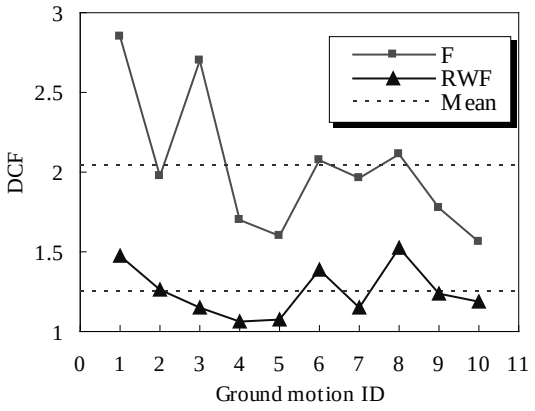

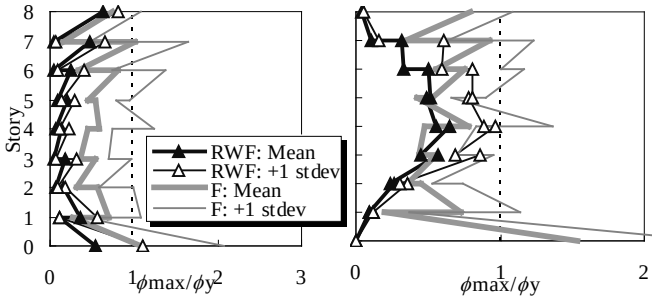

Figure 7 Drift concentration factors (DCF) of rocking wall-frame and pure frame

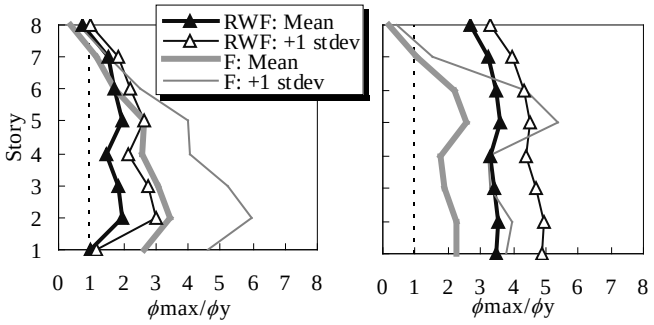

In terms of curvature ductility ϕ_{max}/ϕ_y, Figure 8 and 9 compare the damage mechanism of the rocking wall-frame and pure frame. There's only marginal damage in the rocking wall and columns in the rocking-wall frame structure as the mean and one deviation ductility are almost below 1.0 (Figure 8). On the other hand, damages to the beam ends in the middle span of the rocking wall-frame are increased and more uniformly distributed (Figure 9). They concentrate the energy dissipation of the whole structure.

From these results, the effectiveness of the rocking wall to control the deformation patter and damage mechanism is demonstrated.

Figure 9 Curvature ductility (ϕ_{max}/ϕ_y) in beams

4. CONCLUSIONS

An attempt is made to control the seismic damage mechanism and to prevent weak-story failure in ductile moment frames by continuous stiffness. The effect of continuous stiffness on the drift concentration of frame structures are evaluated through simple numerical models and preliminary equation of estimating the required stiffness ratio α is obtained assuming the controlling target to be the DCF of the 1st mode vibration. Rocking wall-frame system is introduced as a manner to increase the continuous stiffness for reinforced concrete frame. A case study of an 8-story ductile RC frame is provided which demonstrated the effectiveness of the rocking wall to control the seismic damage mechanism.

Abstract: Structures during their service life time may be attacked by one or more aftershocks within a short period following the occurrence of mainshock or different earthquakes occurring at different time. Multiple earthquakes may have the potential to cause more extensive structural damage and property loss due to accumulated effect. Most of previous research focused on the responses of structures due to single earthquake. In this study, reinforced concrete (RC) structure under multiple earthquakes is investigated based on the concept of accumulated damage, and damage accumulation is analyzed in terms of maximum inter-storey drift and damage development. The results demonstrate that the responses of the structures subjected to multiple earthquakes may lead to more structural damage. Under multiple earthquakes in different sequence, the subsequent damage evolution is not consistent.

1. INTRODUCTION

Around the world, there are many areas where earthquakes occur as a series shocks. After an earthquake of large magnitude (referred to as mainshock), many induced multiple earthquakes or aftershocks (hereafter referred to as the general name of aftershocks) will occur due to the reason that the fault rupture does not usually relieve all accumulated energy at once (Figure 1). Earthquake aftershocks may have the potential to cause more extensive structural damage and property loss due to accumulated effect. Occasionally, they can result in building collapse. This risk of collapse is very high for previously damaged buildings. These buildings in 2008 Wenchuan, China, are generally unstable and may collapse in an aftershock (Figure 2). The study of aftershocks will be one of branches of the more familiar study of modern Performance-based Earthquake Engineering (PBEE).

Figure 1 Aftershock distribution for the 2010 Haiti earthquake through 21 January 2010 (from USGS)

Figure 2 Damaged buildings in Wenchuan earthquake

Most of previous research focused on the response of structures due to single earthquake, which neglected two main points: (1) the development of accumulated damage of overall structure and its components; and (2) the change of structural dynamic properties. It should be noted that related research about buildings under multiple earthquakes have risen recently (Lee and Foutch 2004, Luco et al. 2004, Li and Ellingwood 2007, Yeo and Cornell 2009, Abdelnabi and Elnashai 2009), however, the focuses of these studies were different. The following section presents the information from the literatures.

It should be pointed out that the earthquake damage survey and shaking table tests are the more direct assessment approaches to evaluate the effect of accumulated damage. However, it is still very hard to grasp the development of the damage accumulation in detail by using these methods. Meanwhile, most of these studies were limited to the specific structures, and there are no the generally conclusions.

In this study, a reinforced concrete (RC) structure under multiple earthquakes based on the concept of accumulated damage is investigated, and damage accumulation is analyzed in terms of maximum inter-storey drift and damage development. Numerical models are established using commercial nonlinear structural analysis program. Ground motions are input using multiple earthquakes concept.

2. RELATED RESEARCH

The related research presented here focused on the responses of structures based on multiple earthquakes or using the concept of residual capacity to account for accumulated damage in structures.

In the previous cited paper by Lee and Foutch (2004), the performance of damaged buildings subjected to a sets of ground motions representing different hazard levels were conducted. Mainshock-aftershock sequences were modeled by back to back identical accelerograms, which is a conservative (unlikely) occurrence.

In 2004, Luco et al. (2004) put forward a static approach for computing the median residual capacity of a mainshock-damaged building in term of the aftershock ground motions. The static approach based on the result of back to back mainshock-aftershock nonlinear dynamic analyses of case-study building models. Such study involved the use of residual capacity (residual roof drift) regarding the effect of aftershock.

Li and Ellingwood (2007) explored the relationship between the mainshock and aftershock in term of their respective intensities, and stochastic structural response and damage patterns were calculated based on two steel moment frames.

A parametric study was conducted by Yeo and Cornell (2009) based on specific case examples to illustrate the effect of ground motion intensity, duration, elapsed time from mainshock, mainshock magnitude, site location and structure periods on aftershock hazard. Such research results are useful for how to quantify the aftershock when considering its effect.

Abdelnabi and Elnashai (2009) made a study of response of RC buildings under multiple earthquakes, and also pointed out the previous research shortcomings. However, the substantial conclusions were absent owing to lack of numerical analysis.

Therefore, this study focuses on the damage accumulation and the change of structural dynamic properties based on a 12-storey RC moment frame subjected reasonable multiple earthquakes.

3. ANALYSIS METHODOLOGY

Computing the effect of multiple earthquakes by numerical simulation, elapsed time from mainshock should be considered. In most cases, we can assume that the structure is under a "static" state before the following earthquakes. In such a "static" state, there are no acceleration, speed and inertia on structure, but there may be residual deformation. In this case, to consider the structure under accumulated damage, the damaged performance will be inherited including structural strength and stiffness degradation, residual deformation and change of damping ratio.

4. SIMULATION OF RC MOMENT FRAME

4.1 Description of the Structure

The elevation and plan of the 12-storey RC building, as well as the typical reinforcement of columns and beams, are shown in Figure 3. The columns have dimensions: 600mm×600mm. The two exceptions are columns B (Figure 3), which have dimensions: 700mm×700mm. All the beams have rectangular cross-sections, with the width of 350mm and height of 500mm. The slabs have a thickness of 100mm. To simplify the analysis, the component dimension does not change in overall building.

The structure was designed according to Code for Seismic Design of Buildings (GB50011-2001) for a fortification intensity of 7, soil type Ⅳ. A permanent load of 8kN/m^2 was assumed, and a live load of 2kN/m^2 was adopted in the design of the structure. The only exception is the roof, which have a permanent load of 9 kN/m^2 and a live load of 0.5kN/m^2. Concrete with quality C30 and Q335 longitudinal reinforcement (yield strength of normalized value amounts to 335MPa) were used for the construction of described building. The transverse reinforcement type is Q235, whose yield strength of normalized value is 235MPa.

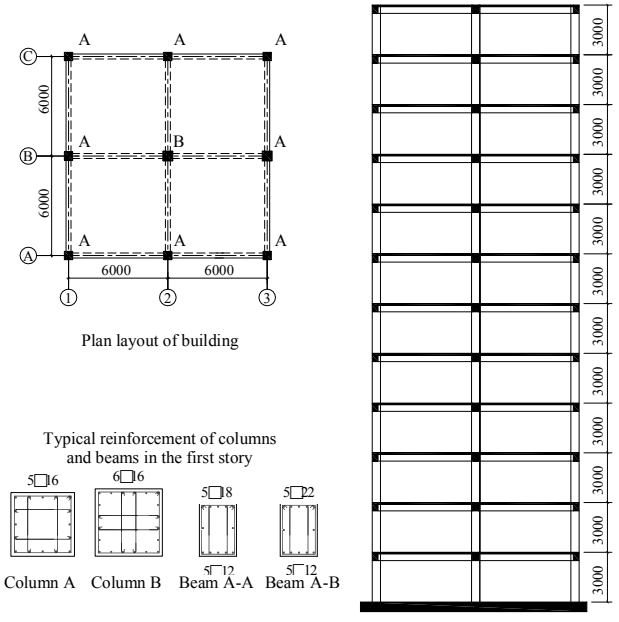

Figure 3 The 12-storey RC moment resistant frame building

4.2 Nonlinear Model for Dynamic Analyses

Nonlinear dynamic analyses were conducted for the 12-storey frame with different ground motions. The computer software for three dimensional nonlinear and dynamic structural analysis CANNY (Li 2009) was selected for the analyses. The mass of each floor was lumped at the column joints according to the tributary areas.

The beams were modeled as linear elastic elements

with two inelastic single-component flexure rotation springs located at the ends of the member. Columns were simulated by multi-axial spring model (called MS model), which was developed to reproduce the behavior of flexure and axial deformation of column element. The MS model has a line element and two multi-axial spring element at the column ends. Meanwhile, the multi-shear-spring model, which was arranged at equal angle in the section at column middle span, was intended to simulate the biaxial shear behavior of column element subjected to bi-directional lateral loads. The frame joints were assumed to be rigid and rigid zones were applied at the ends of each member (although this assumption does not conform to reality). Figure 4 shows the idealization of different members of the studied frames.

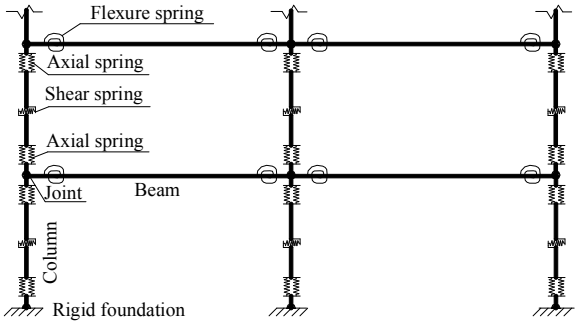

Figure 4 Analytical model of the studied frame

Unlike linear analysis, where the elastic stiffness and percentage of critical modal damping remain constant, in nonlinear analysis the stiffness matrix softens due to inelastic effects, and the relative significance of damping can change dramatically during the analysis. For example, consider a case where the damping matrix is defined based on the initial elastic stiffness and the fundamental period of vibration. If the damping matrix is fixed during the analysis, then as the structure softens and the effective first-mode period elongates, the percentage of damping in the elongated fundamental mode will tend to increase. The relative significance of the damping matrix would increase as the stiffness matrix softens. Considering the structure under multiple earthquakes, such a change of damping ratio ought to be adopted in our study. In the paper, the approach of renew damping at stiffness change is conducted, so it make the program extract mode and re-evaluate the damping coefficients for stiffness matrix proportional damping in the occurrence of stiffness changes.

4.3 Properties of the Selected Ground Motions

The selection of appropriate ground motions for a given structure from available records represents a crucial task in earthquake engineering. The selection of records for the site is generally based on the magnitude, the site-source distance and the local soil condition. Although many aftershock accelerations were recorded in past research, to obtain some general conclusions, some certain ground motions were selected.

Select a representative set of three ground motions were applied as input accelerations based on the site condition, without regard to the fault mechanism, magnitude and attenuation relationships. Quantifying these uncertainties is beyond the scope of this paper.

The selected ground motions included two natural records and one artificial wave. Figure 5 shows the comparison of response spectrum of input seismic waves and design spectrum in GB50011-2001 Code.

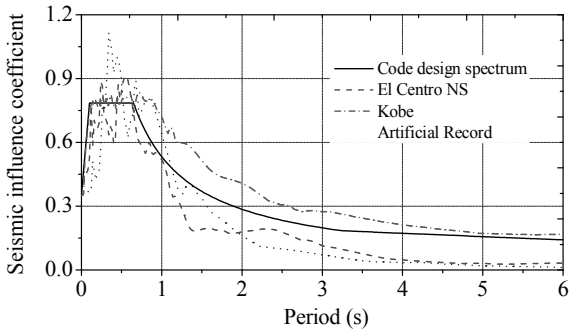

Figure 5 Comparison of response spectrum between code design spectrum and selected ground motions

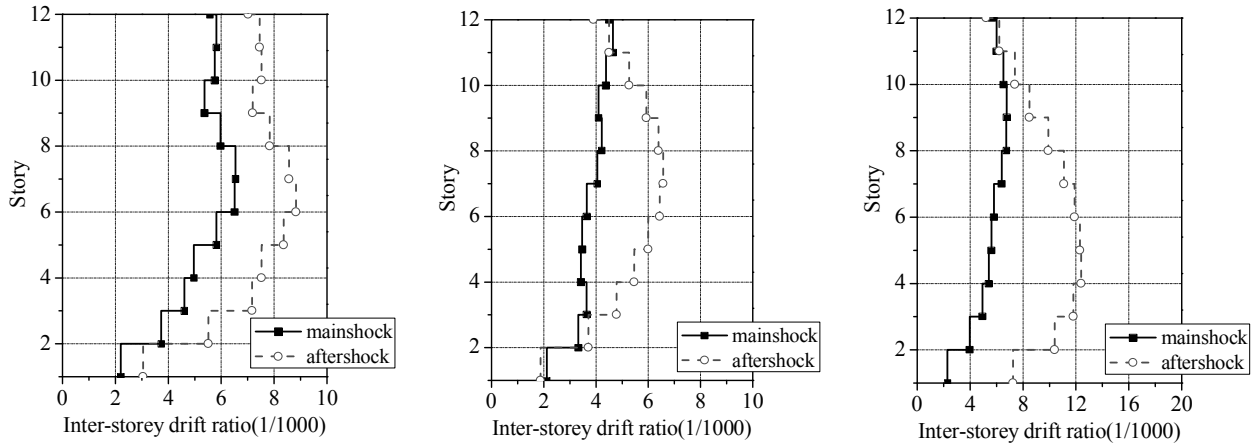
4.4 Analytical Procedures

Researchers have to agree that the characteristics between a mainshock and its following aftershock is related on many factors, including intensity or magnitude, the effect of duration, elapsed time from mainshock and site location, all of which exhibit some stochastic effects. Identifying all such information is a complex task that beyond the scope of this paper.

Referring to the research approach adopted by Lee and Foutch (2004), the mainshock and aftershock accelerograms were repeated in this study with appropriately scaled intensity for simplicity. This is a deterministic and extreme condition procedure. The hazard levels were considered by the following way: 2% and 63% probability of exceedance in 50 years.

In the proposed methodology, same ground motion was selected with different intensity as its aftershock under the assumption that some certain degree of correlation in aftershock locations is potentially to be expected given that they are induced by the mainshock.

5. ANALYSIS RESULTS



5.1 Damage Development under Different Hazards

Assuming that the structure did not experience a local and global collapse, the damage states of the building were recorded under different intensity ground motions, which simulated the effect of aftershock.

To simplify the outcome, some typical components, including three columns and two beams at Floor 1, were selected to show the damage development. Table 1 indicates the damage pattern that subjected to different hazard levels.

Table 1 Comparison between damage of multiple earthquakes to some typical components

Component	El Centro		Kobe		Artificial wave	
	2%/50	63%/50	2%/50	63%/50	2%/50	63%/50
C1 (X1-Y1 1F)	50.0% concrete tension crack at bottom ends	67.5% concrete tension crack at bottom ends	60.8% concrete tension crack at bottom ends	60.8% concrete tension crack at bottom ends	68.1% concrete tension crack at bottom ends	component yield
C2 (X2-Y1 1F)	39.1% concrete tension crack at bottom ends	56.6% concrete tension crack at bottom ends	50.1% concrete tension crack at bottom ends	60.8% concrete tension crack at bottom ends	60.1% concrete tension crack at bottom ends	component yield
C3 (X2-Y2 1F)	50.0% concrete tension crack at bottom ends	77.1% concrete tension crack at bottom ends	61.7% concrete tension crack at bottom ends	61.7% concrete tension crack at bottom ends, 5.7% concrete tension crack at top ends	61.7% concrete tension crack at bottom ends	61.8% concrete tension crack at bottom ends
B1 (X1-X2 Y1 1F)	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of left ends cracks	Concrete of two ends cracks
B2 (X1-X2 Y2 1F)	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of two ends cracks	Concrete of left ends cracks	Concrete of two ends cracks

(a) El Centro (b) Kobe (c) Artificial wave

Figure 6 Comparison of inter-storey drift between mainshock and aftershock

An amount of additional damage occurred for the aftershock analysis. Significant differences of damage development were observed between different ground motions.

5.2 Inter-storey Drift Analysis

The second input of 63%/50 accelerograms resulted in the inter-storey drift of overall structure further increased. Results for the building are shown in Figure 6.

Compared to El Centro and Kobe, the second input of artificial wave leads to the inter-storey drift increase obviously. This is consistent with the damage development results shown in Table 1, which indicates that more damage develops under artificial input.

5.3 Change of Natural Period of Vibration

The change of natural period of vibration is a good indicator to performance evaluation. Previous study had rarely focused on such point. According to the change of nature period, the degradation of structural stiffness could be obtained quickly.

Table 2 Natural period of vibration before and after different ground motions

Input	Undamaged (s)	After 2%/50 Input (s)	After 63%/50 Input (s)
El Centro	1.304	3.34	3.40
Kobe	1.304	3.37	3.50
Artificial	1.304	3.73	4.37

The natural period of building before and after each ground motion input is given table 2.

6. SUMMARY AND CONCLUSIONS

This study focused on the potential effect of multiple earthquakes, which might cause more extensive structural damage and change the dynamic property of the structure. The research about structure under multiple earthquakes has risen recently. However, the focuses of these studies are different.

Three ground motions were selected to evaluate the effect of back-to-back earthquakes on different hazard levels. The results demonstrate that, the second input could cause structural damage and inter-storey drift also increased. It should be pointed out that the purpose of this paper is to describe the effect of multiple earthquakes. However, different ground motions input may produce different results.

The following aftershock is related on many factors, including intensity or magnitude, the effect of duration, elapsed time from mainshock and site location, all of which exhibit some stochastic effects. Accordingly, studies are needed to ascertain these factors in the further research.

Abstract: While hybrid structures that consist of reinforced concrete columns and steel beams exhibit advantages from both structural and constructional viewpoints, they are expected to provide repairable performance for post-seismic immediate occupancy. This paper introduces a new type of RC column-steel beam connection for this purpose. The joint region is composed of face plates, stiffening web with holes and connecting bolts. Based on the experimental study, nonlinear finite element analysis is carried out to investigate the mechanical behavior of such connection. A detailed three-dimensional finite element model is developed, which takes into consideration the nonlinear material behavior of steel and concrete, as well as the surface-to-surface contact problem. The finite element model is validated using the pseudo-static test results of precast RC column-steel beam subassemblies previously obtained. Stress fields in the steel components and concrete obtained from the analytical study are presented to determine the internal mechanisms of the joint region. Experimental and analytical results show that such connection form offers a reliable connecting quality. Stiffening web inside joint contribute to the shear resistance capacity of such hybrid connection. Concrete diagonal strut is observed between the horizontal stiffeners in the analytical results.

1. INTRODUCTION

Hybrid frames that consist of reinforced concrete (RC) columns and steel (S) beams have gained increasingly concern due to its widely accepted advantages. The effective combination of such two kinds of structural members enables long span floor framing and reduces significantly the weight of the building. While such hybrid structures exhibit advantages from both structural and constructional viewpoints, they are expected to provide repairable performance for post-seismic immediate occupancy.

Prefabricated RCS frames system can be developed as a main alternative for this purpose. The reinforced concrete columns and composite floor system can be produced in factory and fabricated at the construction site, instead of conventional cast-in-site construction method. Such industrialized construction method of buildings offer significant advantages, such as shortened construction time, less construction site waste, less environmental emissions, and reduction of energy and water consumption. Furthermore, structural members can be replaced easily when suffering from earthquake, and the damaged members can also be reused for other purposes, resulting in material cost savings. Therefore, prefabricated RCS frames offer a substantial opportunity to provide repairable performance for post-seismic immediate occupancy and promote the sustainable development of structural engineering.

Connection technologies have significant influence on the repairable performance and seismic behavior of such RCS frames. Numerous joint details have been developed in the recent decades to make the RCS frame systems practical. The through-beam-type RCS hybrid joint in which steel beams running continuously through column panel zones has been studied in previous work by the authors (Shiekh et al. 1989, Parra-Montesinos and Weight 2000, Liang and Parra-Montesinos 2004). Extensive research work has focused on the development of RCS connection details and seismic behavior of RCS hybrid connection. However, joint details in such connection are considered complicated, so that some operation difficulties still exist in concrete placement, as well as longitudinal bars passing through flanges and stirrups passing through webs, especially when beams are framing into the joint region from more than one direction. In addition, connection behavior varies with different joint details such as face bearing plates, steel band plates, and so on. Through-column-type has been studied, as shown in the work by Kuramoto and Nishiyama (2004). Another connection is so-called “end-plate bolted connection”, in which bi-directional bolts holes in the joint region largely weaken shear capacity of concrete in the joint region, such connection has been researched in

previous work by the author(Ma. 2003). The engineering application of RCS hybrid frame systems has been limited due to the existence of problems in such RCS hybrid connection. Therefore, advanced research work for developing a new type of RCS hybrid connection is needed.

Based on the research of above RCS hybrid connections, a new type of RCS connection was proposed. The joint region is composed of inside stiffening web, steel cover plates, horizontal stiffeners and connecting bolts. The concrete in the joint region is encased by face plates and embedded with stiffening webs, which can largely enhance the shear resistance capacity of joint. Drilling holes or welding studs on stiffening webs can be adopted to provide shear transferring capacity between the stiffening webs and the surrounding concrete in the joint region. End-plate bolted connection between steel beam and RC column is adopted, thus the steel beams can be replaced when it suffers severe seismic damage.

An experimental program involved RC column-steel beam subassemblies has been conducted under low cyclic reversed loading to investigate the seismic behavior of prefabricated RCS subassemblies and the efficiency of the new type of joint detail. In order to further clarify the mechanical characteristic of the new type of RCS connection, nonlinear numerical simulation of two RC column-steel beam connections under monotonic loading was carried out using ANSYS program.

2. EXPERIMENTAL PROGRAM

2.1 Description of Test Specimens

Half scale RC column-steel beam subassemblies were designed following a strong column-weak beam philosophy, which simulated interior joint for RCS frames. The cross-sections of the columns were 250mm ×250mm, and the cross-sections of the beams were 248mm × 124mm × 5mm × 8mm, which were Q235 grade. Eight HRB400 grade longitudinal bars which diameter was 16 mm were arranged symmetrically, and 6mm–diameter stirrups with 100 mm spacing were used in each column, as shown in Figure 1. Concrete grade of the column was C40.

Details of steel components of the connection are shown in Figure 2. Steel components composed of stiffening webs, face plates, batten plates and horizontal stiffeners were welded as a steel assembly. The thickness of the stiffening webs with holes was 8mm for specimen 1 and 6mm for specimen 2. Three batten plates were welded to the face plates in order to observe the concrete cracking, and there were no stirrups in the joint region. The thickness of the face plates was 20mm, while the thickness of the batten plates was 6mm. The depth of the face places was 440mm.

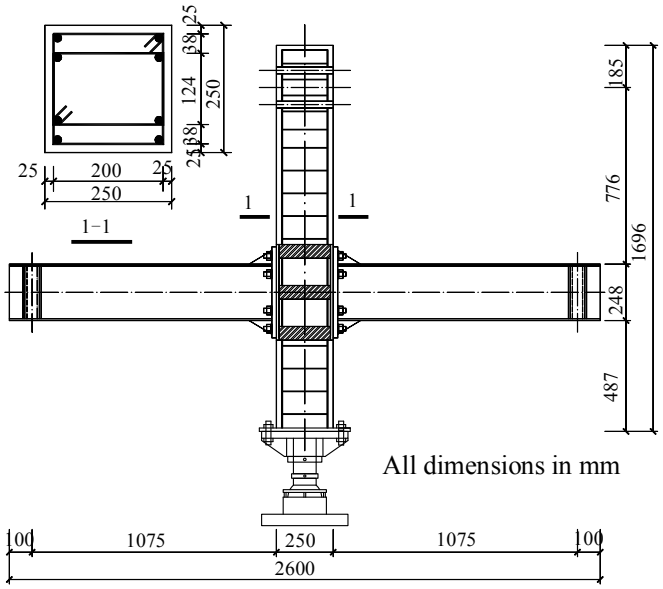

Figure 1 Details of Specimens

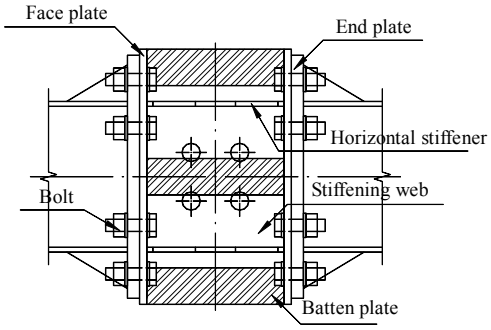

Figure 2 Connection Details

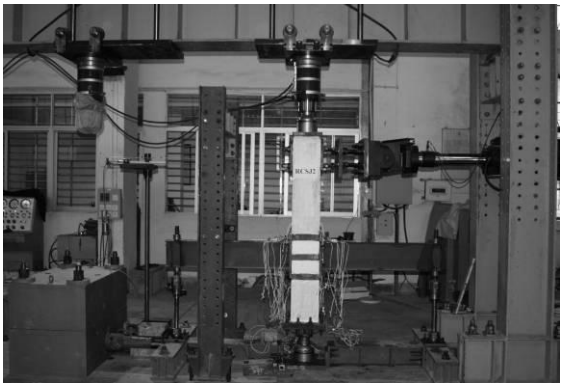
Steel beams and steel components in the joint region were shaped in the factory, gas shielded welding was applied in the steel welding work to ensure welding quality. High strength bolts (grade 10.9M20) were adopted in the connection. During the preparation of



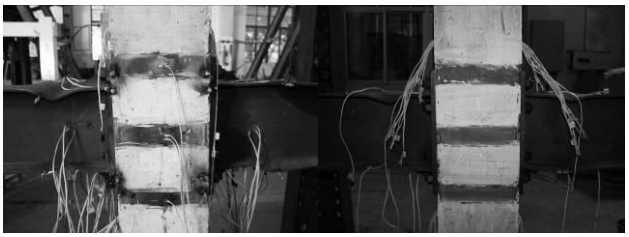


Figure 3 Test Set-up

specimens, steel assembly was installed into the column reinforcement before placing concrete. The bolts were fixed on the face plates by welding. After the columns were shaped, steel beams were installed on the precast columns.

The test setup used for the experimental program is shown in Figure 3. During the test, the constant axial compressive load was held at the top of the column by a hydraulic jack. The lateral cyclic reversed loading was applied at the top of the column. The lateral load was reversed once starting from 60kN and increase by 20kN for each cycle, lateral displacement was repeated in three cycles after specimens yielding, each at the story drift angles of 1/50, 1/35, 1/25.

2.2 Test Results

Visual observation revealed that specimens performed similarly with plastic hinges formed at the beam ends near the end-plates, where local buckling took place at the beam flanges and webs, and shear failure of the concrete panel were not observed even at the final stage of loading, only minor damage such as some diagonal cracks were observed in the joint region, as shown in Figure 4. In addition, the end-plate bolted connection behaved well during the entire test.

(a) Specimen 1 (b) Specimen 2

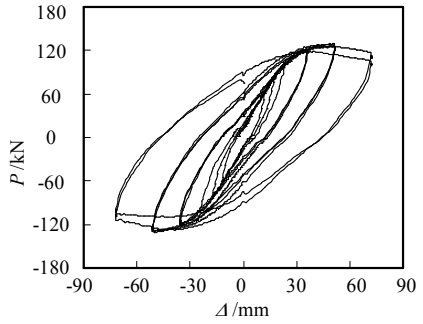

Figure 4 Failure Mode

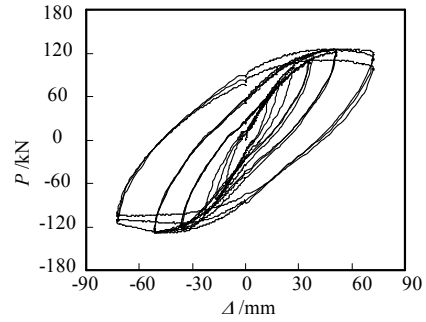
As shown in Figure 5, shuttle-shaped hysteretic responses of lateral load versus story drift for each specimen were observed. At large displacement cycles, during which flexural plastic deformations occurred at the beam ends, plump hysteretic loops were noticed, At 1/35 drift, the specimens reached their peak strength, and large residual deformation were observed. The specimens exhibited stable responses with only minor decay in strength and stiffness during repeated cycles at the same drift level, retaining more than 85% of their peak strength at the end of the tests.



3. ANALYTICAL MODELING

3.1 Element type

Several kinds of element were adopted in the finite element models. Solid65 element was used to model the concrete of column. This type of element is defined by eight nodes having three degrees of freedom at each node, which is capable of cracking in tension and crushing in compression. A value of zero was entered for all real

(a) Specimen 1

(b) Specimen 2

Figure 5 Load versus Story Drift Hysteretic Curves

constants which turned the smeared reinforcement capability of Solid65 element off. Steel beams and all steel plates were modeled using Solid45 element, which has plasticity, stress stiffening capabilities. No real constant set exists for the Solid45 element.

Longitudinal bars and stirrups in the column were modeled using Link8 element, which is a uniaxial tension-compression element with three degrees of freedom at each node. In order to avoid large amount of elements and shorten the computation time, high strength bolts were simplified using Beam4 element, which is a uniaxial element with tension, compression, and bending capabilities.

The interface between the end-plates of beams and the face plates of the joint region was simulated by defining contact pairs with the 3-D target surface element Target170 and the surface-to-surface contact element Contact174. The face plates of the joint region were chosen as the target surface, and the end-plates were chosen as contact surface. The target surface is paired with its associated contact surface via a shared real constant set. The coefficient of friction for the steel contact surfaces was taken as 0.45.

3.2 Material Properties

The uniaxial stress-strain relationship for concrete in compression was simulated with multi-linear isotropic model. Since the axial compression ratio applied on the column is so small that the effect of stirrup confinement is not obviously, Saenz concrete constitutive material model was used, which can be expressed as follows:

$$\sigma = \frac{E_c \varepsilon}{1 + \left(\frac{E_c}{E_c'} - 2\right)\frac{\varepsilon}{\varepsilon_0} + \left(\frac{\varepsilon}{\varepsilon_0}\right)^2} \quad (1)$$

Where E_c is the elastic modulus of the concrete, and E_c' is the secant modulus corresponding to peak stress of stress-strain curve. ε_0 is the strain corresponding to the peak stress of stress-strain curve. The nonlinear compressive stress-strain curve for concrete is shown in Figure 6.

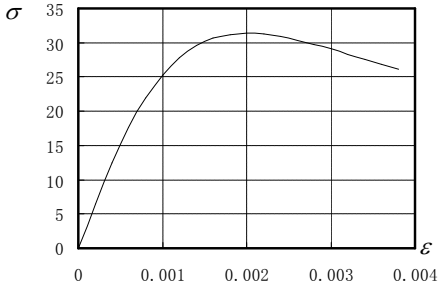


Figure 6 Stress-Strain Curve of Concrete

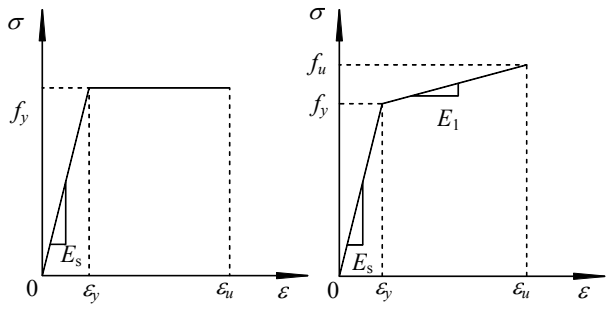

In addition, Willam-Warnke failure model was used as the failure criterion for concrete, where several coefficients are required to input. Additional concrete material data, such as the shear transfer coefficient β_t for open cracks and β_c for closed cracks are also needed. The shear transfer coefficients β_t and β_c control the amount of shear transfer across the cracks. The values of 0.35 and 0.8 were used in the model for β_t and β_c, respectively. The Poisson's ratio was assumed to be 0.2 for concrete. The elastic modulus of concrete, uniaxial compressive and tensile strength was calculated as follows:

$$E_c = \frac{10^5}{2.2 + \frac{34.7}{f_{cu,k}}} \quad (2)$$

$$f_{ck} = 0.76 f_{cu,k} \quad (3)$$

$$f_{tk} = 0.26 f_{cu,k}^{2/3} \quad (4)$$

Where $f_{cu,k}$ is the cube compressive strength of concrete, f_{ck} is the uniaxial compressive strength, f_{tk} is the uniaxial tensile strength.

(a) (b)

Figure 7 Stress-Strain Curves of Steel

The Von Mises yielding criterion with kinematic hardening rule was adopted for all steel materials in the finite element analysis. Elastic-perfectly plastic model was adopted to simulate the stress-strain relationship of all steel plates, as well as flanges and webs of beams, as shown in Figure 7(a). The bilinear stress-strain relationship was used to model the longitudinal bars and stirrups of the columns as shown in Figure 7(b), where E_1=0.01E_s. The elastic modulus E_s and yielding strength f_y were obtained from the testing of material properties, as listed in Table 1. Poisson's ratio was assumed to be 0.3 for steel materials in this analysis.

Table 1 Input Parameters of Steel

Type	f_y (MPa)	E_s (MPa)	E_1 (MPa)
Flange	270.7	1.91×10^5	-
Web	301.9	2.05×10^5	-
Plate (t=6mm)	350.4	1.89×10^5	-
Plate (t=8mm)	339.2	1.94×10^5	-
Longitudinal bar (d=16mm)	490.0	2.19×10^5	2.19×10^3
Stirrup (d=6mm)	428.3	1.95×10^5	1.95×10^3

3.3 Finite Element Mesh

Simplification was made in the modeling so as to avoid detailed modeling and shorten the computation time. The solid model was established according to the geometrical configuration and dimensions of the test specimens. Boolean operations including Glue and Overlap were applied in the solid modeling. The model was segmented by work plane at the location of steel plates or reinforcement in order to facilitate the mesh. Mapped meshing of solid was conducted after the element types and material properties were attributed to the corresponding parts. The meshing of the reinforcement is a special case compared to the volumes. The nodes of reinforcement element were created in the meshing of the concrete volume. The interface between the steel plates and concrete was assumed to have a full bond condition, and the slip between the bars and concrete was also neglected in the analysis. A general view of the three-dimensional finite element model is shown in Figure 8.

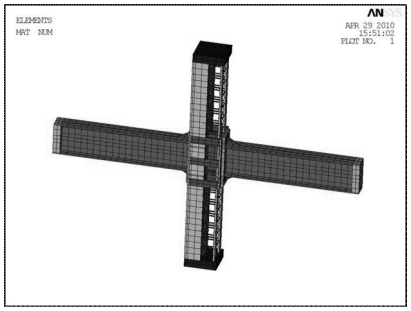

Figure 8 Finite Element Model

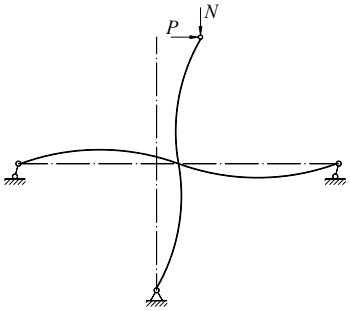
3.4 Boundary Condition and Solution

The boundary conditions of the analytical model were created to be similar to those of the test specimens, as shown in Figure 9. The nodes of the middle line at the bottom of the column were restrained in three translational degrees of freedom, and the nodes located at the beam ends were restrained in the vertical y direction and lateral z direction to enable the horizontal movement of beams. Elastic blocks were placed both at the top and bottom of the column, as well as the beam ends, such operation can avoid stress concentration at the restrained area and achieve convergence better.



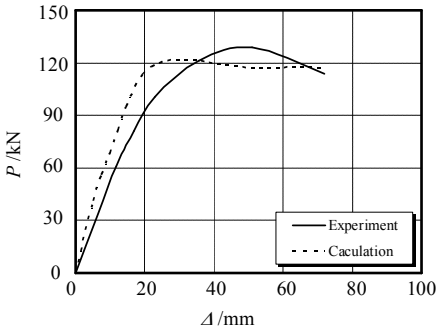


Figure 9 Boundary Condition

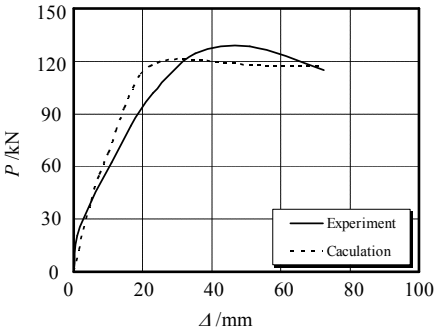
Loading process can be divided into three steps. Temperature load was applied to the bolts to generate the pretension of bolts and the compressive effect between the plates, and then the axial load was applied to the top face of the column. Before displacement was applied to the column, all nodes located at the top face of the column were coupled in the horizontal x direction to ensure all nodes move together, thus, horizontal displacement was applied to the main node. The applied displacement was divided into a series of increments called load steps and load substeps. To predict and control load step size increments, the options of automatic time stepping, linear searching and freedom predicting were turned on in the analysis in order to achieve convergence of the operation. Full Newton-Raphson equilibrium iteration method was adopted in the solution process of nonlinear analysis.



4. ANALYSIS RESULTS AND DISCUSSION

4.1 Comparison of Numerical and Experimental Results

Lateral load versus story drift curves of the analytical results under monotonic loading are compared with experimental load-displacement skeleton curves, as show in Figure 10. In general, load versus displacement response obtained from the numerical analysis showed good agreement with the skeleton curves of experimental results. Difference of the two curves may caused by the existence of frictional force and some initial gap in the test set-up. It is observed that the analytical curve decline earlier than the experimental one, it is due to the fact that elastic-perfectly plastic model is adopted for the steel beam, and the strain hardening is neglected.

(a) Specimen 1

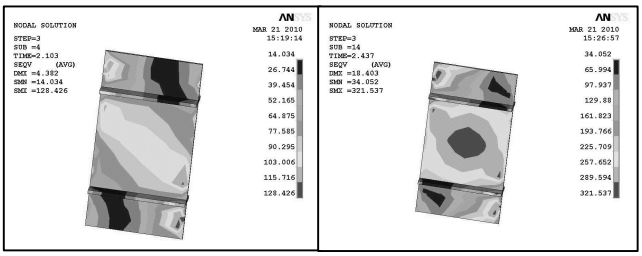
(b) Specimen 2

Figure 10 Comparison of Numerical and Test Results of P-Δ curves

The yield strength and maximum strength of the connections are shown in table 2. The yield strength was obtained by energy equivalent method. It can be seen from Table 2 that the finite element analysis results show fairly good agreement with the experimental ones in terms of yield and maximum strength for each connection.

Table 2 Comparison of Numerical and Test Results

Specimen	Yield Strength(kN)		Maximum Strength(kN)	
	$P_{y,c}$	$P_{y,t}$	$P_{max,c}$	$P_{max,t}$
1	106.15	101.63	121.98	129.10
2	110.70	98.62	121.31	128.42

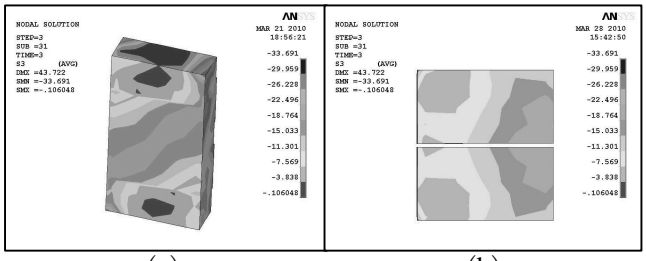


Note: The subscript c and t represent the calculation and experimental results, respectively

4.2 Stress Distribution of Numerical Results

The numerical simulation also provides some extra valuable results which were hard to measure during the testing, including the stress distribution of steel components and concrete in the joint region.

The Von Mises stress distribution of inside stiffening web for specimen 2 is shown in Figure 11. It can be noticed that diagonal principal stress flow of stiffening web formed between the horizontal stiffeners before yielding, and then yielding area expand gradually with the load increasing. It is indicated that stiffening



web contributes to the shear resistance capacity of such connection.

(a) (b)

Figure 11 Stress Distribution of Stiffening Web

The stress distribution of the concrete in the panel zone of specimen 2 at the ultimate stage is shown in Figure.12. It can be seen that a diagonal strut is formed in the concrete between the horizontal stiffeners to resist the shear force of the panel zone. Therefore, the diagonal strut model can be used in the shear capacity analysis for concrete in the panel zone. It can be also observed that the effect of diagonal strut decrease outward.

(a) (b)

Figure 12 Stress Distribution of Concrete

The stress distribution of the batten plates is shown in Figure 13. It can be noted that the stress of batten plates is small, which is consistent to the experimental observation of strain value. Figure 14 shows the stress distribution of the face plates, which indicates that there are somewhat stress concentrated at the location of tensile bolts.

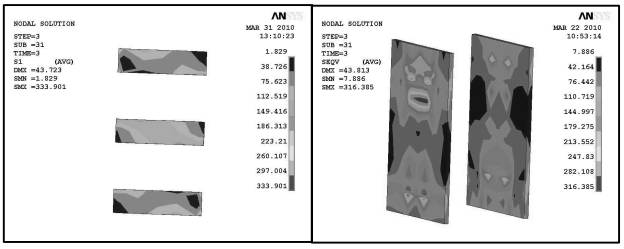


Figure 13 Batten plates

Figure 14 Face Plates

5. CONCLUSION

This paper introduces a new type of RCS connection. Based on the experimental results of connections composed of reinforced concrete columns and steel beams, three-dimensional nonlinear finite element model was established using ANSYS program with appropriate modeling methodology. Finite element analysis was conducted under monotonic loading to analyze the mechanical characteristic of such type of connection. The main results can be summarized as follows:

(1) The lateral load-displacement curves obtained from the finite element analyses are in good agreement with those of the tests. The overall behavior of RCS connection of this type can be efficiently simulated, which allows for further parametric analysis of the new type of RCS connection.

(2) The existence of stiffening web inside joint region is effective for the shear resistance capacity of such connection. Concrete diagonal strut is formed between the horizontal stiffeners in the analytical results, which provide a basis for the theoretical analysis of the shear resistance capacity for the new type of RCS connection.

(3) Both analytical and experimental results indicate that end-plate bolted connection composed of reinforced concrete columns and steel beams is feasible and offers a reliable connecting quality, which facilitates the replacement of steel beams when they suffered from earthquake damage.

Abstract: Composite Concrete Encased Steel (CES) structures composed of steel and fiber reinforced concrete (FRC) have been continuously studied by the authors. In this study, static loading tests of CES shear wall whose anchoring method to connect CES frame with FRC wall panel was simplified were carried out, and the basic structural performance, strength, deformability and failure mechanism of the CES shear wall were investigated. Variables investigated are the anchorage conditions between CES beams and FRC wall panels and the failure mode of the shear walls, the anchorage conditions tested were two types in which longitudinal wall reinforcing bars are connected to CES boundary beams or not, while the failure modes selected are the flexural failure and shear failure of the shear walls. In this paper, structural performance of CES shear wall obtained from the tests are described. The results show that the effect of the anchorage condition of wall longitudinal reinforcement on both shear and flexural strengths of CES shear wall is not significant. The deformability of CES shear wall is slightly improved by omitting anchorage of wall longitudinal reinforcement because the damage area of concrete in wall panel is reduced with increasing slip deformation between walls and boundary beams.

1. INTRODUCTION

Steel Reinforced Concrete (SRC) Structures developed in Japan have good structural performance for resisting lateral forces imposed by wind and earthquakes, and have been adopted for medium-rise, high-rise, and super high-rise buildings. However, the number of SRC buildings constructed has decreased since the 1990s. Although the decrease might be caused by the development of a new structural engineering system called the High-strength concrete structure or Concrete-Filled Steel Tube (CFT) structure, the main reason seems to be the construction problems that increase construction costs and lengthen construction schedules. Even so, it could be important that SRC structures provide better seismic performance in comparison with other structural systems. So, the authors aim to develop a structural system with as good seismic performance as SRC structures and good workability, and have conducted a continuing development study on composite Concrete Encased Steel (CES) structures composed of steel and fiber reinforced concrete (FRC) as shown in Figure 1.

In the experimental study on CES columns, CES beam-column joints and two-bay two-story CES frame, it was confirmed that CES structural system showed stable restoring force characteristics and good seismic performance.

On the other hand, shear wall which is main earthquake resistant member is effective in increasing stiffness and strength for also CES structural system. However, it will be difficult to arrange reinforcement bars in CES structure which have encased steel in beam and column. In recently, there are some researches about method of joint of frame and wall panel on SRC shear wall, it is an important problem to improve workability of joint of frame and wall panel in CES structure.

(a) SRC structure (b) CES structure

Figure 1 Composite Concrete Encased Steel structural system

In this study, Static loading test of CES shear wall whose anchorage method of CES frame and FRC wall panel is simplified was carried out, and basic structural performance, strength, deformability and failure mechanism of the CES shear wall are investigate.

2. OUTLINE OF CES COLUMN TEST

2.1 Description of Specimens

The specimens are designed to simulate the lower two story of multi-story shear wall in medium-high-rise building and scaled to one-third of the prototype walls. Four specimens were prepared in this test.

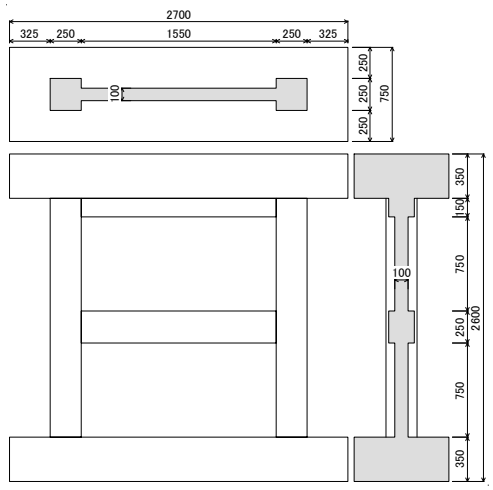

Figure 2 Test specimens

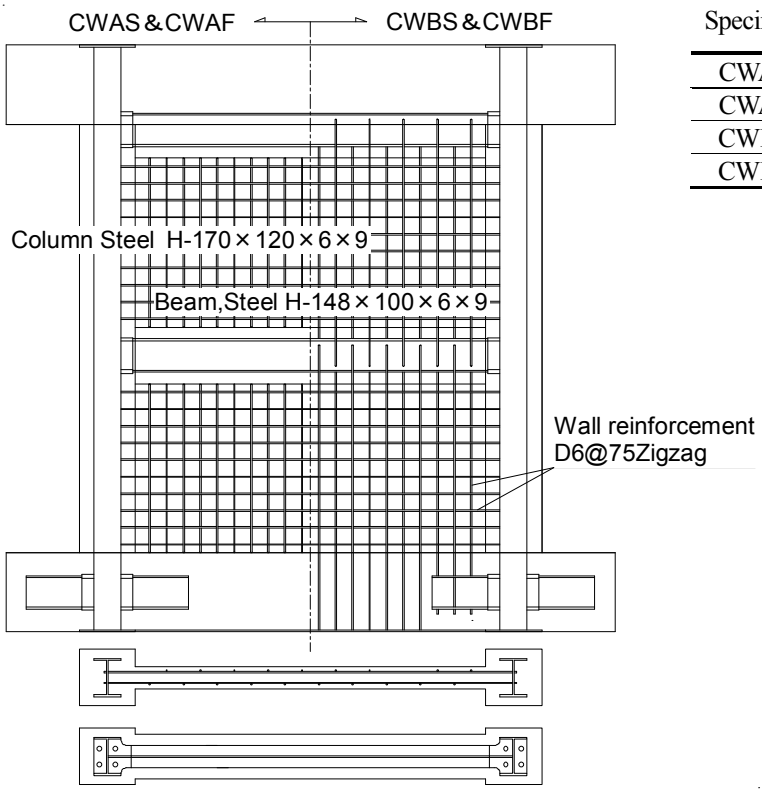

Figure 3 Bar arrangement

Configuration and bar arrangement of specimens are shown Figure 2, Figure 3 and Figure 4. Detail of the section is shown in Table 1. The column has 250 mm square section, the beam has the section of 200 mm×250 mm. The column span length is 1800mm and thickness of wall is 100 mm. Experimental variables are the shear-span ratio and anchorage condition of longitudinal wall reinforcement as shown Table 2. Shear span ratio are 1.1 of specimen CWAS and CWBS, and 1.65 of specimen CWAF and CWBF. Specimen CWAS and CWBS expected to be shear failure. Specimen CWAF and CWBF expected to be flexural failure. Longitudinal wall reinforcement of Specimen CWAS and CWAF is bent in wall panel. On the other hand, longitudinal wall reinforcement of Specimen CWBS and CWBF is anchored to beam or stub as shown in Figure 4. Horizontal wall reinforcement bars in all specimens are securely fixed by welding to steel web of column.

Table 1 Specification of section

Column	BxD (mm)	250×250
	Steel	H-170×120×6×9 ($_{s}p$=4.9%)
Beam	BxD (mm)	200×250
	Steel	H-148×100×6×9 ($_{s}p$=5.2%)
Wall	Thickness (mm)	100
	Longitudinal bar	D6@75 zigzag ($_{w}p$=0.42%)
	Transverse bar	

Table 2 Experimental variable

Specimen	Shear span ratio	Anchorage of longitudinal wall reinforcement
CWAS	1.10	Nonexistence
CWAF	1.65	
CWBS	1.10	180° hook in beam
CWBF	1.65	

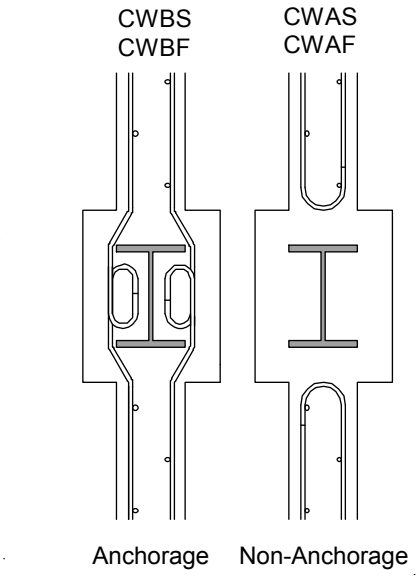

Figure 4 Bar arrangement in the beam

Mechanical properties of concrete and steel used are shown in Tables 2 and 3. Vinylon fibers with a diameter of 0.66 mm and a length of 30 mm were used for FRC. The volumetric ratio of the fibers was 1.0% and the water-cement ratio was 60%.

2.2 Loading Procedure

Figure 5 shows the loading apparatus used. The wall specimens were loaded with horizontal cyclic shear forces by a hydraulic jack of 2,000 kN capacity with applying constant axial force of 1260kN (N/N_0=0.2, N: axial load, N_0: axial load capacity including steel of columns) by two vertical manual jacks of 2,000kN capacity for each. During the testing, the additional moment was also applied to the top of specimens using vertical jacks to keep the prescribed shear-span ratio of 1.1 or 1.65 as the following equations.

Table 2 Material properties of concrete

Specimen		σ_B (MPa)	E_c (GPa)	ε_{c0} (μ)	Age (day)
CWAS	1 story	38.6	24.8	2814	91
	2 story	36.4	26.7	2550	86
CWBS	1 story	42.0	25.7	2587	94
	2 story	30.6	29.5	2558	89
CWAF	1 story	41.2	25.5	2457	100
	2 story	38.6	27.6	2423	95

	Yield strength (MPa)	Tensile strength (MPa)	Elastic modulus (GPa)
PL-6 (SS400)	260	409	190
PL-9 (SS400)	282	418	197
D6 (SD295A)	345	501	190

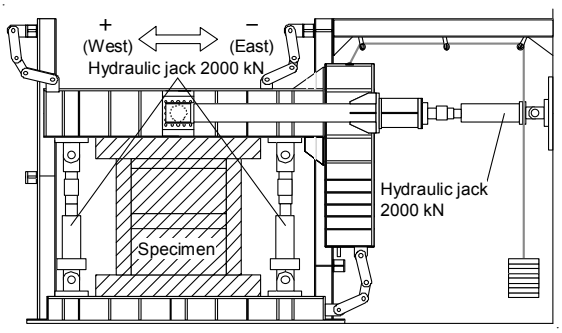

Figure 5 Loading apparatus

$$N_e = \frac{N_c}{2} - \frac{Q}{l}(h-a), \quad N_w = \frac{N_c}{2} + \frac{Q}{l}(h-a) \qquad (1)$$

Where, N_e: axial force of east side jack, N_w: axial force of west side jack, N_c: constant axial force (1260kN), Q: Shear force, l: distance between two vertical jack, h: assumed height of applying shear force, a: actual height of applying shear force.

The loading was conducted by controlling the relative wall drift angle, R, given by the ratio of the height of corresponding to the measuring point of horizontal displacement at the top of the specimen, h (2,050mm), to the horizontal deformation, δ, i.e. R=δ/ h. The horizontal load sequence consisted of two cycles to each story drift angle as shown Table 4.

2.3 Measuring method

Measuring plans of displacement and strains of bars and steel are shown in Figure 6. Measured points of

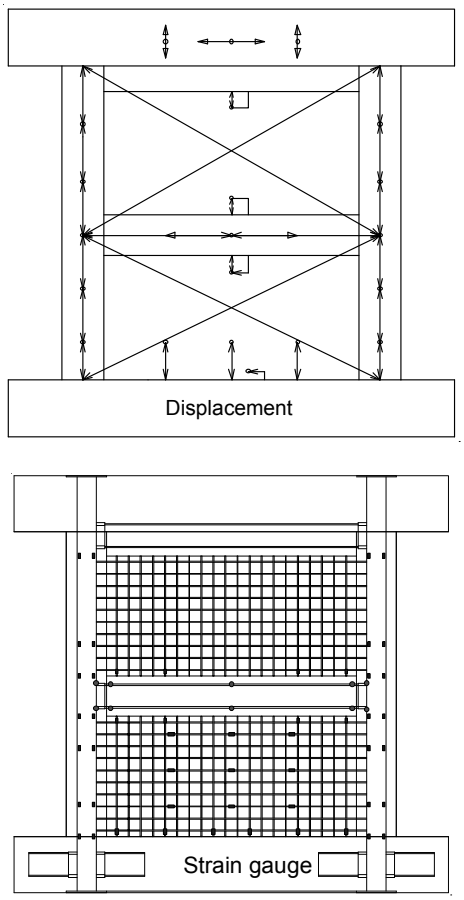

Figure 6 Measured points

Table 4 Loading cycle

R ($x10^{-2}$)	0.0625	0.125	0.25	0.5	0.75	1.0	1.5	2.0	3.0	4.0
δ (mm)	1.28	2.56	5.13	10.3	15.4	20.5	30.8	41.0	61.5	82.0
Cycle	1	2	2	2	2	2	2	2	1	1

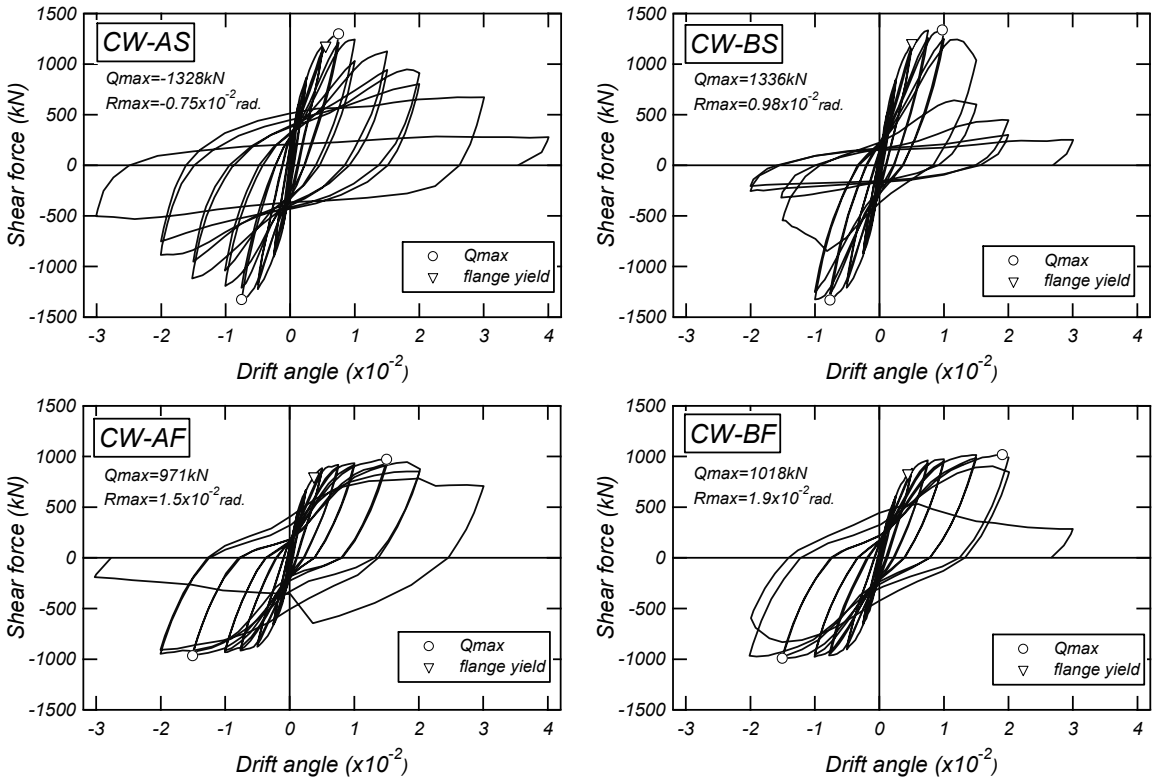
displacement are horizontal displacement, longitudinal deformation of column and partial deformation of wall panel. The strain of steel of column and beam, longitudinal bar and horizontal bar of wall are measured by strain gages. Additionally, widths of crack are measured with crack scale after each loading cycle.

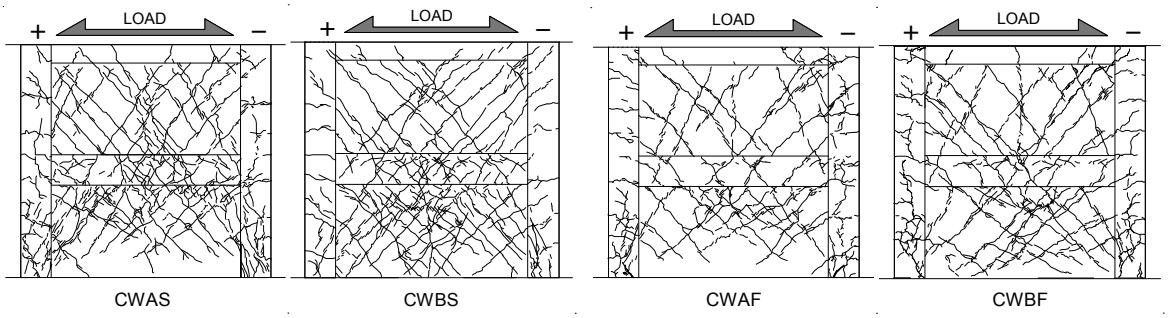
3. TEST RESULTS

3.1 Failure Mode and Hysteretic Characteristics

Figure 7 shows the shear force versus drift angle relationships for all specimens. Figure 8 shows cracking pattern of each specimen after load cycle of 0.0075 and 0.03rad..

Results of Specimen CWAS and CWBS which are





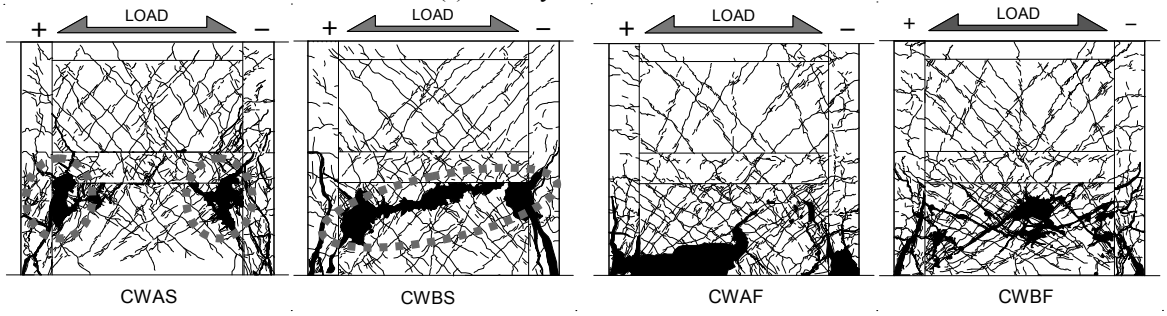


Figure 7 Shear force versus drift angle relationships

(a) After cycle of 0.0075 rad.

(b) After cycle of 0.03 rad.

Figure 8 Cracking patterns

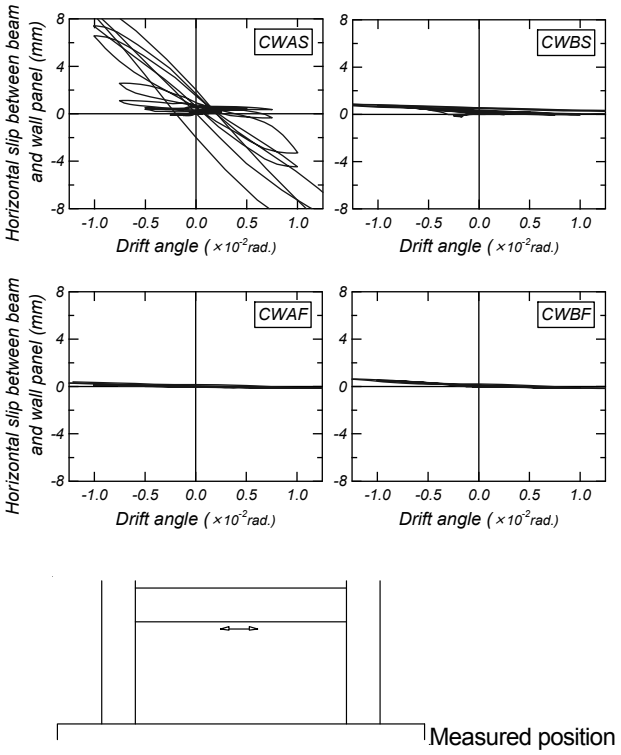

Figure 9 Horizontal slip between beam and wall panel

shear failure type are shown. As to Specimen CWAS without anchorage of wall reinforcement, steel flange of column yielded in the cycle of 0.0075 rad., and then maximum shear force reached 1328kN. As to Specimen CWBS with anchorage of wall reinforcement, steel flange of column yielded in the cycle of 0.005 rad., and then maximum shear force reached 1336kN in the cycle of 0.01rad.. Maximum shear forces of both specimens are almost same. However, deformability between Specimen CWAS and CWBS is different. After peak, shear forces of Specimen CWAS decreased slowly. But shear forces of Specimen CWBS decreased steeply in the cycle of 0.015rad..

Seeing cracking pattern shown in Figure 8, it is found that Shear failure occurred across the first-story wall in Specimen CWBS in final load cycle. On the other hand, Specimen CWAS showed much shear cracks at the upper corner of first-story wall in the cycle of 0.0075rad, and damage of concrete of Specimen CWAS concentrate at the upper corner of first-story wall in the cycle of 0.03rad., and it is shown that final damage condition is also different between Specimen CWAS and CWBS.

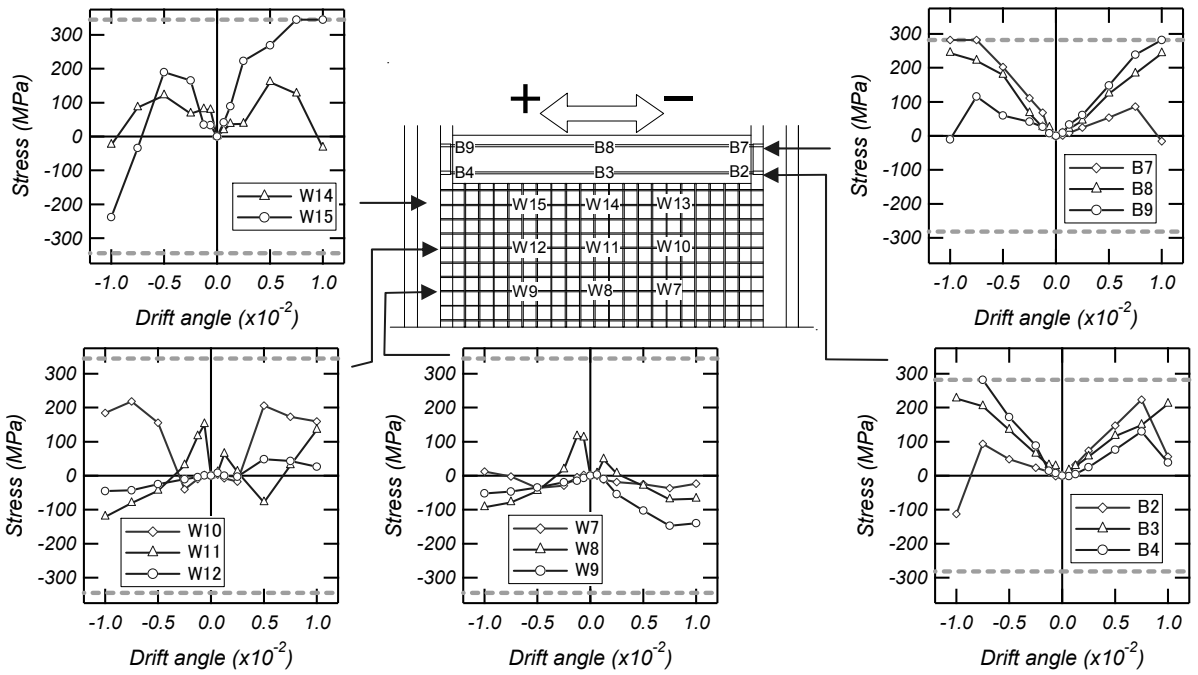
Figure 9 shows horizontal slip between boundary beam and wall panel. In Specimen CWAS, the slip increase in the cycle of 0.01rad. after reaching maximum shear force. But the slip hardly occurs in Specimen CWBS. Therefore, , it is thought that discrepancy is shown in deformability between Specimen CWAS and CWBS, because damage area of concrete of wall panel in Specimen CWAS is reduced by occurring slip under the beam after reaching maximum shear force due to without anchorage of wall reinforcement.

Results of Specimen CWAF and CWBF which are flexural failure type are shown. In Specimen CWAF without anchorage of wall reinforcement, steel flange of column yielded in the cycle of 0.005 rad., and then maximum shear force reached 971kN in cycle of 0.015ra.. In Specimen CWBF with anchorage of wall reinforcement, steel flange of column yielded in the cycle of 0.005 rad., and then maximum shear force reached 1018kN in the cycle of 0.02rad.. Maximum shear forces of both specimens are almost same with or without anchorage of wall reinforcement. Specimen CWAF showed steep strength deterioration in the positive direction loading of 0.03rad. and Specimen CWBF showed steel strength deterioration in the negative direction loading of 0.03rad. as shown in Figure 7. It is found that deformability of Specimen CWBF with anchorage of wall reinforcement is slightly poor.

As the results of these tests, it is though that the effect of anchorage condition of wall longitudinal reinforcement on shear strength and flexural strength of CES shear wall is small. And deformability of CES shear wall slightly improves by omitting anchorage of wall vertical reinforcement.

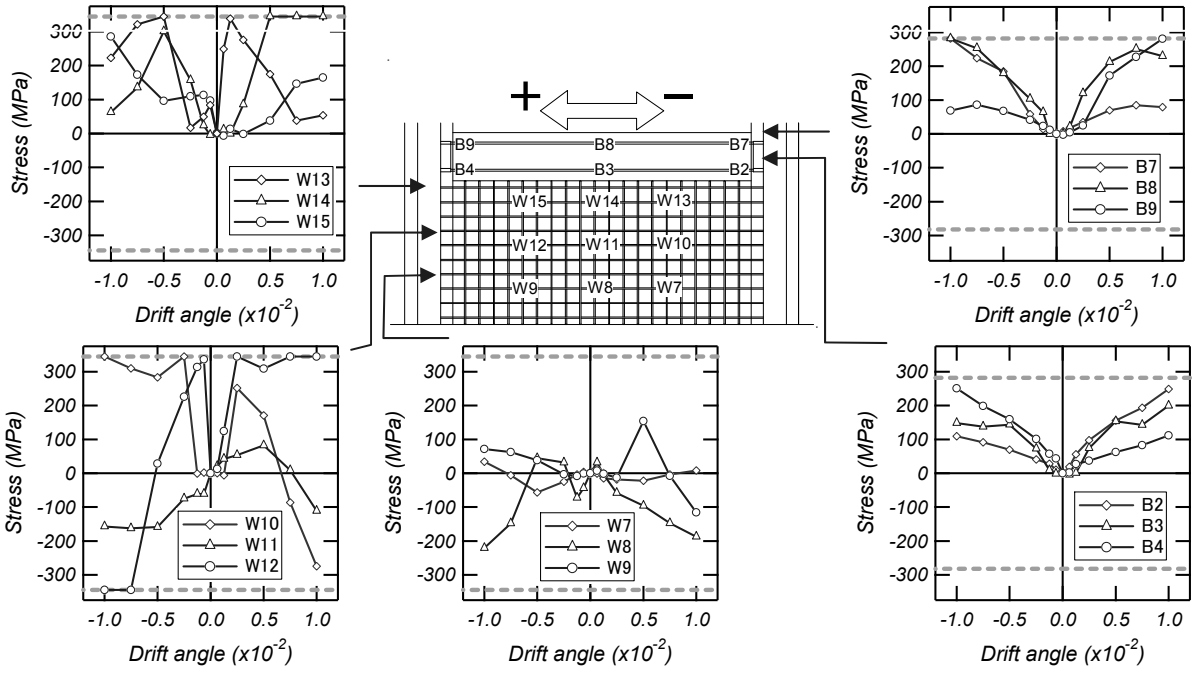
3.2 Stress of Reinforcement Bars and Steel

Figure 10 shows stress of horizontal wall reinforcement bars and steel flange of beam of Specimen CWAS and CWBS which exhibited shear failure until load cycle of 0.01 rad. On the assumption that the hysteresis characteristic of a steel bar is bilinear, the stress was calculated using strain measured by the strain gauge. And dashed line in these figures is yield stress shown in table 3. Data which can not be measured is not plotted in these figures. Stress at the five position are shown, upper flange and under flange of beam, upper section, mid section and under section of wall panel.



As for Specimen CWAS, Horizontal wall reinforcement at upper section yielded at drift angle of 0.0075 rad. when reached maximum shear force. As for Specimen CWBS, Horizontal wall reinforcement at upper and mid section yielded until drift angle of 0.0075 rad. when reached maximum shear force. And stresses of the wall reinforcement at under section are low. These situations correspond to observed damage situation of concrete as shown in Figure 7 of cracking pattern.

Seeing stresses of steel of beam, steel of beam was subjected to tensile force during the load. And either upper flange or under flange of steel beam approximately reach yield stress. It is confirmed that steel of beam work to resist against shear force effectively.



3.3 Curvature of Steel of Column and Beam

Figure 11 shows curvature distribution of encased steel of CES frame of Specimen CWAS which exhibited shear failure. the curvatures were calculated using strain measured by the strain gauge.

In the steel of boundary beam, it is confirmed that reversely symmetric moment occur corresponding to the curvature distribution. In view of side columns, although the effect of boundary beam is seen in west side column, curvature distribution shows almost linear shape at the small

a) CWAS

a) CWBS

Figure 10 Yield situations of horizontal wall reinforcement bars and steel flange of beam
(Dashed line is yield stress of material)

displacement (R=0.0625×10^{-2}rad.) .

Then, curvature distributions are more visible in the at the R of 0.75×10^{-2}rad. when Specimen CWAS reached maximum shear force. When steel of column of first-story is shown, it is confirmed that curvatures in position of circle in the graphs are increase, and moment distribution is estimated from the shape of this curvature distribution as shown in Figure 12. This means the forces dominantly act to side column in external direction. Moreover, it is thought that diagonal compressive force acts in the concrete wall panel surrounded by CES frame and CES frame exhibit the constraint effect on diagonal compressive force.

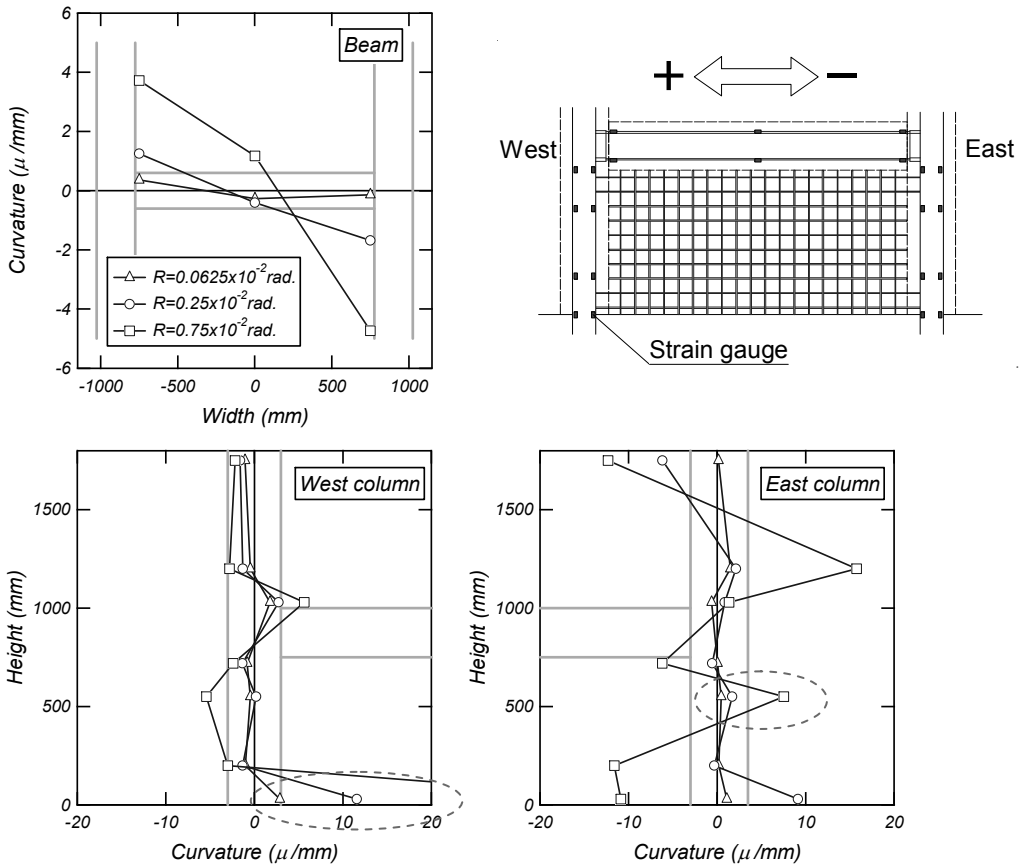


Figure 11 Curvature of steel of CES frame

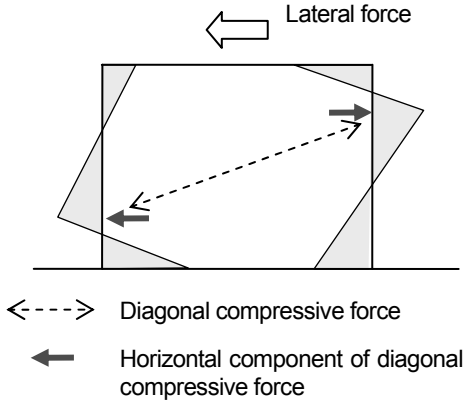

Figure 12 Moment acting to side column at the first-story

4. CONCLUSIONS

Static loading test of CES shear wall whose anchorage method of CES frame and FRC wall panel is simplified was conducted in which the test variables are anchorage condition of longitudinal wall reinforcement and the shear-span ratio. The Failure mode, lateral load carrying capacity and deformability of CES columns were examined. The following conclusions can be drawn.

The specimen CWBS with anchorage of wall reinforcement showed shear failure across the first-story wall panel, the specimen CWAS without anchorage of wall reinforcement showed shear failure at the region of upper corner of first-story wall panel. It is found that fracture region of concrete is different.

It is confirmed that the effect of anchorage condition of wall longitudinal reinforcement on shear strength and flexural strength of CES shear wall is small.

The deformability of CES shear wall slightly improves by omitting anchorage of wall longitudinal reinforcement, It is because that damage area of concrete of wall panel is reduced by occurring slip under the beam after reaching maximum shear force due to without anchorage of wall reinforcement.

It is thought that CES frame exhibit the constraint effect on diagonal compressive force acting in the concrete wall panel surrounded by CES frame.

Abstract: Braced frames are stiff, strong systems, and they are desirable and economical earthquake resistant structural systems in urban areas. However, the design procedures used for braced frames varies from country to country, and their inelastic seismic behavior is not easily evaluated. With concentrically braced frames, seismic behavior is dominated by tensile yield and post-buckling deformation, and this behavior is not well-understood and viewed with distrust. Buckling restrained braced frames are used, but the design requirements and perceived ductility demands vary widely. Recent experimental and analytical research to better understand and evaluate braced frame behavior is summarized. These research results are discussed to provide a better understanding of the seismic performance of different braced frame systems. Methods for improving the seismic performance of braced frames are described, and potential weaknesses or deficiencies of various braced frame systems are noted. In particular it will be noted that the connections used to form the braced frame and the geometry of the bracing system play major roles in defining the seismic performance. The results of recent nonlinear dynamic analyses will be summarized to show the importance of accurate modeling of system nonlinear behavior, and the impact of potential design changes to current US design procedures will be noted.

1. INTRODUCTION

In the US, buildings are designed to remain elastic for small, frequent earthquakes to assure serviceability, but cyclic, inelastic deformation assures that the structure retains its integrity, minimizes loss of life, and prevents collapse during large infrequent events. Special concentrically braced frames (SCBFs) are stiff, strong structures that meet serviceability limits states and provide economical seismic design. During inelastic deformation, the brace buckles in compression, yields in tension, and sustains inelastic post-buckling deformation. Plastic hinges form in the brace due to P-δ moments, and this yielding contributes to the post-buckling yield behavior. SCBFs have special seismic design requirements to insure good inelastic performance. These effects lead to the one-sided axial force-deflection behavior of a braced bay seen in Fig. 1a. SCBFs braces are placed in opposing pairs, and the resulting system has inelastic hysteretic behavior illustrated in Fig. 1b. The braces are attached to the beams and columns by gusset plate connections such as illustrated in Fig. 2. The brace end rotation associated with brace buckling, causes large rotation demands on the gusset plate connection during these larger earthquakes.

Engineers recognize the complex inelastic behavior of SCBFs, and buckling restrained braces (BRBs) have been developed as an alternative system. BRBs are patented structural items where the brace is a small core element encased in a stiff outer casing as illustrated in Fig. 3. The core element is not bonded to the encasing material, and it is free to slip and strain independently of the casing. Therefore, no stress is transferred between the casing and core element. The resulting brace theoretically yields in tension and compression and can tolerate large inelastic axial deformations. As a result, BRBs are highly regarded by engineers and have been used with increasing frequency in recent years. A significant body of research has been completed on their performance, but this research has primarily focused on axial load and the deformation capacities of isolated braces. In the US, BRBs also employ gusset plate connections, but they alleviate the gusset plate rotation required for brace buckling. Nevertheless, BRBs sustain large seismic deformations during severe earthquake loading, and these large frame deformations are the focus of this research.

a) Brace Axial Force-Deflection Hysteresis b) Resulting Frame Lateral Load-Deflection Hystersis

Figure 1 Behavior of Special Concentrically Braced Frames

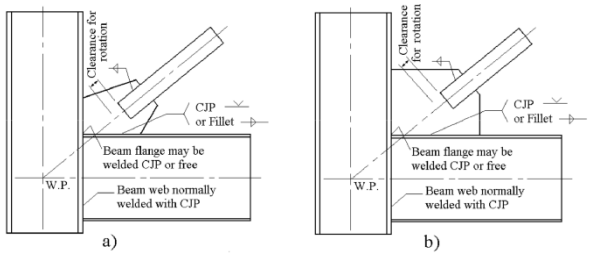

Figure 2. Schematic of Typical Gusset Plate

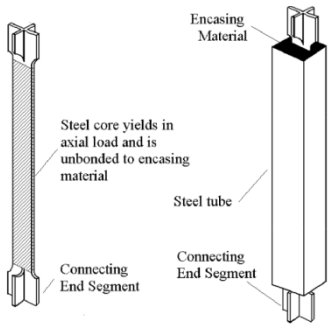

Figure 3. Schematic of Buckling Restrained Brace

2. GUSSET PLATE CONNECTIONS

While gusset plate connections are used for both the SCBF and BRBF systems, there are some differences in their gusset plate connection designs. AISC Seismic Provisions have numerous SCBF and BRBF design requirements, which are intended to assure good inelastic performance (AISC 2005a). For SCBFs, brace slenderness limits are applied to assure that the frame provides adequate ductility during post-buckling deformation, and additional framing system requirements balance the lateral resistance between tensile and compressive braces and control yielding in the beam due to unbalanced brace forces in V- or Inverted V-braced systems. Gusset plate connections are designed by variations of the AISC Uniform Force Method (UFM) (Thornton, 1991; AISC, 2005b), which was originally developed for wind load design. The UFM is adapted to seismic applications by designing the connection to resist the expected tensile ($R_y A_g F_y$) and compressive ($R_y A_g F_{cr}$) resistance of the brace. The expected brace resistances are much larger than the factored design loads. Rectangular high strength steel tubes are commonly used for the brace, and the tube is slit to slip over the gusset plate for the brace-to-gusset interface.

Net section fracture of the brace may occur at the end of the slit, and net section reinforcement is often required. The tubes are normally joined to the gusset plate with fillet welds sized to develop the expected tensile resistance of the brace, and block shear must also be checked for this interface joint. The Whitmore width (Whitmore, 1950) of the gusset plate is defined at the end of the brace-to-gusset interface by projecting a 30^o angle from the start to the end of the bolted or welded joint, and the area associated with this Whitmore width is used to define the area resisting the compressive buckling, tensile yield, and fracture capacities of the gusset. The Thornton method is commonly used for evaluation of this gusset plate buckling, and it uses the Whitmore width with an average effective buckling length of the plate over this width. The effective length coefficient is typically 0.65 for corner gusset plates and 1.2 to 1.4 for midspan gusset plates. The gusset plate must accommodate end rotation due to brace buckling, and this is normally accomplished by the $2t_p$ linear clearance model illustrated in Fig. 2. This requirement commonly results in large gusset plate dimensions and consequently thicker gusset plates. Once the gusset plate geometry and thickness are defined, the bolts or welds joining the gusset plate to the beam and column are sized by the equilibrium forces associated with the UFM. Welds are often fillet welds on both sides of the plate, but complete joint penetration welds may also be employed.

The beam-column connection also affects SCBF performance. Forces that are transferred by the brace to the beam or column or by drag struts to the braced bay frequently must be transferred through this beam-column connection. Some engineers use CJP welds between the beam and column flanges to assure full force transfer (see Fig. 2). Other engineers think that this welding is costly and unneeded, and they may use only web attachments. These combined requirements and practices result in wide variations in gusset plate connection design.

BRBFs have similar gusset plate design requirements, but there are also distinct differences in their design. The connection design utilizes the expected capacity of the brace, but the expected capacity of a BRB includes the strain hardening in tension and compression expected during inelastic deformation. These result in very large connection design forces, especially for the brace in compression. Since BRBs are designed to avoid brace buckling, end rotation due to buckling of the brace is not expected. As a result, the 2tp clearance zone illustrated in Fig. 2 is not required, and the gusset plates are more compact than those used for SCBF systems. The large expected forces lead to thick, stiff gusset plates.

The use of the expected brace forces for connection design is a rational design concept, but it sometimes leads to the mistaken perception that a bigger, stronger gusset plate makes a better connection. As a result, gusset plate connections are generally relative stiff and strong for both SCBF and BRBF systems.

3. RESEARCH PROGRAM

A comprehensive research study addressing the seismic behavior of SCBF and BRBF braced frames has been initiated. The research includes both analytical and experimental investigations. Thirty-six full scale SCBFs and 7 full scale BRBFs have been tested. These tests realistically simulated the demands, capacities, and performance of the braced frames and the gusset plate connections. Figure 4 shows the test setup used for most test specimens. The specimens were subjected to a cyclic

inelastic deformation history based on the ATC-24 testing protocol, although a few tests employed a near-fault deformation history. The experimental results were used to develop, calibrate and verify analytical models that were used to extend the experimental results.

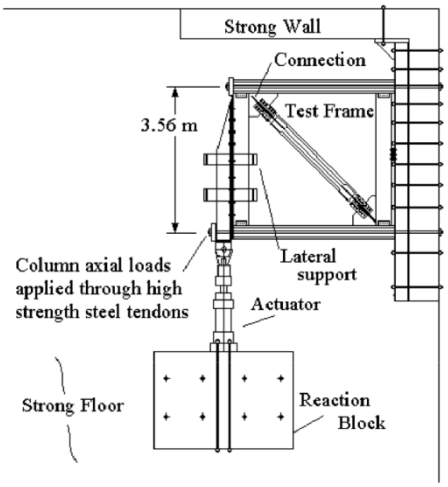

Figure 4. Typical Test Setup

4. SUMMARY OF SCBF RESULTS

The SCBF experimental results are too comprehensive for complete description here, but Fig. 5 illustrates the results from 4 different tests (Johnson 2005, Herman 2006, Kotulka 2007, Clark 2009, Powell 2010, Lumpkin 2009, Lehman et al. 2007). The frame geometry, beams, columns, and braces were identical for these 4 specimens, but the connections were different. Comparison of the 4 plots in Fig. 5 shows that there are dramatic differences in performance with these seemingly similar braced frames. The maximum inelastic deformation capacity shown in Fig. 5b is more than 2.5 times the maximum capacity of the specimens shown in Figs. 5a and 5d. The maximum resistance for the test specimen shown in Fig. 5d is approximately 40% larger that achieved with other specimens. This simple comparison clearly shows that the gusset plate design plays a major role in the inelastic performance of the SCBF system.

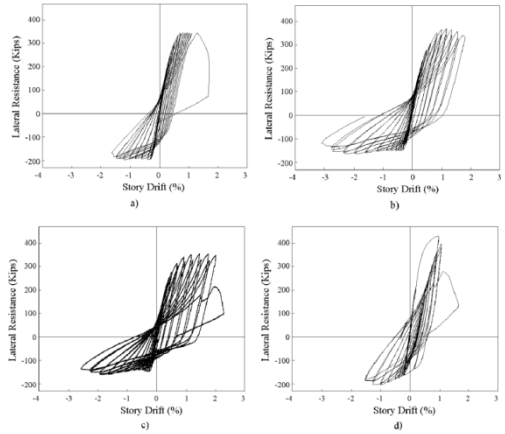

Figure 5. Typical SCBF Results

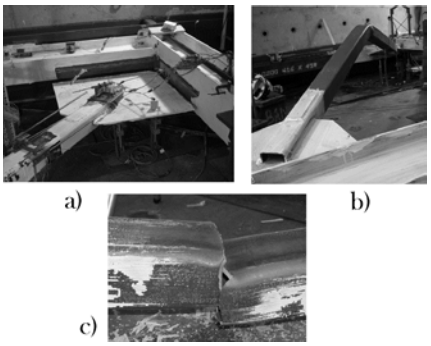

Figure 6. Photos of SCBF Tests

A wide range of behaviors were observed in these tests. More ductile specimens developed brace buckling with large out-of-plane deformations as shown in Fig. 6b. Ultimately these braces developed localization of yielding and brace tearing and fracture as shown in Fig. 6c. However, the deformation achieved before brace fracture was highly dependent upon gusset plate design. Extensive yielding and limited weld cracking was noted in the gusset plates, and this yield occurred regardless of the connection design. Weld cracking was generally controlled by the use of demand critical weld metal, but the tests clearly showed that the welds must be designed to develop the plastic capacity of the gusset plate rather than the UFM. Specimens with stiffer and stronger gussets also noted extensive yielding in the beams and columns and the reentrant corners of the gusset.

A number of observations were made from the experimental research, and a few key conclusions are noted here. These include:

1) Welds joining the gusset plate to the beam and column must be designed to achieve the plastic capacity of the gusset plate rather than the expected plastic capacity of the brace and the UFM.
2) The $8t_p$ elliptical clearance model significantly increases the inelastic deformation capacity of rectangular gusset plates. It permits smaller, more compact gusset plates, which reduce the size of the relatively rigid connection zone, and as a consequence reduce damage to the welds, beams and columns adjacent to the gusset plate. The vertical 6tp clearance zone provides similar performance for midspan gusset plates.
3) Yielding in the Whitmore width of the gusset plate is a desirable yield mechanism if it starts after initiation of yielding and buckling of the brace. This yielding minimizes damage to the welds and reduces local buckling and yield deformation in the beams and columns.
4) The strength and stiffness of the gusset plate must be adequate to assure that the brace develops it full resistance and inelastic deformation capacity, but it should not be excessively stiff or strong, because this causes early brace fracture.
5) The effective length of the brace should be taken as the true brace length when these rules are employed.
6) Tapered gusset plates may provide good end rotational capacity for the brace, but they may result in thicker gussets or greater inelastic demands on the gusset plate and the welds.

To incorporate these conclusions a balanced design procedure was proposed (Roeder et al. 2005, 2012). This balanced design method utilizes the $8t_p$ elliptical clearance model for corner gusset plates and a $6t_p$ vertical clearance band for midspan gusset plates. These clearance models establish the basic size and geometry of the connection. Plate thickness, weld size, and other gusset requirements are determined from yield mechanisms and failure modes, but these failure modes are evaluated with balance factors (β factors) rather than the resistance factors commonly used in design. The proposed procedure is similar to current design methods in that the framing elements are designed to resist the factored loads, and the connection design utilizes the expected tensile yield ($R_yF_yA_g$) and compressive buckling ($R_yF_{cr}A_g$) capacities of the brace for design. A balanced design procedure is used to evaluate the resistance associated with each yield mechanism and failure mode for the frame and the connection. The consequence of this method is a 46% increase in the resulting inelastic deformation of the system prior to initial failure over that achieved with the current SCBF design method.

The inelastic deformation capacity achieved with SCBFs varied depending upon the brace type and the gusset plate connection design procedure. SCBFs with HSS rectangular tube braces achieve somewhat less inelastic deformation capacity than SCBFs with wide flange braces. Frames designed by current procedures with rectangular tubes achieved total inelastic deformation ranges between approximately 1.5% and 5.6% prior to initial failure with an average value of approximately 3.5%. SCBFs with HSS rectangular tubes but designed with enhanced balanced design procedure noted above achieved total inelastic deformation ranges of between approximately 3.9% and 5.4%, with an average value approximately 46% larger than that achieved by current design method. Frames designed by this enhanced method on average had significantly less inelastic deformation and damage to the beams and columns. SCBFs designed by the enhanced gusset plate design procedure with wide flange braces achieved total inelastic deformation ranges between 5.5% and 6%..

5. SUMMARY OF BRBF RESULTS

Severn BRBFs were tested. Six of the specimens were single-story frames with bolted connections (Christopulos 2005). These frames were tested in the apparatus as illustrated in Fig. 4. BRBF5 was a single-story specimen designed with a rectangular gusset with slip critical bolts and the core plate of the BRB was oriented in the plane of the braced frame. This specimen was designed to simulate current design practice for bolted BRBF gusset plate connections. The AISC Uniform Force method was used to design the gusset after considering the strain hardening of the brace in tension and compression. Typical strain hardening factors of 1.5 to 1.55 were used for tension and compression in the connection design. The bolts were designed as slip critical bolts considering the brace load capacity after strain hardening of the brace. The gusset plate and rib plate thicknesses match the BRB core thickness (19 mm) according to usual practice. The plate was quite stiff and the nominal design stress in the plate based upon the Whitmore width was quite small. The rib plate was extended to within 25mm of the face of the beam flange.

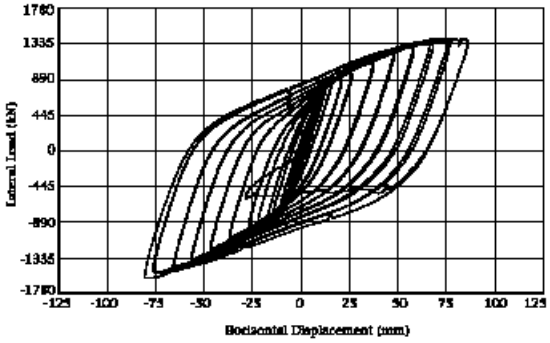

Figure 7. Force-Deflection Behavior of Reference Specimen.

Figure 7 shows the resulting story shear force-deflection plot for this test specimen. The hysteresis curves are full with substantial energy dissipation. However, the frame reached moderate story drift angles of 2.5% and -2.4%. This resulted in a total story drift range of approximately 4.9%. The frame experienced large deformations and yielding in the beams and columns adjacent to the gusset plates at this deformation as illustrated in Fig. 8. This beam yield deformation led to out-of-plane rotation of the beam flange and web and nearly rigid body rotation of the gusset plate. The gusset connection rotation produced an eccentricity in the BRB, and this resulted in large out-of-plane deformation demands on the BRB. This caused the ultimate out-of-plane plastic deformation failure of the brace shown in Fig. 9.

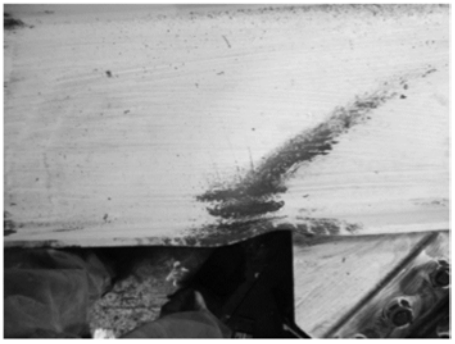

Figure 8. Local Yielding in the Beam Adjacent to Gusset

Figure 9. Out-of-Plane Plastic Deformation of BRB

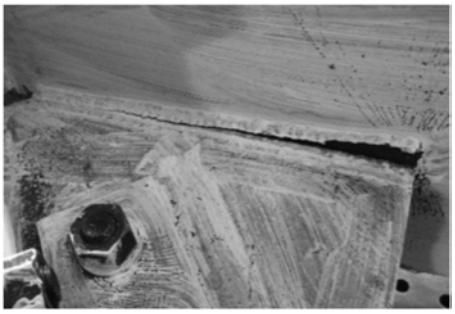

Figure 10. Crack Initiation and Ductile Tearing of Welds.

Significant inelastic deformation damage to the beams and columns in the region of the gusset plate connections occurred. Local yielding initiated at drift levels less than 1%, and the severity and extent of yielding increased as the deformation of the frame increased. Figure 8 is a photo showing the extent of yielding in the beam at the corner of the gusset plate at the end of the test. Welds attaching the gusset plate to the beams and columns initiated cracking at drifts slightly less than 2%, and the crack length grew in a ductile manner through increasing inelastic deformations. At the end of the test, the weld crack adjacent to the gusset had grown to a significant length as shown in the photo of Fig. 10.

Other variations of the single-story bolted connection specimens were tested, and some variations achieved story drift ranges up to 5.4%. However, all specimens had extensive yielding in the beams and columns, and some dramatic failure modes were noted. Figure 11 shows a beam flange fracture at the edge of the gusset plate for specimen BRBF1. This fracture occurred after extensive yielding of the beam, and it limited the total inelastic deformation range to 4.2%.

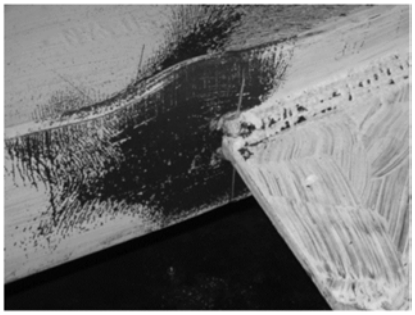

Figure 11. Beam flange fracture noted with BRBF1.

Specimen BRB6 was also a single-story bolted connection, it was manufactured in a different lot. It ultimately developed weld fracture of the gusset as shown in Fig. 12. Current gusset plate design procedure designs the gussets for the maximum expected axial load in the BRB, but the actual stresses in the gusset are much larger than the design stresses because of the frame deformation, and these stresses and the deformations associated with the local yielding place increased demands on the welds.

Hysteretic curves for the bolted single-story BRB test frames were full with good energy dissipation. The accumulated plastic strains observed in the BRBs of this test program where comparable and consistent with those observed in other past research. However, the total inelastic deformation capacity of the frames was disappointing. Past tests on BRBs suggest that larger deformations of the brace are possible. The maximum story drifts achieved in these tests were larger than those normally expected with small or moderate seismic events, but they were smaller than commonly expected for extreme, infrequent seismic events such as required in US practice. The observed limitation in the frame deformation capacity frequently was caused by the gusset plate connection and the inelastic damage induced in the beam and column by the connection rigidity. The BRBs provide good inelastic behavior in that they did not cause the ultimate failure.

Figure 12. Gusset weld fracture for specimen BRBF6.

A 3-dimensional 2 story BRBF with pin-ended braces was tested at the University of Minnesota MAST facility. Results of this test are not fully analyzed, and conclusions are somewhat limited. Because of the pinned end BRBs, the gussets were more compact than those required for the bolted gussets, but they were still relatively thick and stiff. Significant inelastic deformation in the framing members was also noted in this frame. Figure 13 shows weld cracking at the gussets because of the extensive yielding in the connection area. Figure 14 shows the extensive column yielding at the gusset location. While results are preliminary, the inelastic deformation was somewhat larger than noted with the bolted connection tests, since the total inelastic deformation range was approximately 7% before failure of the BRB.

6. CONCLUSIONS

A comprehensive study of the inelastic seismic performance of SCBF and BRBF systems has been completed. The study includes a wide range of experiments and inelastic analyses. Little discussion of the inelastic analysis is provided here due to space limitations. The research shows that inelastic deformation capacity of both BRBFs and SCBFs is highly dependent upon their connection to the other framing members. A balanced design procedure, which significantly increases the inelastic deformation capacity of the SCBF system, was developed, and this procedure significantly increases the deformation capacity achievable from a given system. This procedure results in lighter more compact gusset plates and it reduces the inelastic deformation in the framing members. BRBs are very ductile with large deformation capacity when loaded under axial load. However, when employed in a frame structure, they cause significant local yielding in the beams and columns and this yielding may ultimately reduce the deformation capacity achieved by the BRBF system.

SEISMIC DESIGN OF RECENT PROJECTS ON TOKYO TECH O-OKAYAMA CAMPUS

Toru Takeuchi

Professor, Dept. of Arch. & Build. Eng., Tokyo Institute of Technology, Japan

Abstract: This paper briefly reports the seismic design concepts of recent projects realized on Tokyo Tech O-okayama campus. We first describe the superstructure of the new library named the Glass House. The discussion includes the structural design and its seismic performance. We then describe the seismic retrofit design of the Secretariat 1st Building originally built in 1967. New energy-dissipating diagonal louvers are adopted for this retrofit deign; they are developed from the integrated façade concept used in the retrofit of the Midorigaoka-1st building.

1. INTRODUCTION

The 8th International Conference on Urban Earthquake Engineering will be held in March 7-8, 2011, at the O-okayama Campus of the Tokyo Institute of Technology. By March, several construction projects near the conference venue will be completed, and some of them are notable from the viewpoint of seismic design. This paper briefly describes the design of two projects recently carried out on the Tokyo Tech O-okayama campus.

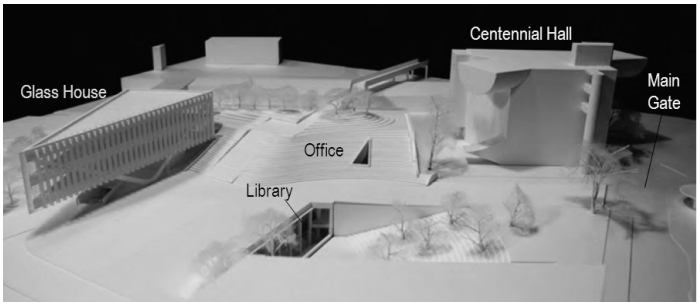

Figure 1 New Library, Tokyo Institute of Technology

2. THE NEW LIBRARY

2.1 Project Outline

The existing library at Tokyo Tech was built in 1970, and in recent evaluations, it was found to have insufficient seismic performance. Several retrofit designs were considered, but they were not adopted because of the deterioration of the concrete materials. They also would have required additional frames in the interior spaces which reducing the functionality of the library. Thus, the university decided to build a new library as part of its 130th anniversary celebrations. The authors proposed an underground library to maintain an unobstructed view along the axis from the main gate to the main building and to keep valuable documents away from sunlight. However, a small above-ground building was added to the design; it is intended for students' study and discussions and is a symbol of the library. This building has been named as Glass House. Figures 1 to 3 show the expected view, a sectional view, and the plan of the B1 level. The library facility consists of the underground library, service office under an artificial hill, and the Glass House. The library is spread over two levels, B1 and B2, and the main entrance is located under the Glass House. Dry pits are distributed around the underground library, to supply the natural lights to the floors.

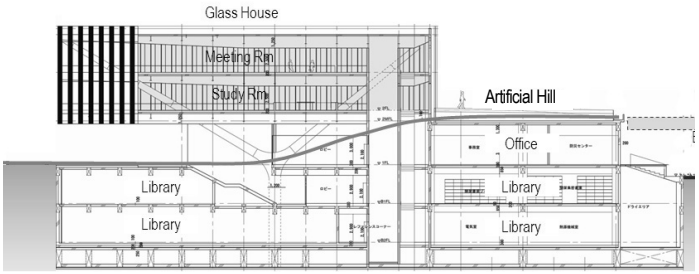

Figure 2 Section of New Library

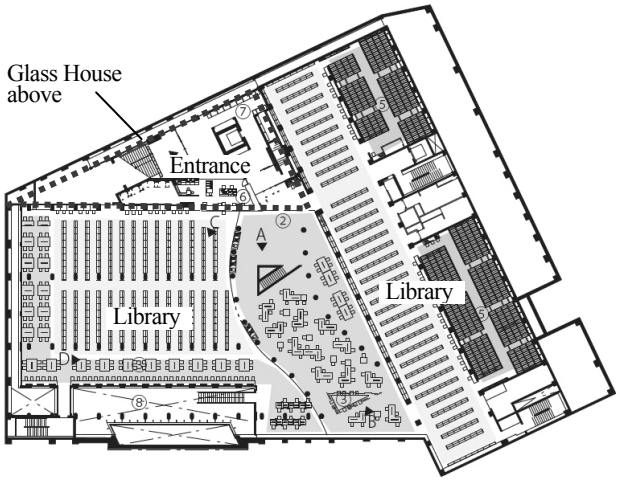

Figure 3 Basement Plan of new Library

2.2 Glass House Structure

The structural system of the Glass House is shown in Figure 4. This building has three triangular stories. Each floor is supported by three sets of V-shaped diagonal columns, and perimeter beams to connect them each other. Perimeter frames composed of perimeter beams and plate columns in second and third floors form a Vierendeel truss. The toe of the plan is a 15 m cantilever, supported by a pair of diagonal columns. The overturning moment of the whole structure is anchored by the back diagonals. The EV shaft composed of truss frames with concrete walls receive about 50% of the horizontal force. The EV shaft and perimeter frames are connected by steel floor beams and concrete slabs.

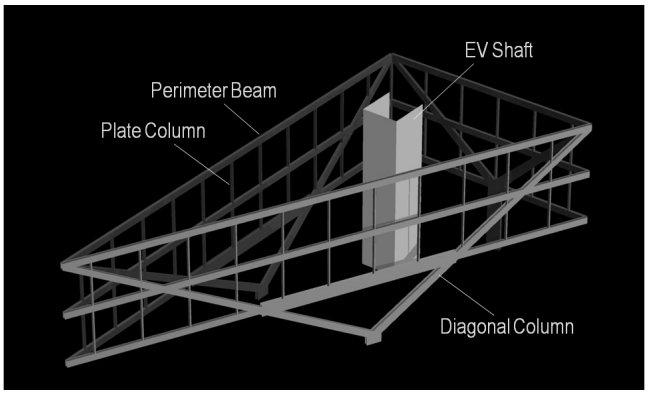

Figure 4 Structural System of Glass House

Figure 5 shows the details of the steel structure. All the diagonal columns, perimeter beams, and plate columns are designed with double-plate sections connected with thin stiffeners. The axial force and bending moment are transferred through the double plate only, and connections at the stiffeners are not required. This system simplifies the connection between the diagonal columns and perimeter beams and is also effective for easy site-welding. These systems are already sketched in the preliminary design stages as shown in Figure 6(a).

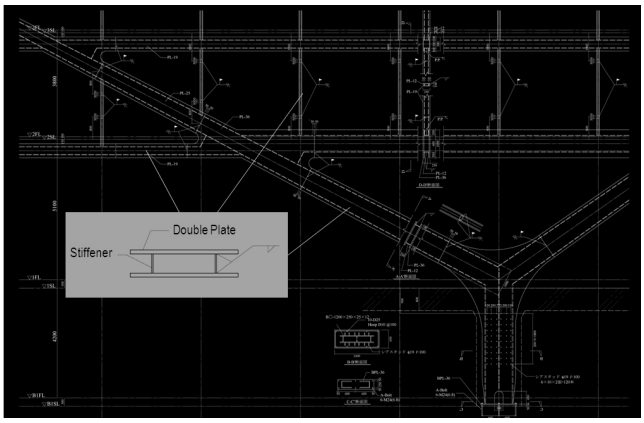

Figure 5 Details of Glass House Structure

Figure 6(b) also shows alternative structural systems considered at the preliminary design stage. Options included the as truss option or parabola option, but the simplest system directly supporting the toe was selected. There were also discussions whether vertical strut and diagonal damper member should be attached around the supporting diagonal columns as in Figure 6(c). However neither was employed to avoid the obstruction around the entrance.

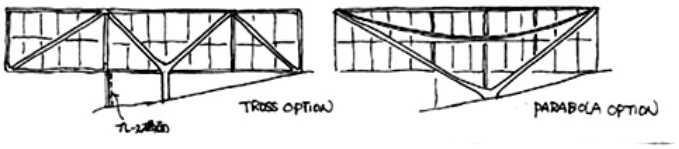

Figure 6(b) Alternative Structural System at Early Stage

2.3 Seismic Performance of Structure

Figure 7 shows the bending-moment distributions under vertical loads. Because the vertical strut has been omitted, bending moments appear for the second floor perimeter beam between the two diagonal columns. To withstand this

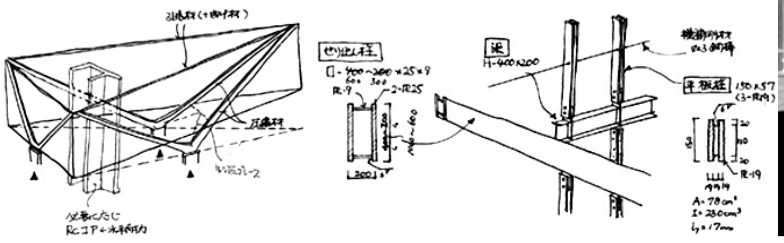

Figure 6(a) Structural Sketches at Early Stage

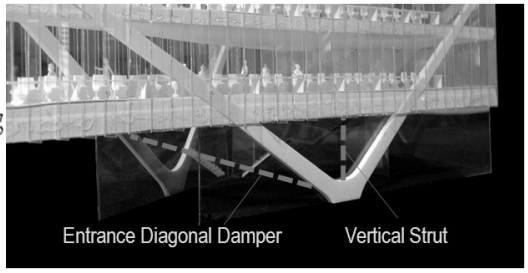

Figure 6(c) Additional Members Considered

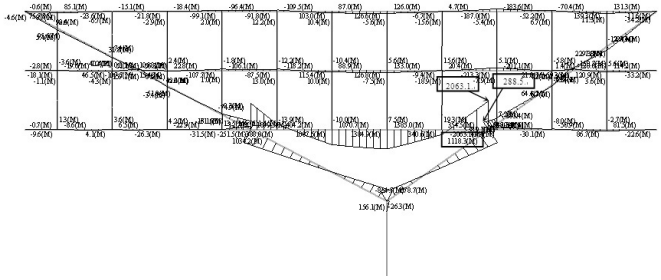

Figure 7 Bending Moments under Vertical Load

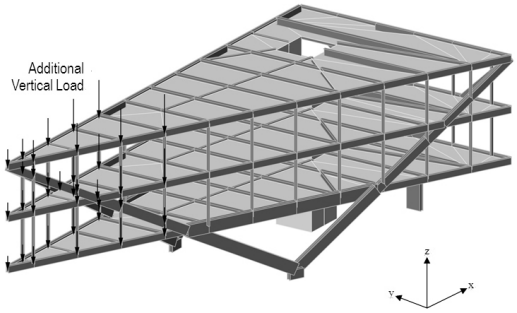

Figure 8 Vertical Seismic Loads in Cantilever Zone

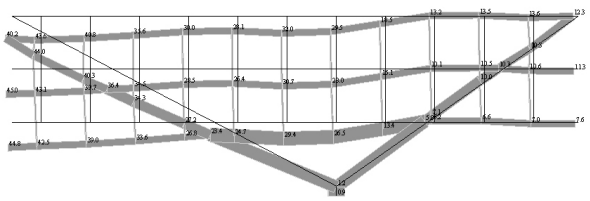

Figure 9 Deflections under Vertical and Seismic Loads

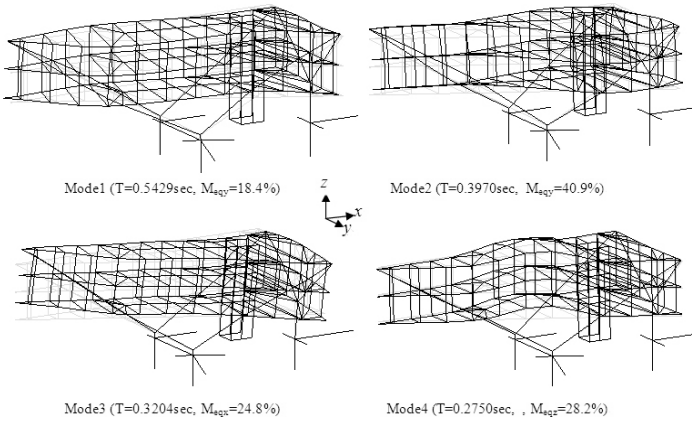

Figure 10 Vibration Eigenmodes

bending moment, the depths of the perimeter beams in this zone were increased from 500 mm to 1000 mm. Thus, the structural system of this building is not a pure axial system, but include partial bending elements.

In the seismic design, a static seismic force of base-shear C_0=0.2 was considered for the allowable stress design, and a base-shear of C_0=0.4 was considered for the ultimate strength design. A vertical seismic force of 1.0 times the self -weight was also considered, as shown in Figure 8, to estimate the vertical response excitation. Figure 9 shows the deflection distribution under vertical and seismic loads. The maximum vertical deflection at the toe is estimated to be around 45 mm.

To analyze the dynamic characteristics, eigenvalue analyses were carried out. Figure 10 shows the vibration modes and natural periods obtained. Because the entrance diagonal damper has been omitted, the twisting modes first appear as the forsta and second modes, which dominate the vibration in the y- (transverse) direction. The natural periods of these modes are 0.54 and 0.40 sec, respectively. The third vibration mode excites vibrations in x- (longitudinal) direction and vertical vibrations in the toe zone, the natural period of which is 0.32 sec. the fourth mode is vibration of the Vierendeel truss in the z- (vertical) direction around the bending zones between the diagonal columns, the natural period of which is 0.28 sec. All these vibration modes have similar natural periods, and the seismic response of this structure is expected to include the combination of these modes. The measured vertical natural period at the toe zone in the construction site was about 0.23 sec. which generally meets the analyses considering the effect of the live loads and the stiffness of the curtain walls.

Y-dir.	0.39	0.31	0.46

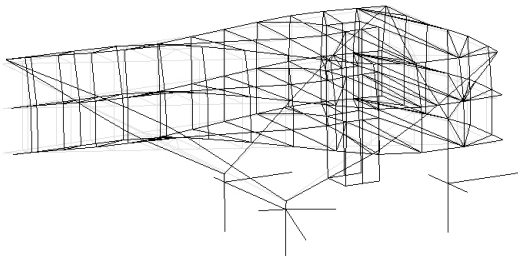

Figure 12 Maximum Deflection in Time-History Analysis

Figure 13 Completion of Steel Structure

The seismic performance of the structure is also evaluated by time-history analyses. The acceleration response spectrum of the seismic input is shown in Figure 11.Because the dominant natural periods are around 0.3 to 0.5 sec., about 1000 cm/sec^2 of acceleration is expected to be excited. In the analyses, all members are assumed to be elastic, and the damping is set as $h = 0.02$ for the first mode. The results are compared with static analyses in Tables 1 and 2. Table 1 indicates the maximum deflections of the toe in each direction. In the x - and y - directions, the maximum values obtained by the time-history analyses are two to three times of the static ultimate loads. In the z - direction, the values under static loads exceed the results from the time-history analyses, because of the additional vertical seismic loads shown in Figure 8. Table 2 shows the maximum story drift under both estimations. Again, the values of the time-history analyses are around two to three times the static results, and both satisfying required drift limit of 1/200=0.5%. The maximum vertical acceleration calculated at the toe is about 1900 cm/ sec^2, but the displacement amplitudes are relatively smaller than the static evaluations.

In these conditions, all the members remain within the ultimate strength. This means that the structure of the Glass House generally stays within the overall elastic limit for seismic input shown in Figure 11.

Construction work started April 2009, and is expected to be completed in February 2011. Figure 13 shows a view of the construction site in November 2010, the steel structure of the Glass House has been completed.

3. SEISMIC RETROFIT OF SECRETARIAT BUILDING

3.1 Project Outline

The secretariat 1st building (Figure 14) on O-okayama campus, located just beside the main building, was constructed in 1967 and designed by the famous architect, Professor Kiyoshi Seike. In a 2007 evaluation, the seismic performance of this building was judged to be insufficient, and was decided that the retrofit is necessary.

The building has a unique front façade composed of the president's office with vertical concrete louvers supported by pilotis columns. As shown in Figure 15, four stories of office floors are attached behind the front block. The evaluated seismic indexes are plotted in Figure 16. The required level is Is = 0.7. The x - (longitudinal) direction frame has enough strength except for the first floor, but the y - (transverse) direction frame is insufficient for the first to third floors. The concrete strength satisfied the designed strength and the chemical neutrality of the concrete was not progressed. To reinforce the longitudinal frames, additional concrete walls or braces along the windows of the office blocks and between the front pilotis columns were considered. However, this concept had problems:

1) To prevent alteration of the building's appearance, additional braces between the front columns should be avoided.
2) In the office floors, the spaces between the columns are occupied by various facilities, so additional braces

Figure 19 Diagonal Louver Mock-ups

between the columns are not desirable. Concrete walls that block the windows are not acceptable.

3.2 Retrofit Concept

The integrated façade concept is applicable to this situation. This concept aims to design a new façade that simultaneously improves the architectural features, the seismic performance, and the energy efficiency. The concept was first applied to the seismic retrofit of Midorigaoka-1st building in 2006; as in Figures 17(a) and 17(b). (Takeuchi et al.2006) The new façade is composed of seismic energy dissipation braces, horizontal louvers, and glasses. Because hysteretic dampers are used as energy dissipation braces, the seismic performance retains the elasticity of the main frame up to a Level-2 earthquake. The authors also developed diagonal energy-dissipating louvers with the diagonal parallel louvers acting as buckling-restrained braces. Diagonal parallel louvers in the east and west walls of buildings are known to be effective for controlling sunshine.

The buckling-restrained braces have small sections as 80mm x 150mm, providing 300kN of yield strength. Sections of each louver are designed to reflect the sunshine into the room. Figures 18 show images of the conventional steel-brace retrofit (Figure 18(a)) and the diagonal energy-dissipating louver concept (Figure 18(b)). In the proposed method, the obstruction of the inner space is minimized and the interior appearance is improved. The efficiency of this system is confirmed by a mock-up test (Figure 19) and an element structural test (Figure 20). The figure indicates the presence of stable hysteresis loops up to 2% axial strain ratio, which is equivalent to 1% story drift.

3.3 Retrofit Design

For the secretariat 1st building, the above concept was considered. However, it is not desirable to attach the new louver to the outside, because the original office block façade has sophisticated site-casting walls and is one of the masterpieces characterizing this building. Therefore, we proposed distributing the diagonal louvers inside between the wall and columns, as shown in Figure 21. This treatment decreases the thermal control, but still reduces the direct sunshine effectively. Each diagonal brace has 300kN of yield force and stable hysteresis for dissipating the seismic energy after the yielding. Because this type of buckling-restrained braces has complete symmetrical hysteresis between compression and tension, a one-way diagonal layout provides

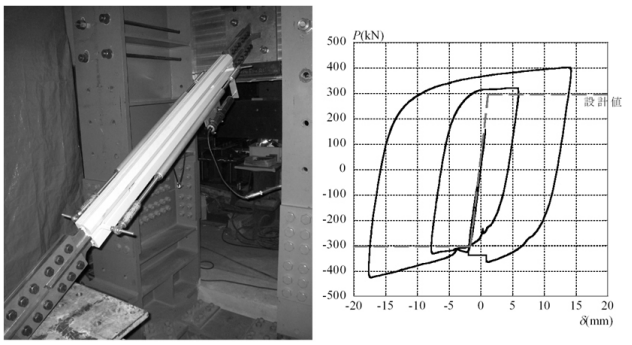

Figure 20 Structural Test of Diagonal Louver

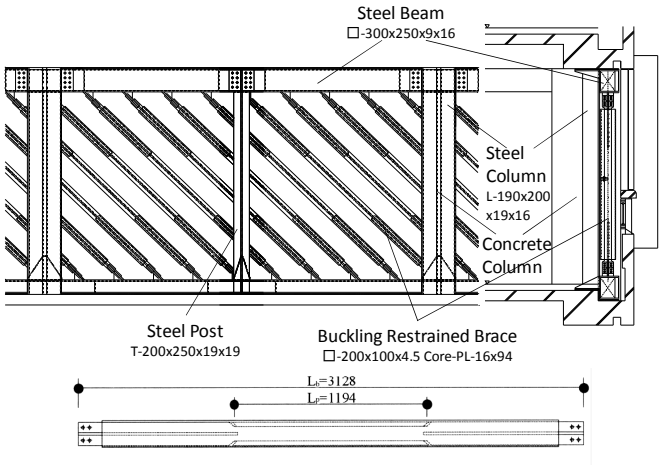

Figure 21 Layouts of Diagonal Braces

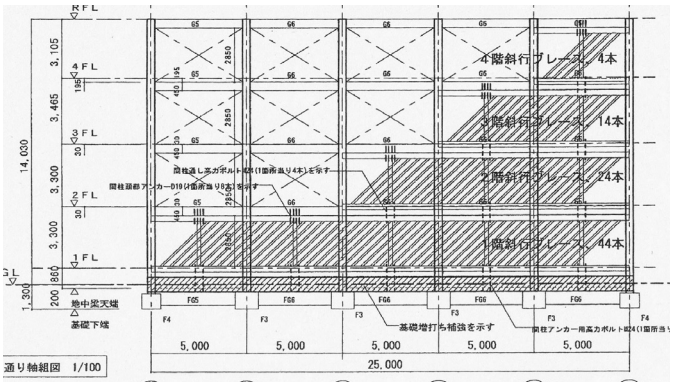

Figure 22 Layouts of Diagonal Braces in South Facade

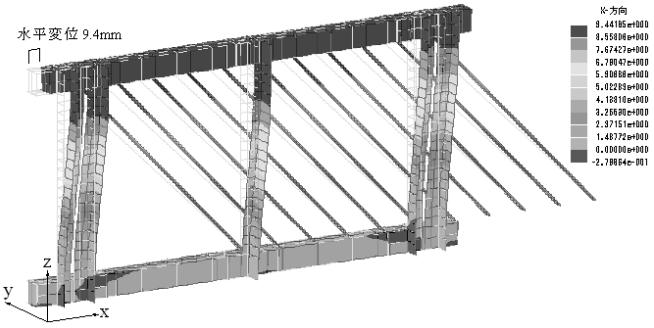
the same performance in both directions. Ten diagonal braces are distributed in one bay between column-to-column which consist 2000kN strength of shearwall, which is equivalent to ordinary steel-brace reinforcement. Each brace has a section of 100mm x 200mm with the conventional composition of buckling-restrained braces. As in Figure 21, the length of the plastic zone in each brace is set to about 1/3 of the total length, to obtain a small yield deflection for dissipating energy from a small story-drift angle.

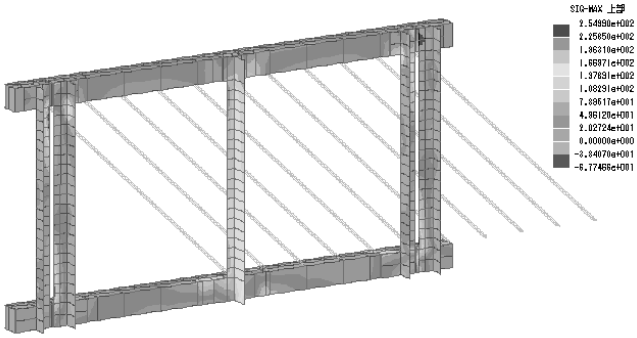
To transfer the seismic force to these braces, an outer frame composed of box beams and L- or T- section columns is provided and attached to the existing concrete columns. These frames are attached in the perimeter zone between the columns and outer walls, and they are fixed by anchor bolts and epoxy resin. The diagonal brace layout in the south façade is shown in Figure 22. The braces are fully distributed on the first floor; they are decreased on upper floors, because the required additional shear strength is less. The figure shows that the diagonal braces form large triangular elements.

The additional braced frames are placed on the existing frames with eccentricity, and the elastic deformation of the outer frames decreases the effect of hysteretic damping. To confirm these effects, we carried out FEM analyses as shown in Figure 23. In the FEM analyses the outer frames and core plates of the diagonal buckling restrained braces are modeled with shell elements, and shear forces equivalent to the yield forces of the braces are applied to the outer surface of the existing columns. The deflection distributions of the frame are shown in Figure 23(a). The maximum horizontal deformation was about 9.4 mm, which is equivalent to a story drift angle of 0.28%. (about 1/350). The existing fame is considered to start deteriorating from 0.4% rad. (1/250) story drift, and the brace is expected to dissipate energy between these story drifts. The stress distributions of the frame are shown in Figure 23(b). At the brace yielding point, the frame is fully within the elastic range. The effects of these energy dissipation braces are discussed below.



3.4 Seismic Performance of the Structure

The current Japanese seismic retrofit design recommendations use the seismic index defined as;



$$I_{Si} = F_i \cdot C_i = \frac{Q_{Ei}}{Q_{ui}} \cdot \frac{Q_{ui}}{\left(F_{esi} \cdot Z \cdot R_t \cdot A_i \cdot \sum W_i\right)} = \frac{Q_{Ei}}{\left(F_{esi} \cdot Z \cdot R_t \cdot A_i \cdot \sum W_i\right)} \qquad (1)$$

where, Q_{Ei} is the elastic response shear force in the i^{-th}-story, Q_{ui} is the ultimate shear strength of i^{-th}-story, F_{esi} is the multiplier for stiffness ratio and eccentricity ratio, Z is the site effect, R_t is the acceleration spectrum index, C_i is the shear strength coefficient in the i^{-th}-story, F_i is the ductility factor in the i^{-th}-story, W_i is the Weight in the i^{-th} -story, A_i is the height multiplier reflecting the first vibration mode.

Eq.(1) indicates the seismic index defined by the product of the shear strength coefficient and the ductility factor based on the property of energy conservation. When this concept is applied to damper-added structures, Kuramoto et al. (2002), Takeuchi et al. (2010) propose introducing D_h factor to evaluate the response reduction by equivalent damping, as follows;

(a) Deflection Distribution

(b) Stress Distribution

Figure 23 FEM analyses for Braced Frame

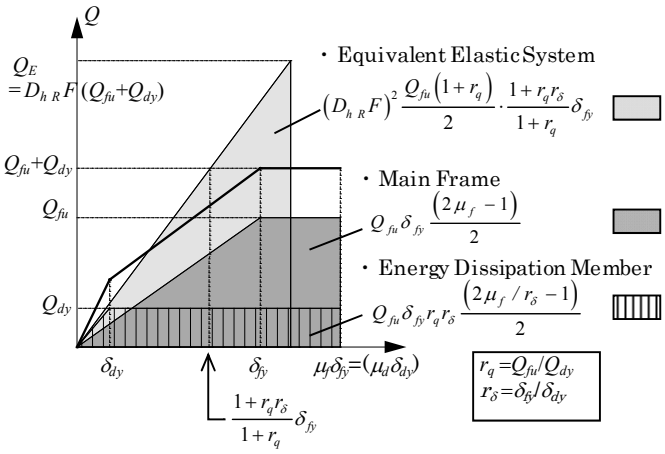


Figure 24 Seismic Index with Energy Dissipation Members

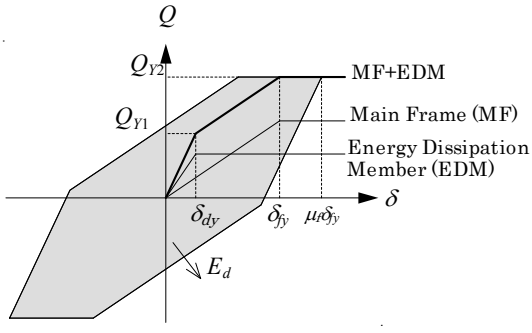

Figure 25 Equivalent Damping Ratios

$$ {}_R F = F / D_h \tag{2} $$

$$ D_h = C_{ec}\sqrt{\left(1+\alpha h_0\right)/\left(1+\alpha h_{eq}\right)} \qquad \left(\alpha = 25, h_0 = 0.02\right) \tag{3} $$

$$ C_{ec} = 1/\left(1 - 0.025\ K_d / K_f\right) \tag{4} $$

where, h_0 is the original damping ratio, h_{eq} is the equivalent damping ratio considering effect of energy-dissipation elements, C_{ec} is the reduction factor for hysteresis bias.
Introducing Eq.(2)-(4), Eq.(1) becomes

$$ I_S = \left(C_f + C_d\right)\cdot {}_R F = \frac{\left(C_f + C_d\right)\cdot F}{D_h} = \frac{C_f \cdot F_f + C_d \cdot F_d}{D_h} \tag{5} $$

Where, the shear strength coefficient of the existing frame is

$$ C_f = Q_{fu} / \left(F_{es} \cdot Z \cdot R_t \cdot A_i \cdot \sum W_i\right) \tag{6} $$

and the shear strength coefficient of the additional damper is

$$ C_d = Q_{du} / \left(F_{es} \cdot Z \cdot R_t \cdot A_i \cdot \sum W_i\right) \tag{7} $$

Figure 23 indicates the proposed relationship between the *Is* index and the hysteresis of the frame and dampers. In this relationship, D_h F can be calculated from the following equation.

$$ D_h\ {}_R F = \sqrt{\frac{2\mu_f - 1 + \left(2\mu_f - r_\delta\right) r_q}{1 + r_q r_\delta}} \tag{8} $$

where r_q and r_d are the shear strength ratio and yield deflection ratio between the existing frame and dampers. When F_f is 1.0-1.3, the equivalent F_d is distributed above 3.0, and this value is used in the following.

To estimate D_h, the equivalent damping ratio h_{eq} is required. When the existing frame is at elastic limit (μ_f= 1.0 in Figure 24), the equivalent damping ratio h_{eq} can be estimated by the following equation.

$$ h_{eq} = h_0 + \frac{1.6}{\pi} \times \left\{ \frac{\delta_{dy}}{\delta_{fy}} \frac{\left(K_d / K_f\right)\left(\delta_{fy} - \delta_{dy}\right)}{\left(K_d / K_f\right)\delta_{dy} + \delta_{fy}} \right\} \tag{9} $$

In this project, the stiffness ratios of the braces to the existing frames K_d/K_f range from 2.0 in the first floor to 0.5 in the fourth floor, and the yield ratios are estimated to be δ_{dy}=9.3 mm and δ_{fy}=13 mm. The estimated seismic index in the x-direction after the retrofit is shown in Figure 26. The numbers of braces are distributed so as to satisfy *Is* > 0.7 with their yield shear strength (labeled "After" in the plot). The plot labeled "Substantial" contain the values derived from Eqs.(5) and (9). The substantial indexes are distributed around *Is*=1.0, which means that the retrofitted structure will generally withstand an earthquake with a response of 1000cm/sec^2 up to the elastic limit of the existing frames.
The retrofit construction began in July 2008 and completed in March 2009. Figure 27 shows the attachment of the frames and braces. All works was carried out using only chain-blocks and human power. Each component was divided into pieces of less than 100 kg connected by friction bolts and site welding. The completed interior view is shown in Figure 28(a) and an exterior view is shown in Figure 28(b). The additional braces do not affect the interior space, and the effect on the existing façade is considered to be minimal.

4. CONCLUDING REMARKS

We have presented the project outlines for the superstructure of the new library building and the secretariat building retrofit, and discussed their seismic performances. Generally the structures are designed to withstand level-2 earthquake with maximum acceleration response of 1000cm/sec^2 at their elastic limit. They are expected to be usable after such an earthquake. Another new building, the environment and energy innovation center is also under construction. This building is covered by solar panels and has buckling -restrained braces at the perimeter frames, as shown in Figure 29(a) and (b), and designed to retain similar seismic performance. Their locations of the projects on O-okayama campus are indicated in Figure 30.

Abstract: Recent breakthroughs in fiber reinforced concrete technology have made it possible to utilize High Performance Fiber Reinforced Cementitious (HPFRC) materials for structural applications including seismic retrofit. For this purpose, an innovative retrofit system that consists of HPFRC infill panels that are acting as energy dissipation fuses has been developed. The seismic performance evaluation of the infill panel retrofit system was validated through large scale hybrid simulation testing series of a 2-story steel moment-resisting frame, designed based on older seismic provisions in California. These tests were conducted at the NEES facility at University of California at Berkeley. The proposed retrofit system was proven to be able to reduce maximum story drift ratios and residual deformations of the retrofitted steel moment resisting frame relative to bare frame performance. This paper summarizes the experimental validation of the proposed HPFRC retrofit system. The available experimental data is also utilized for the development of phenomenological analytical models that are implemented in the OpenSees simulation platform and permit the seismic assessment of retrofitted steel moment resisting frames in a Performance Based Earthquake Engineering context.

1. INTRODUCTION

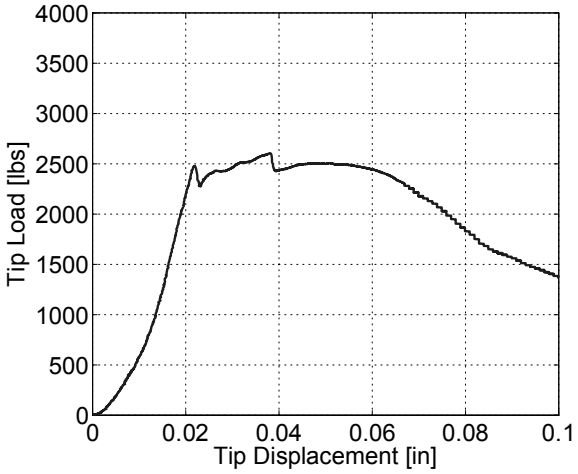
Recent earthquakes around the world have demonstrated that steel moment frame structures designed based on older seismic provisions (UBC 1994) might be seismically deficient due to premature fracture of beam-to-column connections at fused zone or column flange often noted as "divot" zone (FEMA 351). Further, important facilities such as hospitals that have been designed in the 1980s and it is likely that their seismic vulnerability is high, should remain operational to minimize human casualties and economic losses after a major earthquake. Seismic retrofit is an economic solution to upgrade existing infrastructure.

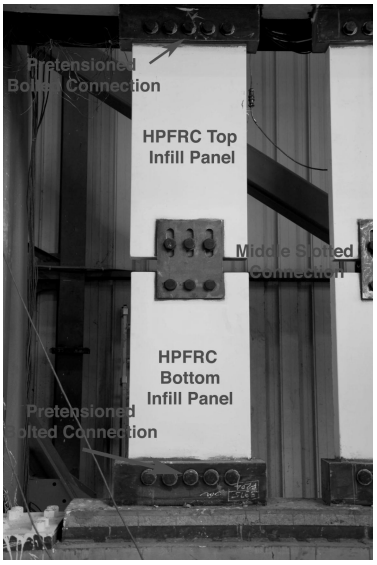
In 1990s the Federal Emergency Management Agency (FEMA) and the State of California developed a program for seismic rehabilitation strategies summarized in FEMA 356 (2000). The main strategies of these rehabilitation techniques in the United States typically involve (1) global modification of the structural system and (2) local modifications of isolated components of the structural and nonstructural system (e.g. steel, fiber reinforced composite jackets, beam-to-column connection modification improvements). The emphasis is on global modification techniques that involve: (a) the use of reduced steel thickness shear walls (Bruneau 2005) that allow shear buckling and act as an energy dissipation mechanism; (b) ductile fuse elements that move plastic deformation ways from beam-to-column connections (Leelataviwat et al. 1998); (c) self-centering systems (Ricles et al. 2001, Christopoulos et al. 2002, 2008, Tremblay et al. 2008); (d) buckling restraint braces that primarily enhance the strength of the structural system (Clark et al. 1999, Wada et al. 1998, Lopez et al. 2002, Uang and Kiggins 2003); (e) passive energy dissipation devices including various types of dampers (Constantinou and Symans 1992, Soong and Spencer 2002, Kasai et al. 2010).

Recently, infill panels have become popular for structural applications including seismic retrofitting. Jung and Aref (2005) using polymer matrix composite (PMC) infill panels showed that damping as well as lateral resistance of existing steel frames can be increased. Using recent breakthroughs in fiber reinforced concrete technology, Kesner and Billington (2005) utilized High Performance Fiber-Reinforced cementitious (HPFRC) composites to seismically retrofit vulnerable steel moment frame structures. This system was redesigned and evaluated extensively through an experimental program that included a large number of infill panel component tests (see Olsen and Billington 2009, Hanson and Billington 2009) and a series of large-scale hybrid simulation tests of a 2-story steel moment frame designed in 1980s in California. These tests were conducted at the Network for Earthquake Engineering Simulation (NEES) facility at University of California at Berkeley. This paper discusses the experimental and analytical validation of the proposed retrofit system for existing steel moment frame structures subjected to earthquakes.

2. PROPOSED SEISMIC RETROFIT SYSTEM

The proposed infill panel system for seismic retrofit of existing steel frame structures is based on an HPFRC mix originally developed by Naaman (2003). Its 28 day compressive strength f_c' is in the range of 5ksi to 7ksi and its ultimate tensile strength is higher than its first cracking strength accompanied by multiple cracking during inelastic deformation of HPFRC components. An example of the monotonic response of a standard ASTM beam from a 4-point bending strength is shown in Figure 1. From this figure it can be seen that prior to strength deterioration the HPFRC beam has a plastic deformation capacity of about 0.04 inches (i.e. a ductility of about 0.06/0.02 = 3.0).





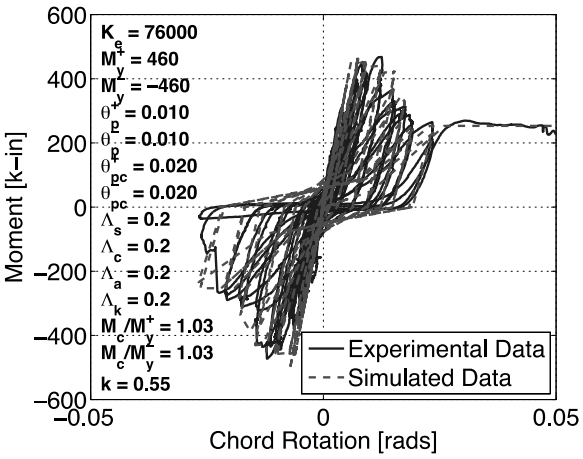


Figure 1 Monotonic load-displacement curve of ASTM HPFRC beam based on a 4-point bending test

The system shown in Figure 2a consists of two precast HPFRC infill panels. These panels utilize welded wire fabric (WWF) and Grade 60 steel reinforcement. The two panels are hand-bolted together at story mid-height with a slotted steel connection that is shown in the same figure. This connection guarantees that the point of inflection of the infill panel system stays at mid-height when one or both infill panels experience inelastic deformations during an earthquake. The same connection also prevents any out of plane movement due to axial load that may build up in the panel system because of lateral and vertical loads. The bottom panel is pre-tensioned with a steel channel that is installed at the top of the floor slab with a regular technique. The top HPRFC infill panel is also pre-tensioned with a steel channel that is welded at the bottom flange of the upper floor steel beam with fillet weld on the site.

Olsen and Billington (2009) and Hanson and Billington (2009) tested experimentally alternative infill panel configurations. They evaluated the cyclic performance of HPFRC panels with different reinforcement ratios and geometries (tapered versus rectangular panels). These tests illustrated that the infill panel system has a pinched hysteretic response (see Figure 2b) and is able to dissipate energy at least up to 5% story drift ratios.

3. PROTOTYPE STEEL STRUCTURE

In order to evaluate the effectiveness of the proposed HPFRC infill panel system discussed in Section 2 of this paper as a seismic retrofit, a prototype steel structure designed in 1980s is utilized. This structure is a 2-story by 3–bay office building with 90ft x 90ft rectangular plan view. Its structural system consists of perimeter moment resisting frames (MRFs). The geometric properties of the steel sections of the perimeter moment resisting frames are shown in Figure 3. The predominant period of the building is 0.75sec in the loading direction of interest (east-west). The building does not meet the retrofit objectives specified in ASCE 41 (2007). Thus, it is retrofitted with the HPFRC infill panel system discussed in Section 2. Five individual HPFRC infill panel systems are installed in the first bay of the steel moment frame shown in Figure 3. The period of the

retrofitted prototype frame is 0.39sec. A 2/3-scale model of the retrofitted steel moment frame was tested at the Network for Earthquake Engineering Simulation (NEES) facility at University of California at Berkeley. The test specimen and experimental program is discussed in detail in the next section.

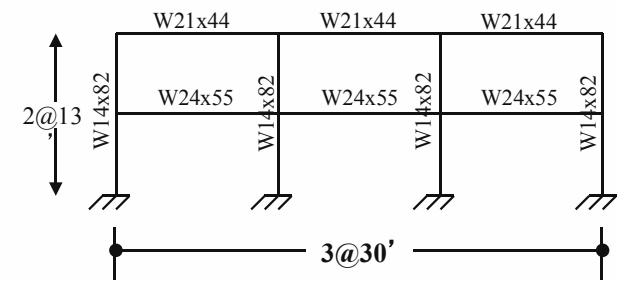

Figure 3 Steel moment frame designed based on 1980s

4. TEST SPECIMEN & EXPERIMENTAL PROGRAM

The 2/3-scale frame of the prototype steel moment frame discussed in Section 3 is scaled based on similitude laws summarized in Moncarz and Krawinkler (1981) for strength and stiffness. The steel sections were selected such that the web and flange slenderness ratios h_f/t_f, $b_f/2t_f$ are almost the same with the original sections of the prototype moment resisting frame in order to achieve the same component deterioration parameters and minimize scale effects. Details related to the testing procedure, test setup, and the testing protocol are discussed in this section.

4.1 Hybrid Simulation

The state-of-the art hybrid simulation technique is utilized for the test series discussed later in Section 4.4. This technique allows testing of the retrofitted part of the moment resisting frame (1-bay frame) only and the rest of the steel moment frame is modeled numerically in the OpenSees (2009) analysis platform. The Open-source Framework for Experimental Setup and Control (OpenFresco) is used to conduct the hybrid simulations (Takahashi and Fenves 2006, Schellenberg 2008). The explicit Newmark integration algorithm with fixed number of 10 iterations is used for the integration of equations of motions. This is a direct integration scheme. The selection of the integrator was based on extensive number of numerical studies that were conducted prior to the testing program and were based on coupled simulation (Lignos and Billington 2010) through a generic adapter element approach implemented in OpenFresco (Schellenberg et al. 2007). For these simulations the HPFRC infill panel system was modeled with a pinching hysteretic response that follows the modified Ibarra-Krawinkler model degradation rules (Lignos and Krawinkler 2009). An example calibration of the hysteretic response of this model against component tests is shown in Figure 2b. The initial 2x2 stiffness matrix needed to conduct the hybrid simulations was determined based on pull-back tests prior to the testing sequence discussed in Section 4.3 of this paper. In this paper, the hybrid model refers to the physically subassembly tested in the lab and the numerical model that is carried in the OpenSees simulation platform.

4.2 Test Setup and Test Frame Description

The 2/3-scale model of the prototype steel MRF consists of W10x45 steel columns. The first and second floor beams are W14x26 and W10x30, respectively. All the sections are made of A995 Gr. 50 steel. The test frame together with the test setup is shown in Figure 4. The test frame is welded on a W14x311 steel beam in order to guarantee "fixed" conditions at the base of the steel columns.

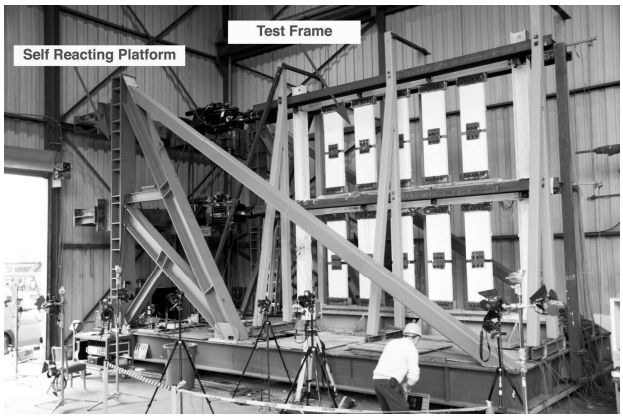

Figure 4 Test frame after completion of the test setup

Although the beam-to-column connections of the prototype steel MRF were pre-Northridge connections, the four moment resisting connections of the test frame were designed as standard welded unreinforced flange (WUF) connections in accordance with FEMA 350 (see Figure 5). This was decided for safety reasons in order to avoid any control instability of the two actuators because of connection fracture during testing. However, fracture is modeled in the numerical portion of the hybrid model based on the modified Ibarra-Krawinkler model (Lignos and Krawinkler 2011).

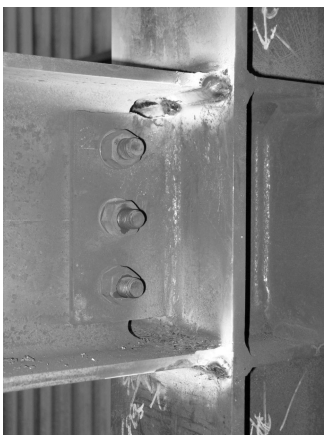

Figure 5 Typical WUF connection of the test frame

A concrete slab was fabricated to realistically simulate the connection between the steel channels with the concrete slab. Figure 6 shows the formwork for this slab after pouring the concrete.

The test frame is built on a self-reacting platform shown in Figure 4 that was designed to eliminate deflections for the maximum expected base shear of the test frame during the two testing phases. In order to eliminate out of plane deformations of the test frame, a lateral support system is designed that consists of longitudinal beams that allow sliding of the test frame through slotted sliders that are greased to eliminate friction. The friction force between the test frame and the lateral support system was practically zero based on the measurements of the instrumented diagonal elements that are bolted on the self-reacting platform and provide lateral resistance to the lateral support system.

Figure 6 Slab details of the test frame after the pouring of concrete

Two 250kips dynamic actuators are connected with the test frame at each floor level with a specially designed beam extension that was stiffened to avoid shear buckling of the beam web. In total, 170 channels were used to instrument the test specimen. Most of them were strain gages. A laser scanner was also utilized that scanned the bottom story right column and exterior infill panel. The scans were synchronized with the data acquisition system.

4.3 Numerical Modeling

The numerical portion of the hybrid model (highlighted 2-bay frame shown in Figure 3) was modeled with elastic beam – column elements and concentrated plasticity springs at their ends. These springs follow a bilinear hysteretic response including component deterioration based on the modified Ibarra Krawinkler model implemented in OpenSees (Lignos and Krawinkler 2011). The model was also able to simulate fracture of beam-to-column connections. Deterioration parameters for the steel beams and columns of the numerical subassembly were extracted from a recently developed steel component database that includes information for more than 300 steel beams (Lignos and Krawinkler 2009, 2011). P-Delta effects were modeled with a leaning column that was connected with axially rigid links with the steel MRF. More details about modeling of the numerical portion of the hybrid model can be found in Lignos and Billington (2010).

4.4 Testing Protocol

Two testing phases are designed for verification of the effectiveness of the proposed seismic retrofit system with the infill panel system. During the first phase, the test frame was subjected to 3 ground motions sequentially. The first ground motion was 30% of the fault normal Petrolia record (1992, Cape Mendocino). This motion represents a Service Level Earthquake (SLE) with 50% probability of exccedence in 50 years at the first mode period of the retrofitted steel MRF. The test frame was then subjected to two Design Level Earthquakes (DLE). The first one was the 70% of the unscaled Petrolia record (noted as DLE-I) and the second one is the unscaled Canoga Park record from the 1994 Northridge earthquake. Figure 7 shows the unscaled acceleration spectra of these two ground motions.

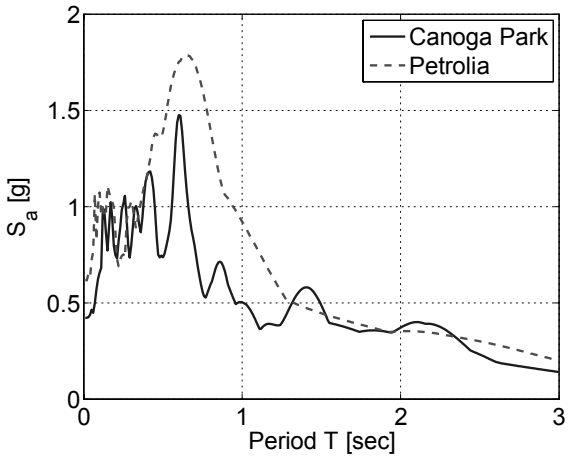

Figure 7 Unscaled acceleration spectra of Petrolia and Canoga Park ground motions

After completion of testing phase I, all the HPFRC panels were replaced with a new set with nominally identical material properties with the first set of panels. Testing phase II included the same SLE motion with Phase I for comparison purposes, followed by a Maximum Considered Earthquake (MCE), which was the 100% of the Petrolia record. For exploratory purposes, after the completion of Phase II, the hybrid model with the severally damaged infill panels was subjected to the 70% of the unscaled JR Takatori record. Due to brevity, information related to this ground motion is not part of this paper.

5. EXPERIMENTAL RESULTS AND DISCUSSION

5.1 Global Response During Testing Phase I

During the first testing phase, the retrofitted test specimen reached about 1% maximum story drift ratios (SDR) at both

stories during SLE. There was partial energy dissipation through micro cracking of the HPFRC infill panels. This can be seen from Figure 8 that shows the base shear versus first story drift of the hybrid model. The base shear in this plot is normalized with respect to the seismic weight of the test specimen.

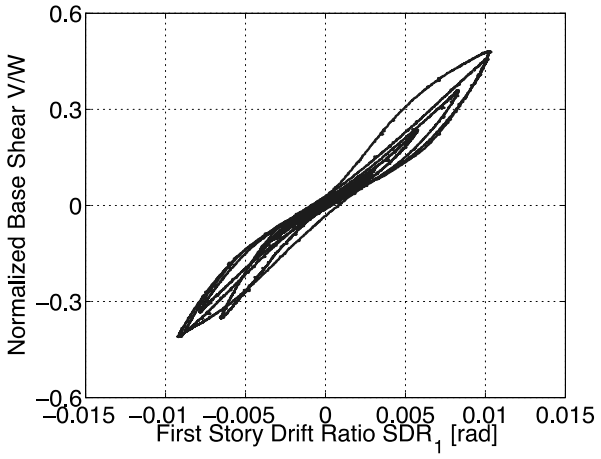

Figure 8 Normalized base shear versus first story drift ratio during SLE ground motion (testing Phase I)

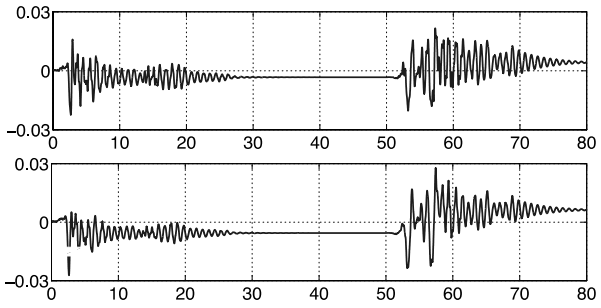
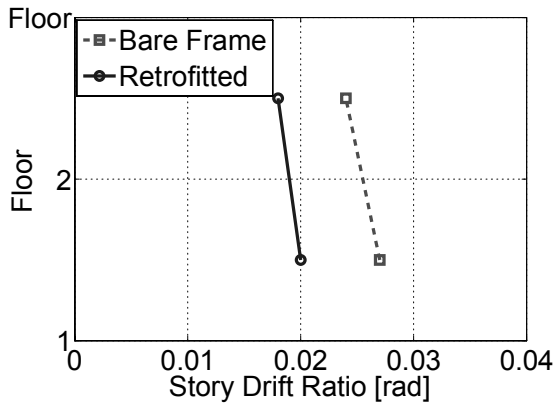
During the DLE-I (70% Petrolia) the hybrid model did not exceed more than 1.9% maximum SDR. After the completion of this ground motion the residual SDRs in both stories was less than 0.5%. Similarly, when the hybrid model was subjected to the unscaled Canoga Park record (DLE-II) the maximum SDRs that the specimen experienced were in the order of 3% in the first story. This can be seen from Figure 9 that shows the story drift ratio histories for the first and second story of the test specimen for test phase I.





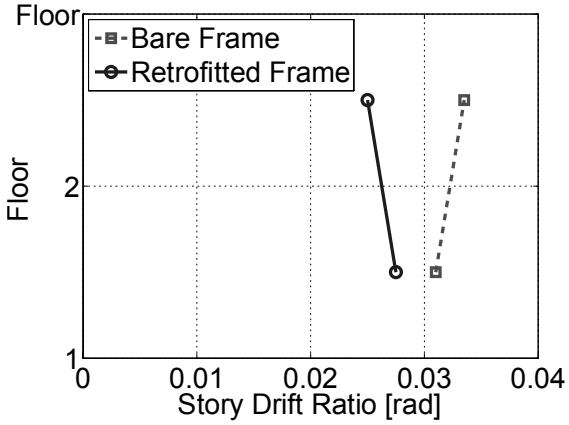


Figure 9 Story drift ratio histories of the hybrid model during testing Phase I (DLE-I, DLE-II)

Comparing the maximum story drift ratios for DLE-I and DLE-II with the ones of the bare frame response it can be seen that in both cases the seismic retrofit system meets the retrofit objectives by means of maximum story drift ratios. This can be seen in Figures 10a and 10b that show a comparison of maximum SDRs of the retrofitted frame with respect to the bare frame performance for DLE-I and DLE-II, respectively.

(a)

(b)

Figure 10 Comparison of maximum story drift ratios of retrofitted and bare frame for testing Phase I; (a) DLE-I; (b) DLE-II

5.2 Observations for Infill Panels During Phase I

After DLE-I ground motion a typical damage pattern of the infill panel system is shown in Figure 11a. Few flexural cracks are evident but not as much as one would expect considering the component tests. More distributed cracking was observed to the infill panels that were adjacent to the steel columns and the set that was located at the center of the span. The main reason for this damage pattern is that the boundary conditions of the top and bottom part of the infill panels are not fixed since the beams deform in double curvature. Another reason is the effect of loading history on the panel response (symmetric cycles versus few cycles and monotonic push during an earthquake). An HPFRC infill panel typically failed completely at the base connection with the steel channel due to rigid body motion (see Figure 11b). After this failure the panels were rocking. This failure mode was observed to 3 panels only during DLE-I. There were no damage observations for the rest of the panels. This implies that after one design level earthquake the infill panel system does not need to be replaced and the steel moment frame is fully operational. However, after DLE-II all the panels were severally damaged and were fully replaced.

(a)

(b)

Figure 11 Infill panel damage patterns after testing Phase I

5.3 Structural Damage Observations After Completion of Testing Phase I

The retrofitted steel moment frame after the completion of Phase I did not have any notable structural damage. The steel beam-to-column connections at the first and second floor slightly yielded as it can be seen from Figure 12 that shows the first floor beam. Note that there was no indication of local buckling in any of the steel beams.

Figure 12 Structural damage after completion of testing Phase I at the first floor beam

Similarly, the two columns at the base yielded as shown in Figure 13 that shows the base of the first story column. This agrees with the hysteretic response of the analytical model.

Figure 13 Structural damage after completion of testing Phase I at the first story column at the base

5.4 Global Response During Testing Phase II

After completion of testing Phase I all the HPFRC infill panels were replaced with a new set. The 2x2 initial stiffness matrix of the retrofitted specimen used in testing Phase II was almost identical with the one obtained prior to testing Phase I. The reason was that there was no lateral torsional buckling in testing Phase I in any of the steel beams (i.e. no unloading stiffness deterioration). Thus, the response of the retrofitted specimen during SLE in Phase II was almost identical with the one during Phase I for the same level of intensity. During the MCE (unscaled Petrolia record) the hybrid model exhibited 3.5% SDR in the first story, as can be seen in Figure 14 that shows the story drift ratio histories during SLE and MCE ground motions for testing Phase II.

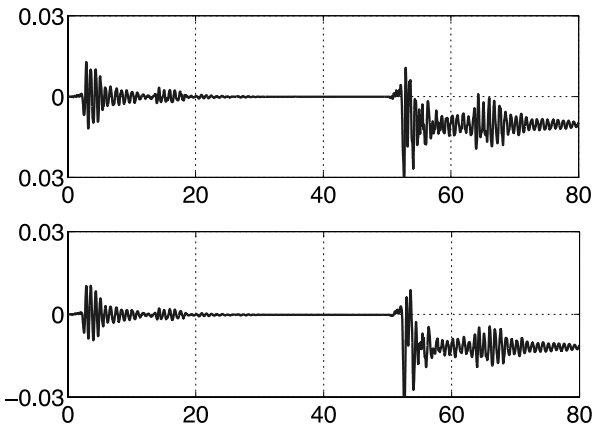

Figure 14 Story drift histories of hybrid model during testing Phase II for SLE and MCE ground motions

A comparison between the maximum story drift ratios of the retrofitted and bare frame during testing Phase II can be seen in Figure 15. From this figure, it is evident that the HPFRC infill panel system is effective as a seismic retrofit system for existing steel moment frame structures designed based on older seismic provisions. The same can be concluded by looking at the residual drifts in both stories of the hybrid model.

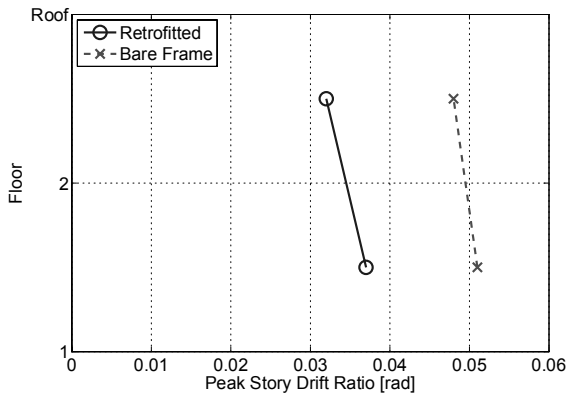

Figure 15 Comparison of maximum story drift ratios of retrofitted and bare frame for MCE during testing Phase II

5.5 Observations for Infill Panels During Phase II

A typical damage pattern of the infill panel system after MCE is shown in Figure 16. Flexural cracks were evident compared to Phase I. Similarly with testing Phase I, more distributed cracking was observed to the infill panels that were adjacent to the columns and the center of the span. The general observation is that all the infill panels were severally damaged during MCE and the failure at the bottom (or top) of the connection line with the steel channel was consistent.

Figure 16 Infill panel damage patterns after the completion of MCE ground motion

5.6 Structural Damage Observations After Completion of Maximum Considered Earthquake

Most of the inelastic behavior of the test specimen during the MCE ground motion occurred in the HPFRC infill panels. Even if the specimen exhibited 3.5% rad SDR in the first story, there was no indication of local buckling in any of the beam-to-column connections of the physical subassembly. This can be seen in Figure 17 that shows the first floor beam at the major peak of the unscaled Petrolia record. Yielding was only observed through the flacking of the white paint that was used for damage observations prior to testing Phase II. More over, none of the connections modeled numerically deteriorated in strength (i.e. local buckling did not occur). An interesting observation was that the bottom flange of the first and second floor beams yielded in between the steel channels during the MCE ground motion. This happened due to shear distribution of the infill panels that resulted to additional bending in the steel beams as shown in Figure 17.

Figure 17 First floor beam at peak of MCE ground motion

6. SUMMARY AND CONCLUSIONS

This paper summarizes the experimental validation of a recently developed infill panel system made of High Performance Fiber Reinforced Cementitious (HPFRC) material for seismic retrofit applications of existing steel moment frame structures. The effectiveness of the HPFRC infill panel system as a seismic retrofit was validated through a two-phase large-scale hybrid simulation testing series that was conducted at the NEES facility of University of California at Berkeley. A 2/3 scale of a 2-story steel moment frame was subjected to a sequence of Design level and Maximum Considered earthquake events. The main conclusions from the testing program are summarized as follows:

1. Inelastic response in terms of peak story drift ratios and residual deformations of the retrofitted moment frame are reduced compared the bare frame performance for both DLE and MCE events.
2. The HPFRC infill panel system was proven to work effectively for a sequence of design level earthquakes

without having to be replaced in between design level ground motions.

3. No indication of severe structural damage was observed for both DLE and MCE in any of the structural components (beams and columns) of the test frame, including the numerical model.

Abstract: The ability of a structure to resist progressive collapse is affected by a number of factors and the main factors are the storey number, span length, span number and floor area. The factors influencing the progressive collapse and the sensitivity of the collapse to these factors are important in structural design. Currently, studies of these factors are mainly based on elastic static theoretical analysis. However, the collapse mechanism is highly nonlinear in behavior. Therefore, a more sophisticated model should be used to find the factors influencing progressive collapse. In this study, the factors influencing progressive collapse of frame structures will be determined through theoretical analysis and numerical simulation. The numerical simulation method will take into account of the material and geometrical nonlinear properties. The alternate path method will be used in design examples to determine how the factors influencing progressive collapse. Finally, a design method for progressive collapse resistance of frame structures will be proposed.

1. INTRODUCTION

The collapse of WTC buildings in New York City has not only been paid extensive attentions since the "9.11" event, but also reminds that researchers and technicians in structural engineering should deeply reflect on the issues of structural safety due to emergent event. Emergent events are unpredictable as one kind of accidental event, and normally cause direct failures of local components, which possibly induce farther losses of total structure. Such failure mode of progressive collapse reveals the weakness of structure systems to resist initial and progressive failure with great potential of dangers.

Redundancy is a key design feature for the prevention of progressive collapse. Redundancy tends to promote an overall more robust structure and helps to ensure that alternate load paths are available in the case of a structure element failure. Three evaluation criterions are given in the literature (Working groups on concepts and techniques, safety evaluation, design and optimization and code implementation 1990) for the redundancy properties: 1) degree of statical indeterminacy, 2) the ratio of system failure probability to partial unit failure probability, 3) the additional bearing capacity not required for structure design. Visible, redundancy properties are endowed with broader implications.

Redundancy properties of structure firstly depend on the type of structural system. For the no-bracing reinforced concrete (RC) frames involve in this paper, they mainly depend on the stiffness of beam-column connection, storey number, bay number and so on. This paper designs 9 RC frames according to the Chinese Seismic Design Code GB50011-2001 (National standard of PRC 2001a), which have different storey number, bay number, span length and earthquake intensity. Then, the alternate path (AP) method will be used to obtain their progressive collapse properties.

2. PROGRESSIVE COLLAPSE ANALYSIS BASED ON AP METHOD

2.1 The Choice of The Analysis Methods

In order to do the progressive collapse design of building structures, many countries have published the relevant codes one after another. Some of them are very representative, such as "Progressive Collapse Analysis and Design Guidelines for New Federal Office Buildings and Major Modernization Projects" (GSA2003) and "Design of Buildings to Resist Progressive Collapse" (DoD2009) in the United States. The guidelines above recommend the AP method as the basis analysis method for progressive collapse analysis.

Currently the following four procedures are generally recommended to operate the AP method for progressive collapse analysis: linear elastic static (LS) analysis, linear elastic dynamic (LD) analysis, nonlinear static (NS) analysis

and nonlinear dynamic (ND) analysis. Advantages and disadvantages of these approaches have been discussed by Marjanishvili and Agnew (2006).

The progressive collapse of structures is a complex nonlinear dynamic process, so the material and geometrical nonlinear properties should be considered. Nonlinear static analysis and nonlinear dynamic analysis are the main analysis method used in this paper.

2.2 Applied Loads for Static and Dynamic Analyses

In this paper, the load combination of the GSA2003 is selected for the progressive collapse analysis. The GSA2003 proposes the amplification factor of 2 for the static analysis to account for dynamic redistribution of forces. The load combination of the GSA2003 for the nonlinear static analysis is 2(Dead Load+0.25Live Load). This amplified load is applied only in the spans in which a column is removed while unamplified load is applied in the other spans (Fig. 1). The load combination for the nonlinear dynamic analysis is (Dead Load+0.25Live Load).

In this study, the nonlinear static analysis or vertical pushover analysis is applied by increasing the vertical displacement in the location of the removed column to investigate the resistance of the structure against such deformation. Since the vertical pushover method is displacement controlled, the analysis is carried out by increasing displacement to an arbitrary level. In the analysis, vertical load is imposed on all beams with its original loading pattern (Fig. 1) unchanged. At every step during the vertical pushover analysis, i.e., at each level of the vertical displacement, the amount of equivalent load corresponding to the displacement level is determined. The amount of the load is referred to as "load factor", which is the ratio of the equivalent load to the full vertical load.

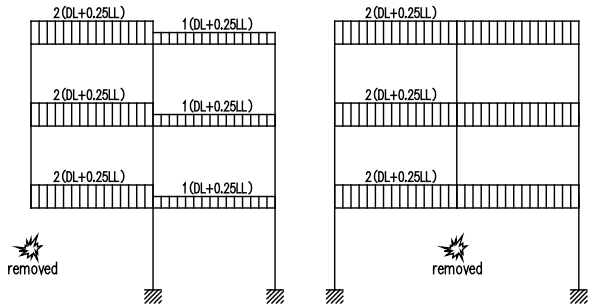

Fig. 1. Applied Load for Static Analysis

For dynamic analysis the guidelines do not recommend to use the dynamic amplification factor. To carry out dynamic analysis, the joint force acting on a column is computed before it is removed. Then the column is replaced by joint loads equivalent of its member forces as shown in Fig. 2. To simulate the phenomenon that the column is abruptly removed, the vertical supporting element should be removed over a time period that is 1/10 of the period associated with the structural response mode for the vertical element removal (GSA2003).

2.3 Loss Scenario

For progressive collapse analysis, the guidelines mandate several loss scenarios. However, only one element removal is required at a time. The cause of element failure is not considered. Statistically (Ellingwood B R et al 2007), the progressive collapse of the public buildings is mainly because the vehicle collisions and car-bomb attack. So the columns of the ground floor are more likely to be damaged than the columns of upper floors; the perimeter columns are more likely to be damaged than the interior columns. So we have considered the loss scenarios of the perimeter columns of the ground floor in this paper.

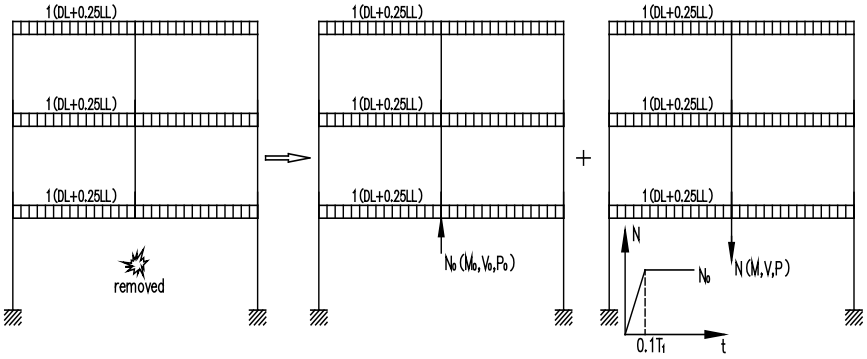

Fig. 2. Applied Load for Dynamic Analysis

2.4 Analysis Program and Evaluation Criterion

Using the commercially available structural analysis software SAP2000, the three-dimensional models of RC buildings are developed. Bernoulli beam elements with localized plastic hinges are used to model material nonlinearity in beams and columns. Geometric nonlinearity is also considered. Plastic hinges are modeled based on the FEMA356 guidelines (Federal Emergency Management Agency 2000). Different performance levels are shown in Fig. 3.

There are different evaluation criterions for the performance of the structure to resist progressive collapse, like strength criterion, deformation criterion and energy

criterion. Since the purpose of this article is to determine how the factors influencing progressive collapse properties, the finite element models have taken some measures to simplify. So deformation criterion and strength criterion are used in this paper.

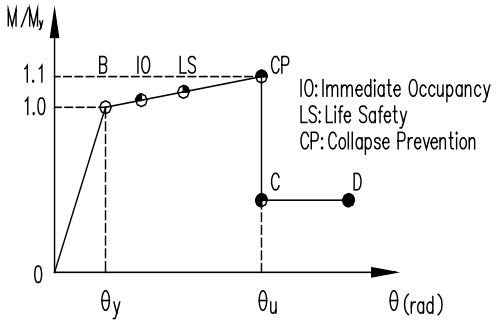

Fig. 3. The plastic hinge model

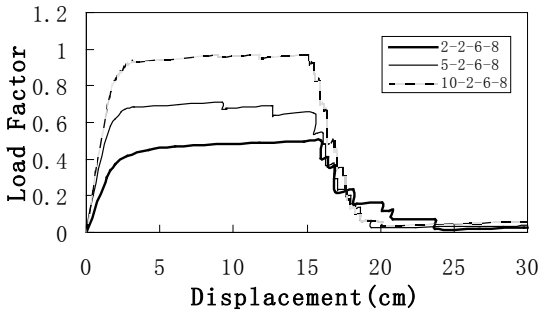
3. STRUCTURAL MODELS AND PARAMETERS

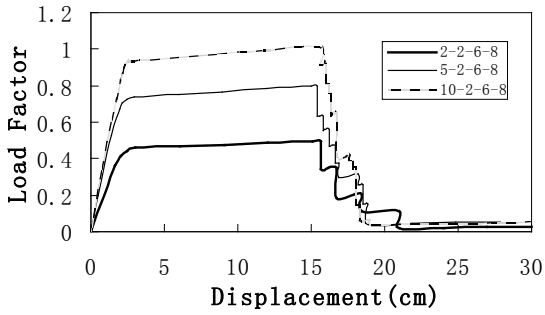
9 RC frames, of which each has the equal spans and storey heights, in different seismic fortification zone are designed according to the Chinese Seismic Design Code GB50011-2001 with PKPM software. The concrete strengths of beams and columns are C30. The longitudinal reinforcements of beams and columns are HRB400 rebar (fy=360 MPa) while the stirrups are HPB235 rebar (fy=235 MPa). The dead load (DL) on the roof is 8.5 kN/m^2 while the other floors are 6.5 kN/m^2 (including the dead weight of the slab). The live loads (LL) are 2 kN/m^2 on both the roof and other floors. The storey height is 3.6m for all the storeies. The major parameters of the 9 frames are shown in Table 1. Influences of storey number, bay number, span length and earthquake intensity to progressive collapse resistance of RC frames are mainly considered.

Table 1. Parameters of Structural Models



Model name	Storey number	bay number	Span length (m)	Seismic fortification intensity(degree)	Section size of column (mm×mm)	Section size of beam (mm×mm)
2-2-6-8	2	2	6	8	400×400	200×500
5-2-6-8	5	2	6	8	550×550	300×550
10-2-6-8	10	2	6	8	700×700	300×650
5-2-7.5-8	5	2	7.5	8	650×650	300×650
5-2-9-8	5	2	9	8	750×750	350×750
5-4-6-8	5	4	6	8	600×600	300×550
5-6-6-8	5	6	6	8	700×700	300×550
5-2-6-6	5	2	6	6	400×400	200×450
5-2-6-7	5	2	6	7	500×500	250×500

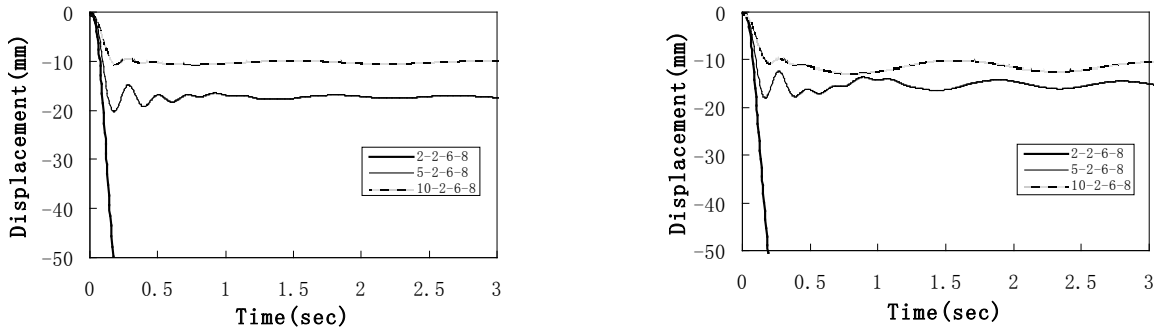
4. CALCULATION RESULTS AND DISCUSSIONS



4.1 Explanation for The Curves

In seismic pushover analysis the relationship between the base shear and the story drift is observed to estimate the seismic load resisting capacity. In this study of vertical pushover analysis, the vertical displacement and the sum of the vertical loads corresponding to the vertical displacement are plotted for various parameters such as span length, number of stories, number of bays and earthquake intensities. Since the vertical load varies with the dimension of the plan and the elevation, the ratio of the vertical load at each step to the specified total vertical load shown in Fig. 1 is plotted in the figures as dimensionless loading parameter.

To confirm the result obtained from the vertical pushover analysis, the ND analysis is conducted with the same model structures. The ND analysis result depicts the vertical deflection of the joint from which a column is removed.



(a) Removal of Center Column

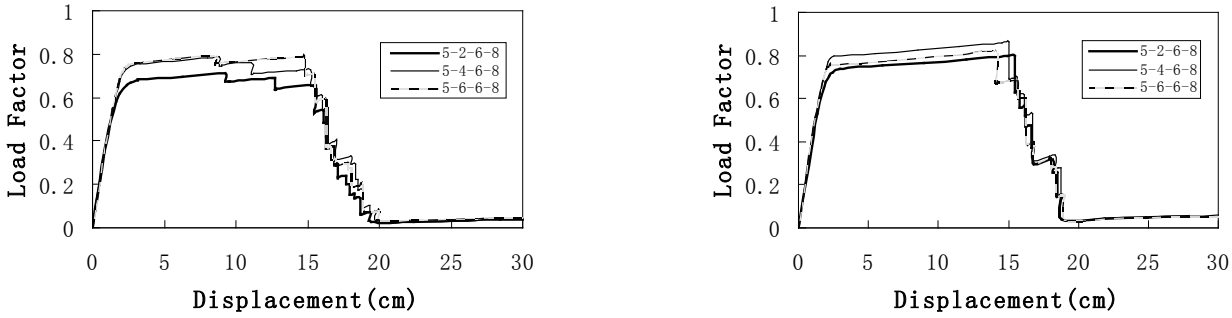
(b) Removal of Corner Column

Fig. 4. Load-Displacement Curves for The Comparison of Different Storey Number

(a) Removal of Center Column (b) Removal of Corner Column

Fig. 5. Displacement Time History Curves for The Comparison of Different Storey Number

4.2 Comparison for Different Storey Number



In Fig. 4, it can be observed that as the number of stories increases both the stiffness and the ultimate strength of model structures increase as well. In Fig. 5, it can be observed that the maximum displacements decrease as the number of stories increases.

This seems to be reasonable considering that as the number of stories increases the number of structural members involved in the load transfer also increases and so do the redundancy and the resistance to progressive collapse.

4.3 Comparison for Different Bay Number

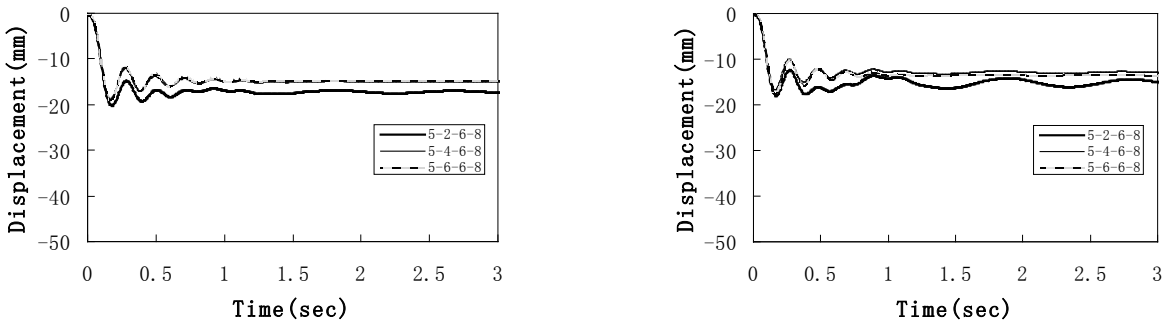


Fig. 6 shows the results of the model structures with 2, 4, and 6 bays. It can be observed that the strength of model structures increases as the number of bays increase from 2 to 4. But this law becomes not obvious when the number of bays continue to increase from 4 to 6. The similar phenomena can be obtained from the displacement time history curves in Fig. 7.

Although the increase of bay numbers will increase the redundancy of the structures, this does not means that the progressive collapse resistance of structures will also be continued increasing as the increase of bay numbers. The analysis results show that only the increasing bays adjacent to the bay in which a column is removed will increase the progressive collapse resistance of the model structures effectively. The increasing bays which are far away from the bay in which a column is removed have little effect to increase the progressive collapse resistance of the RC frames.

(a) Removal of Center Column (b) Removal of Corner Column

Fig. 6. Load-Displacement Curves for The Comparison of Different Bay Number

(a) Removal of Center Column (b) Removal of Corner Column

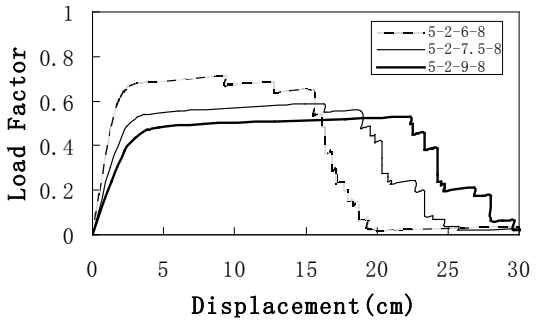

Fig. 7. Displacement Time History Curves for The Comparison of Different Bay Number

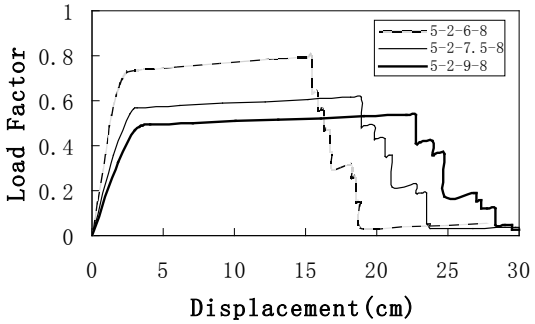
4.4 Comparison for Different Span Length



In Fig. 8, it can be found that both the stiffness and the ultimate strength of model structures decrease as the span length increases. It also can be noticed that the maximum displacements at the limit state of failure increase with the span length.

In Fig. 9, it can be observed that the maximum displacements of model structures increase as the span length increase. This phenomenon is more obvious for the removal of center column.

The reason is that the increase of span leads to the increase of total gravity loads, which results in larger axial compression. It can be found that the collapse possibility becomes larger as span increases.

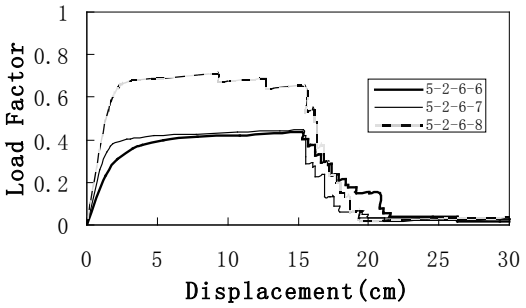
(b) Removal of Corner Column

Fig. 8. Load-Displacement Curves for The Comparison of Different Span Length

(a) Removal of Center Column



(b) Removal of Corner Column

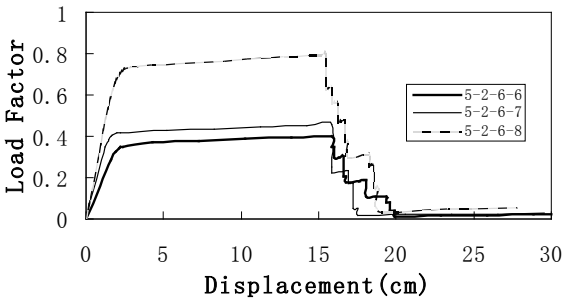


Fig. 9. Displacement Time History Curves for The Comparison of Different Span Length

4.5 Comparison for Different Earthquake Intensity

In Fig. 10-11, the load resisting capability of the structures designed for 8-degree seismic fortification zone according to the Chinese Seismic Design Code increase as compared with those of structures designed for 6 and 7-degree seismic fortification zone. This is reasonable since the members are designed with bigger lateral loads. However, the structures designed for 6 and 7-degree seismic fortification zone have little difference. This is due to the fact that the contribution of gravity load is greater than the seismic load in 6 and 7-degree seismic fortification zones.

Fig. 11. Displacement Time History Curves for The Comparison of Different Earthquake Intensity

5. CONCLUSIONS

This paper analyzes progressive collapse resistances of 9 RC frames which have different storey number, bay number, span length and earthquake intensity, designed according to the Chinese Seismic Design Code. The results show that the progressive collapse resisting capacity of the RC frames increases as the number of stories increases and the span length decreases. The increasing bays adjacent to the bay in which a column is removed will increase the progressive collapse resistance of the RC frames slightly. In the highly seismic area, when the contribution of the seismic load is greater than gravity load, the progressive collapse resistance will increases as the earthquake intensity increases.

Abstract: In seismic design, moment resisting frame is designed to form the overall sway mechanism under severe earthquake. However, it is possible to form the weak column mechanism with the rise of strength of beams and panel zone due to strain hardening. The causes to collapse the weak column type frame are strong bi-axial seismic force, P-Δ effect and deterioration of restoring force. In this study, a series of response analyses of weak column type multi story steel frames under bi-axial ground motion are carried out. In the analysis, realistic hysteresis model of story including deteriorating range is used. From analytical results, collapse behavior and ultimate earthquake resistance of steel frames governed by deterioration of columns are evaluated.

1. INTRODUCTION

In seismic design, moment resisting frame is designed to form the overall sway mechanism under severe earthquake. However, it is possible to form the weak column mechanism with the rise of strength of beams and panel zone due to strain hardening. In the full scale shaking table test of 4 story steel moment frame conducted at E-defense in 2007, Yamada et. al. (2008) and Suita et. al. (2008), specimen building made sway mechanism under design level earthquake. However under extremely strong ground motion, mechanism changed to weak story type and specimen building completely collapsed. The causes to collapse the weak column type frame are strong bi-axial seismic force, P-Δ effect and deterioration of restoring force caused by local buckling in column. Many studies focused on the influence of P-Δ effect to earthquake resistance of moment frame were carried out. But most of them dose not consider the realistic deterioration behavior of column.

In this study, a series of response analyses of weak column type multi-story steel frames under bi-axial ground motion are carried out. Hysteresis model used in analysis based on the realistic behavior of column including the deteriorating range governed by local buckling. From analytical results, collapse behavior and ultimate earthquake resistance of weak column type steel frame under bi-axial excitation is clarified.

2. OUTLINE OF ANALYSIS

2.1 MSS Model

In this study, MSS (Multiple Shear Spring) model, Wada et. al. (1989), shown in Fig.1 is used. In the MSS model, behavior of the story is expressed by the equal shear springs which placed at an equal angle. Analytical model of multi story shear system which placed MSS between each mass has degree of freedom of two horizontal directions in each story. The reason to use this model is that rectangular hollow section steel tube which frequently used as column of steel building structures in Japan has small directionality of the structural characteristics. In addition, behaviors of the columns govern the collapse behavior of structure that forms weak story mechanism. By consideration of accuracy, number of shear springs in a story is 16. P-Δ effect is considerd as negative stiffness, Akiyama (1984).

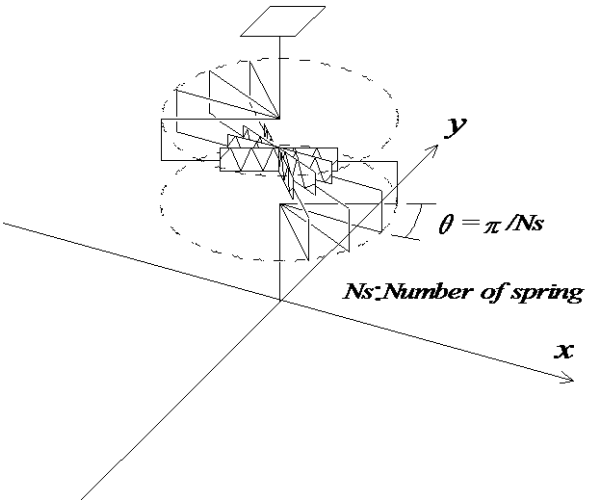

Fig.1: MSS (Multiple Shear Spring) model

2.2 Hysteresis model of the story based on the realistic behavior of column

Hysteresis model used in this analysis consists with skeleton curve which corresponds to the load-deflection relationship under monotonic loading, Bauschinger part, and elastically unloading part, as shown in Fig.2, Akiyama et. al. (1990). Based on the calculated load-deformation relationship of RHS column under monotonic loading including deteriorating behavior governed by local buckling , Yamada et. al (1993), skeleton curve of the story is modeled. In this study, two types of cold-formed RHS column are used. One has section with D/t ratio of 20 which represents columns with enough ductility; the other has section with D/t ratio of 30 which represents columns with poor ductility. Fig. 3 shows the analytical result. In the analysis, axial force ratio set 0.2.

Skeleton curve of the story and load deformation relationship of column corresponds under following assumptions. (1) Yield rotation angle of column is 1/3 of yield story drift angle. (2) Yield story shear corresponds to full plastic moment of column. (3) Beams and panel-zones yield simultaneously with columns. (5) About second modulus of the story, two types of model set. In Model 1, second modulus of story has 1/2 of the second modulus of column. In Model 2, second modulus of story has 1/3 of the second modulus of column. The ratio of the plastic deformation of the column in the plastic deformation of the story becomes 1/2 and 1/3 in the Model 1 and Model 2 respectively. (6) In the deteriorating range, stiffness of the story set same with stiffness of column. Fig. 4 shows the skeleton curve of the story. In the analysis, the skeleton curve of the story divided to the element springs in the MSS.

As the Bauschinger part, Akiyama and Takahashi's model, Akiyama et. al. (1990). is applied.

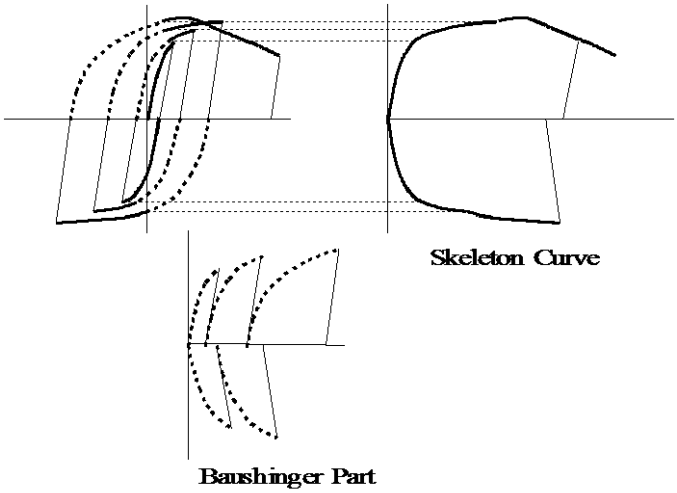

Fig.2: Decomposition of the hysteresis loop

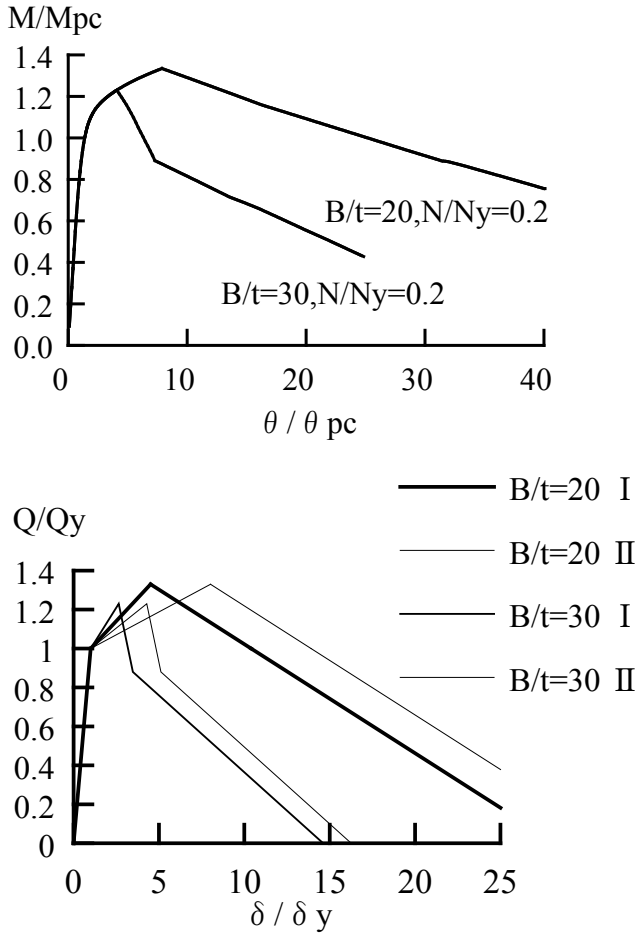

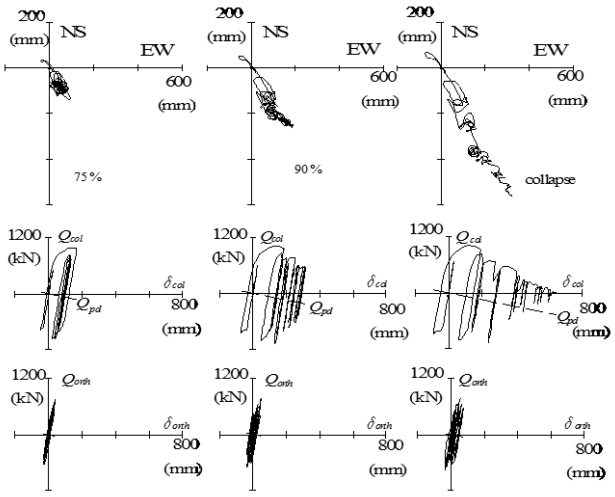

Fig.4: Skeleton curve of the story

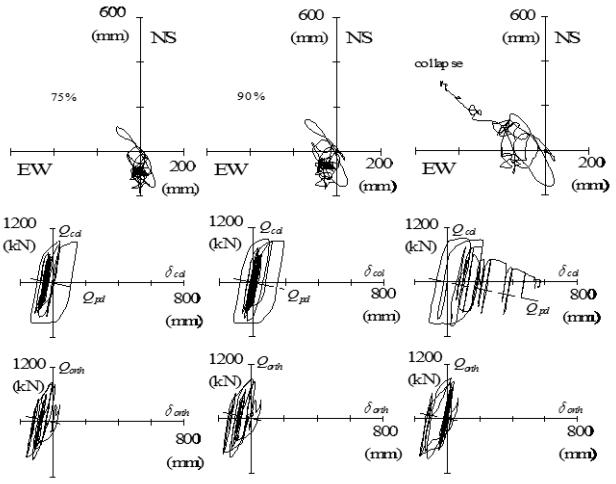
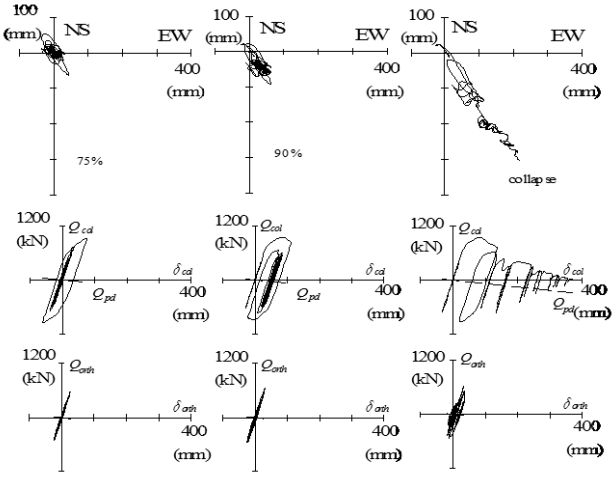
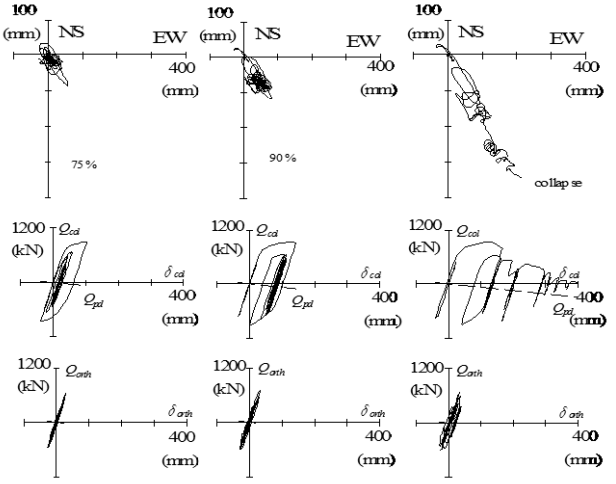


2.3 Parameter

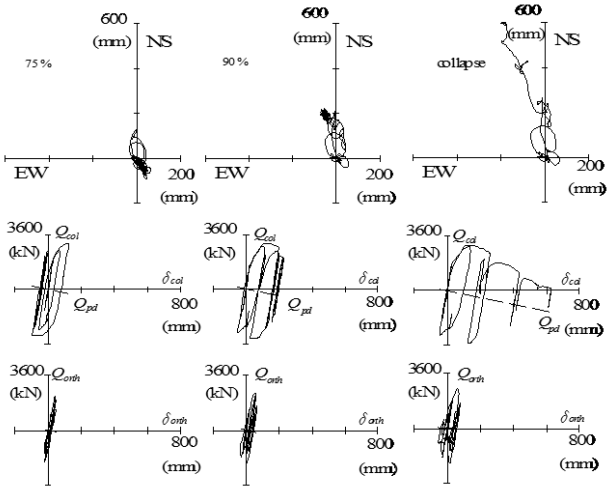
Analytical models are multi-story shear model. Standard model set with number of the story (N) of 3, story shear coefficient of the 1st story (α 1) of 0.3 and yield story drift angle (θ y) of 0.01. Difference of the collapse behavior of multi story steel frame with four kinds of restoring force characteristics set in the former part is examined by using standard model. The influences of other parameters of frame, i.e. number of the story, story shear coefficient of 1st story and yield story drift angle, are examined by changing one parameter from standard model with hysteresis Model 1 of D/t=20. Examined parameters are story number of 9, story shear coefficient of 1st story of 0.5 and yield story drift angle of 0.005. In all models, weight of each story is 1000kN, height of each story is 4m, and distribution of stiffness corresponds to the optimum story shear coefficient distribution. And in order to make weak 1st story mechanism, except 1st story are kept in elastic range.



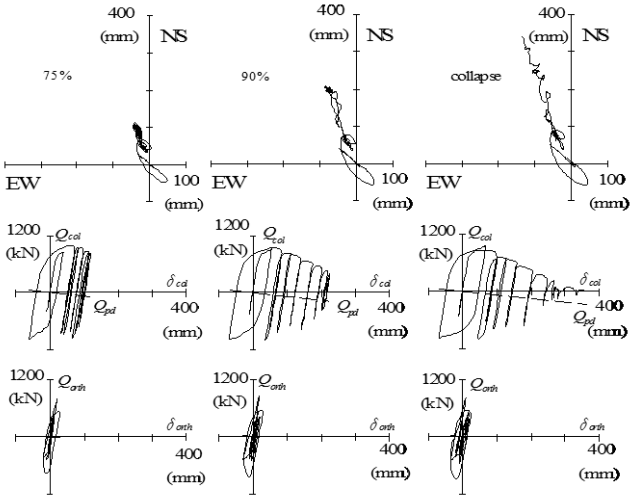
As input waves, JMA Kobe record, El-Centro record, Hachinohe record and Taft record are used. In the analysis, amplification factor is multiplied to the acceleration record in order to change input level up to collapse.



(1) N=3, α_1=0.3, θ_y =0.01, D/t=20 Model 1



(2) N=3, α_1=0.3, θ_y =0.01, D/t=20 Model 2



(3) N=3, α_1=0.3, θ_y=0.01, D/t=30 Model 1

(4) N=3, α_1=0.3, θ_y=0.01, D/t=30 Model 2

(5) N=9, α_1=0.3, θ_y=0.01, D/t=20 Model 1

(6) N=3, α_1=0.3, θ_y=0.005, D/t=20 Model 1

Fig.5: Orbit and hysteresis of 1st story under JMA-Kobe record

3. COLLAPSE BEHAVIOR AND ULTIMATE EARTHQUAKE RESISTANCE OF WEAK STORY TYPE MULTI STORY FRAMES UNDER BI-AXIAL GROUND MOTION

Orbit and hysteresis of 1st story under JMA-Kobe record are shown in Fig.5. Hystereses are in collapsed and its orthogonal directions respectively. In the figure, analytical result of collapse level, 90% of collapse level and 75% of collapse level are compared. In any case, displacement progresses to one direction when the story stiffness becomes negative according to deterioration though bias of the displacement are small until story reaches its maximum strength. Comparing the hysteresis of each model in collapsed direction, in case of Model 2 with D/t=20 even in the collapse level excitation stable behavior is appeared until story reaches its maximum strength. On the other hand, in cases of models with less ductility, displacement progresses to one direction without obvious cyclic behavior under collapse level excitation.

Hysteretic dissipated energy in the collapse direction of collapsed case is shown in Fig.6 divided by the dissipated energy under monotonic loading. Ratios of dissipated energy in the collapse direction to the dissipated energy under monotonic loading are around 1.0 except cases with enough ductility. Even if model has enough ductility、lowest value of the ratio is 1.3. When weak story type steel frame collapse under bi axial ground motion, hysteretic dissipated energy in the collapse direction can be evaluated as approximately same with the hysteretic dissipated energy under monotonic loading.

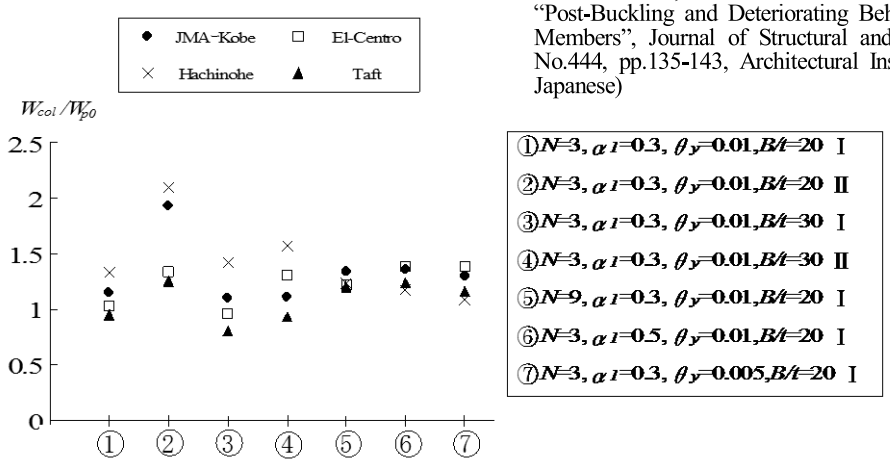


Fig.6: Hysteretic dissipated energy in the collapse direction

4. CONCLUSIONS

A series of response analyses of weak column type multi-story steel frames under bi-axial ground motion are carried out. Hysteresis model used in analysis is based on the realistic behavior of column including the deterioration range governed by local buckling. From analytical results, following conclusions are obtained.

1. Focusing on orbit of the 1st story, displacement progresses to one direction when the story stiffness becomes negative according to deterioration though bias of the displacement are small until story reaches its maximum strength.
2. When weak story type steel frame collapse under bi axial ground motion, hysteretic dissipated energy in the collapse direction can be evaluated as approximately same with the hysteretic dissipated energy under monotonic loading.

Abstract: In this study, a medium scale double layer lattice domes with substructure whose natural period is equal to the natural period of roof structure are made an object of investigation, the effects of yielding of roof members on seismic response behavior of lattice domes are examined by elasto-plastic dynamic response analysis which takes into account the geometrical nonlinearity. In addition, the simplified evaluation method for reductions of seismic response accelerations and displacements at roof members yielding is proposed. The strain energy produced to the upper structure of equivalent double-mass system based on dome model is used for this evaluation method.

1. INTRODUCTION

On seismic responses of lattice domes, when roof structure resonates with substructure large response accelerations occur at roof structure as shown in the work by Takeuchi et al. (2007). As a result, there is a possibility that the members of roof structure yield. In this study, the double layer lattice domes with substructure whose natural period is equal to the natural period of roof structure are made an object of investigation, the effects of yielding of roof members on seismic response behavior of lattice domes are examined by elasto-plastic dynamic response analyses. In addition, the simplified evaluation method for reductions of seismic response accelerations and displacements by roof members yielding is proposed. The strain energy produced to the upper structure of equivalent double-mass system based on dome model is used for this evaluation method.

2. ANALYSIS MODELS AND NUMERICAL ANALYSIS METHODS

2.1 Analysis Models

The analysis model for this study is a medium scale double layer lattice dome with 6000cm span as shown in Figs.1 and 2. Table 1 shows the dimensions of dome. The half subtended angle of the dome is 30 degrees. The member properties for roof structure are shown in Table 2. The members of dome roof are steel tubular sections and these are designed so that combined stresses (compressive or tensile stress and bending stress) of the members under the dead load of the dome will be uniform. The members of substructure are designed so that the story deformation angle under horizontal load with base shear coefficient 0.3 will be less than 1/200. The horizontal stiffness of substructure is set so that the ratio of natural period R_T is adjusted to 1.0. Here, the natural period ratio R_T is the ratio of natural period of substructure with rigid roof to that antisymmetrical 1 wave mode of roof structure without substructure. The stress-strain relationship is assumed to be a bi-linear type for dome roof members and a linear type for the other members. The joints between the tension ring of dome roof and the top of column of the substructure are pin joints. For the boundary condition, the bases of columns are pin supported. The dead load is assumed to be 1.18kN/m^2 for the dome roof in consideration of the structural material weight and finishing material weight, etc.

2.2 Numerical Analysis Methods and Input Seismic Waves

The method of analyses are a time history response analysis and a static buckling analysis those takes into account the geometrical and material nonlinearities. A numerical integration scheme for time history response analysis is the Newmark β = 1/4 method. The time increment Δt is 0.005sec. Rayleigh damping is applied to the dome damping. The damping factor h is 2% for 1st and 2nd (or 3rd) modes. The input seismic waves are two observed earthquake motions El Centro NS (1940) and JMA Kobe NS (1995). The input direction of seismic waves is horizontal x direction.

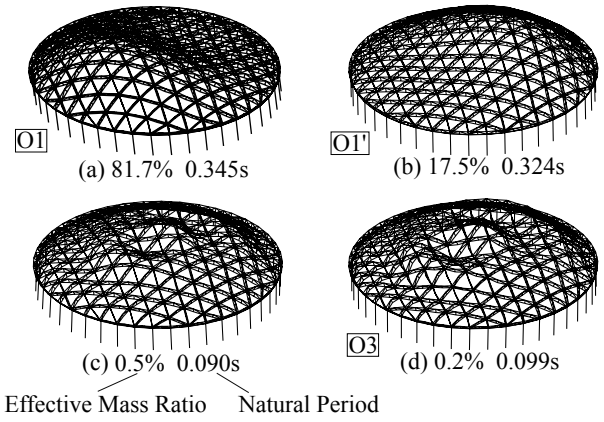

Figure 3 Natural Vibrational Characteristics (in Elastic Range)

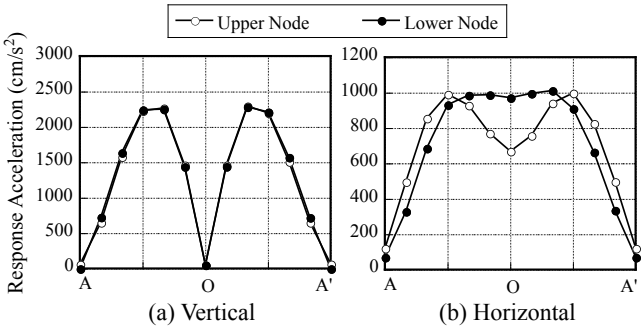

Figure 4 Distributions of Maximum Response Accelerations on line AOA'
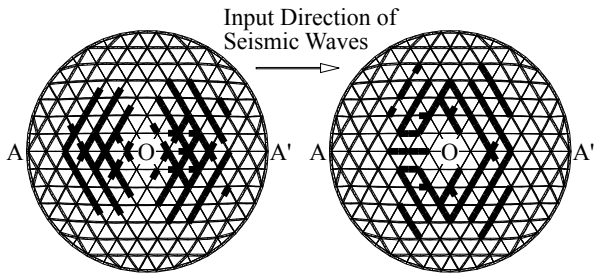
(El Centro NS 25cm/s Input, Elastic Response)

3. ELASTIC RESPONSE BEHAVIOR

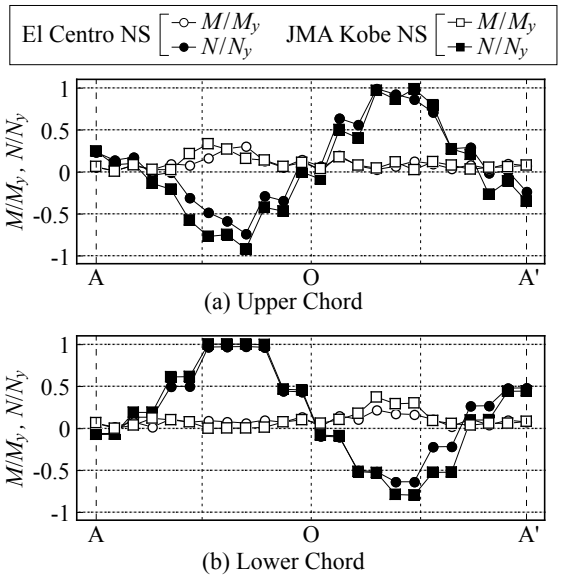
Fig.3 shows the natural vibrational characteristics at elastic range. The shape of mode with maximum effective mass ratio is the antisymmetrical one wave mode (O1 mode). The effective mass ratio of this mode is 81.7%.



The distributions of maximum response accelerations on line AOA' at elastic range are shown in Fig.4. The response accelerations are the relative values between the responses of roof structure and those at top of column of substructure. The distribution shapes of vertical acceleration are the antisymmetrical shape, the influence of O1 mode appear. In horizontal direction, the difference of responses of upper nodes and lower ones is found. This difference occurs because of the rigid body rotation of chord members.

4. EFFECT OF YIELDING OF ROOF MEMBERS ON RESPONSE BEHAVIOR

4.1 Elasto-plastic Response Behavior



At first the responses of dome roof subjected to seismic waves with maximum velocity of 75cm/s are investigated. Fig.5 shows the distributions of yielding roof members when number of yielding members is a maximum. The members yielding occurs in the vicinity of antinode of antisymmetrical one wave mode with maximum effective mass ratio. There is a difference between the distribution of yielding members of upper layer and that of lower layer due to the difference of horizontal responses

between upper nodes and lower ones. Fig.6 shows the distributions of axial forces and bending moments on line AOA' at the same time as Figure 5. N_y is the yield axial force, M_y is the yield moment. The axial forces are dominant compared with the bending moments regardless of the layer. The shape of distribution of axial forces is the antisymmetrical one wave shape.

(a) Upper Chord

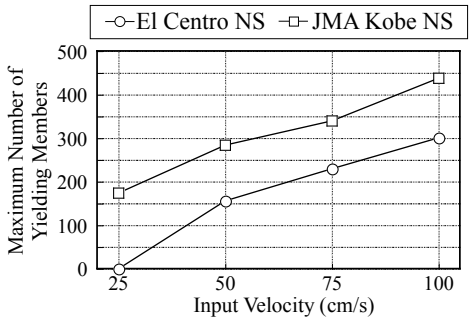
(b) Lower Chord

Figure 6 Distributions of Axial Forces and Bending Moments on line AOA' (at Time of Maximum Number of Yielding members, 75cm/s Input)

Next, the effects of maximum velocity of input seismic wave on elasto-plastic response behavior of dome are examined. The maximum velocities of input seismic waves are 25~100cm/s (at intervals of 25cm/s). Fig.7 shows the relationships between maximum number of yielding members and input velocity of seismic waves. The number of yielding members increases with increase in input velocity. The distributions of maximum response acceleration amplification factors on line AOA' are shown in Fig.8. The maximum response acceleration amplification factors F_{AV} and F_{AH} are defined as Eqs. (1) and (2).

$$F_{AV} = A_V / A_{eq} \quad (1)$$

$$F_{AH} = A_H / A_{eq} \quad (2)$$



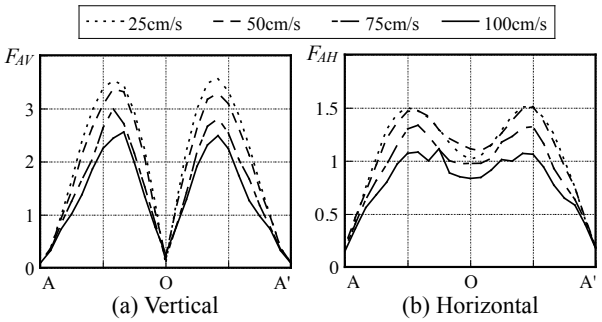


Figure 7 Relationships between Maximum Number of Yielding Members and Input Velocity of Seismic Waves

Figure 8 Distributions of Maximum Response Acceleration Amplification Factors on line AOA' (Upper Layer, El Centro NS)

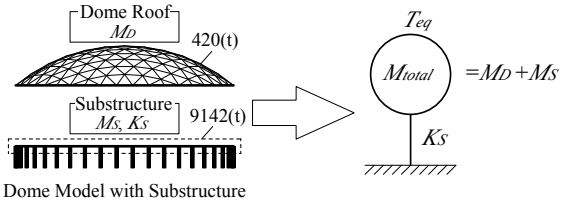

Figure 9 Conversion to Equivalent Single-mass System

where A_V and A_H are the maximum vertical and horizontal response accelerations respectively, A_{eq} is the maximum response acceleration of equivalent single-mass system shown in Fig.9.

As the number of yielding members increase, the response amplification factors decrease uniformly in any node.

4.2 Examination of Reduction of Response Amplification Factor due to Plasticity of Roof Members

In this section, the reason of reduction of response amplification factors due to plasticity of roof members is investigated. At first, the change of natural vibrational characteristics due to plasticity of members is examined. Fig.10 shows the natural vibrational characteristics in elasto-plastic range. Input Seismic wave is El Centro NS with maximum velocity 100cm/s. The vibrational characteristics at the time when the maximum vertical response acceleration occurs are indicated. The natural period of mode with maximum effective mass ratio does not change because of the plasticity of roof members. One of the reasons for this is that the mass of substructure which is assumed to be in elastic state is larger than that

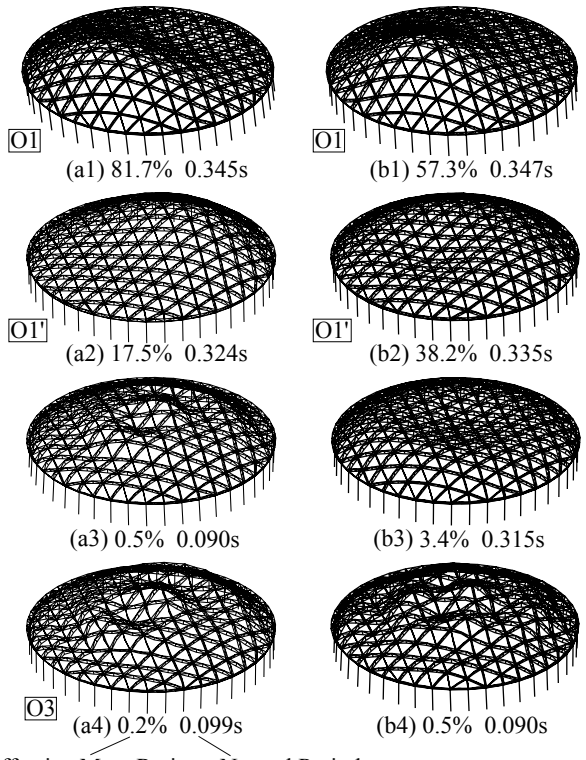

Figure 10 Comparison of Natural Vibrational Characteristics in Elastic Range with Those in Elasto-plastic Range
(Elasto-plastic Range: El Centro NS, 100cm/s Input)

of dome roof. Consequently, the effect of the change of vibrational mode due to the plasticity of roof members on response behavior is small.

Next, we take note of the strain energy produced to the whole dome roof when the maximum response occurs. Fig.11 shows the time histories of strain energy produced to the dome roof. The cumulative plastic strain energy increases every half of natural period of O1 mode. Then the response reduction ratios D_h^{dome} are evaluated from Eqs. (3)~(5)[Kasai et al. (2003)] by using this cumulative plastic strain energy W_P and elastic strain energy W_E.

$$h_{eq} = 0.8\frac{1}{4\pi}\frac{W_P}{W_E} \quad (3)$$

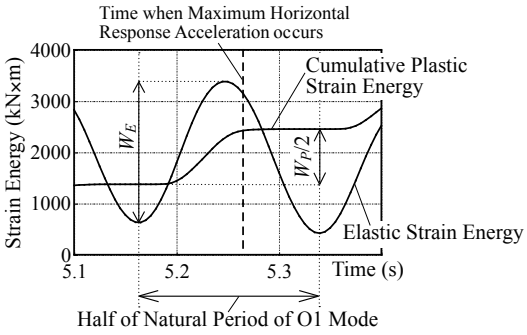
$$h = h_{eq} + h_0 \quad (h_0 = 0.02) \quad (4)$$

$$D_h^{dome} = \sqrt{\frac{1+\alpha h_0}{1+\alpha h}} \quad (\alpha = 25) \quad (5)\text{[Kasai et al. (2003)]}$$

Fig. 12 shows the response reduction ratios D_h^{dome} and D_r^{dome}. D_r^{dome} those are calculated from Eqs. (6)~(9) using the maximum response amplification factors are the response reduction ratios in analysis results.

$$D_{rAV}^{dome} = F_{AV}/F_{eAV} \quad (6) \qquad D_{rAH}^{dome} = F_{AH}/F_{eAH} \quad (7)$$

$$D_{rDV}^{dome} = F_{DV}/F_{eDV} \quad (8) \qquad D_{rDH}^{dome} = F_{DH}/F_{eDH} \quad (9)$$



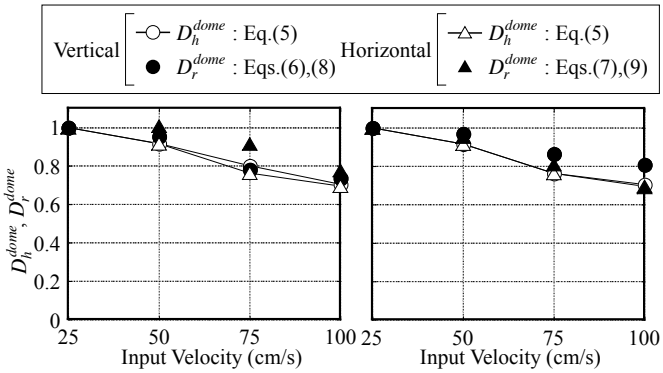


Figure 11 Time Histories of Strain Energy
(El Centro NS, 75cm/s Input)

(a) Response Acceleration (b) Response Displacement

Figure 12 Relationships between Response Reduction Ratios and Input Velocity of Seismic Waves
(El Centro NS)

where F_{AV}, F_{AH}, F_{DV} and F_{DH} are the maximum response amplification factors for acceleration (A) and displacement (D), and for vertical direction (V) and horizontal direction (H) respectively. F_e are the maximum response amplification factors in elastic response.
The estimated response reduction ratios D_h^{dome} agree approximately with the analysis results D_r^{dome}. From the above, the reduction of maximum response amplification factors due to plasticity of members can be explained by the response reduction ratios estimated from the strain energy produced to the whole dome roof.

5. EVALUATION METHOD FOR RESPONSE REDUCTION DUE TO PLASTICITY OF MEMBERS

The response reductions are attempted to evaluate by estimating the strain energy produced to the dome roof from the time history responses of equivalent double-mass system. The equivalent double-mass system is made based on the vibration characteristic of O1 mode. The procedure of making of equivalent double-mass system is shown in Fig.13.

1) The effective mass of O1 mode M_e is computed by eigenvalue analysis (Fig. 13(1)).
2) The stiffness of substructure K_{Se} is determined so that the natural period of single-mass system with

mass M_e shown in Fig.13(2) agrees with that of equivalent single-mass system shown in Fig.9.

3) The stiffness of roof structure K_{De} is determined so that the natural period of equivalent double-mass system shown in Fig.13(3) agrees with the period of O1 mode. The effective mass is apportioned to the upper and lower structures of double-mass system according to the ratio of mass of dome roof to that of substructure.

The mechanical characteristics of double-mass system are the bi-linear type for roof structure and the linear type for substructure. The second gradient of roof structure of double-mass system is determined as half of initial stiffness based on the relationship between horizontal load and horizontal average displacement of dome model by static buckling analysis shown in Fig.14. The initial yield loads of dome model and double-mass system are equal.

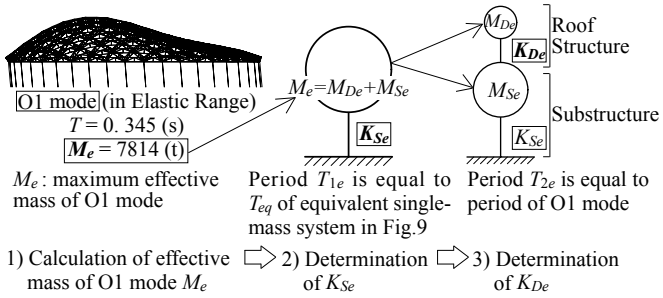

Figure 13 Procedure of Making of Equivalent Double-mass System

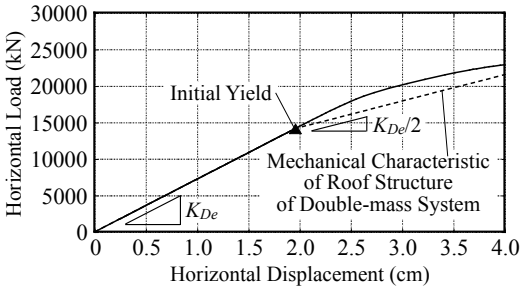

Figure 14 Relationships between Horizontal Load and Horizontal Displacement

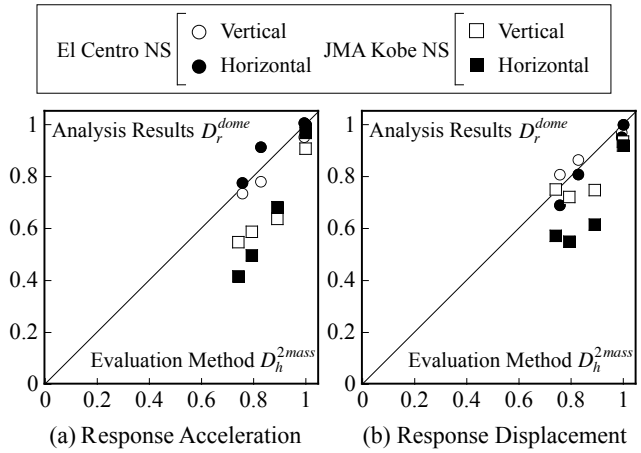

Figure 15 Accuracies of Proposed Evaluation Method for Response Reduction Ratio using Strain Energy of Equivalent Double-mass System

The response reduction ratios of equivalent double-mass system D_h^{2mass} are evaluated by substituting the strain energy of double-mass system W_P^{2mass}, W_E^{2mass} for Eqs. (3)~(5). Fig.15 shows the accuracies of proposed evaluation method for response reduction ratio using the strain energy of equivalent double-mass system. The evaluated response reduction ratios D_h^{2mass} agree approximately with the analysis results D_r^{dome}. Therefore it is possible to evaluate the response reduction ratio of double layer lattice dome by using the equivalent double-mass system.

However, there are several cases those the evaluated values D_h^{2mass} are larger than the analysis results D_r^{dome} because it is impossible to express the pulsating in vertical response displacement of lattice dome subjected to JMA Kobe NS by the response of double-mass system.

6. CONCLUSIONS

It is concluded as follows, from the results of above numerical analyses.

1) The yielding of members of dome roof subjected to seismic waves with maximum velocity 75cm/s occurs in the vicinity of antinode of natural vibration mode with maximum effective mass ratio in the case of the roof structure resonating with the substructure.
2) The maximum response amplification factors of dome roof reduce uniformly in any node without the change of distribution shapes due to plasticity of members of dome roof.
3) It is possible to evaluate the response reduction ratio of double layer lattice dome by using the strain energy produced to the upper structure of equivalent double-mass system based on the vibration characteristic of mode with maximum effective mass ratio of dome model.

THE AISC 2010 SEISMIC PROVISIONS FOR COMPOSITE STRUCTURES: TOWARDS AN APPLICATION OF PBD PRINCIPLES FOR INNOVATIVE CONNECTIONS

Roberto T. Leon[1] and Jong Wan Hu[2]

1) Professor, School of Civil and Environmental Engineering, Georgia Tech, Atlanta, USA
2) Associate Research Fellow, Korea Institute of S&T Evaluation and Planning, Seoul, Korea
Rl58@ce.gatech.edu, jongp24@kistep.re.kr

Abstract: The 2010 AISC Seismic Design provisions represent a major change for composite structures for at least two reasons. First, the provisions for composite structures have been folded into a single document with those for steel; the net result, at least superficially, is that composite construction is considered equivalent to steel in quality and performance. Second, the provisions for composite members and structural systems have become more prescriptive in an attempt to ensure a minimum level of performance. An unintended consequence of this latter item is that some freedom in the introduction of innovative composite connections has been removed. In this paper, a short review of the AISC composite provisions will be given, and a case study on the development of an innovative connection to be used in composite (steel-concrete) moment frames will be described. The innovative aspects of this connection are in the use of partial restraint connections between steel beams and concrete-filled tube columns that utilize a combination of low-carbon steel and shape memory alloy components. A refined finite element model with sophisticated three dimensional solid elements was developed to conduct numerical experiments on the proposed joints to obtain the global behavior of the connection and develop simplified models. Very good agreement was found between the simple and sophisticated models for strength, stiffness and energy dissipation capacity, verifying the robustness of the approach. The paper argues that careful analytical studies can replace the requirement for physical testing present in current steel codes.

1. BACKGROUND

Seismic design provisions for buildings have a long history in the USA, dating back to the Uniform Building Code of 1927. These provisions were steadily but slowly improved until the Applied Technology Council (ATC) issued a comprehensive set of seismic design provisions following the 1971 San Fernando Valley Earthquake (ATC 3-06, 1978). This effort has continued through the issuance of updated provisions by the National Earthquake Hazard Reduction Program (NEHRP). These provisions are developed through the Provisions Update Committee of the Building Seismic Safety Council (PUC/BSSC) (NIBS 2010). They were originally intended to serve as a model and resource code, but were adopted *in toto* into the 2000 version of the International Building Code, the first unified building code in the USA (IBC 2010).

Currently seismic loading provisions have been consolidated into ASCE 7-10 (ASCE 7 2010), while provisions for design of members, connections and structural systems have been remanded to material organizations. Provisions for steel structures began to be developed by the American Institute of Steel Construction (AISC) in the mid 1990s in an effort to provide a single set of consistent specifications for seismic design of metal structures. At that time PUC/BSSC has a small working group on composite structures which had produced a short draft on seismic design of a number of composite members and structural systems (NEHRP 1994). AISC decided to incorporate these provisions for composite structures as Part II of its first seismic design specification (AISC 1997). The structure of the AISC Seismic Specification remained unchanged until its last edition (AISC Seismic 2010), with Part I being a comprehensive and prescriptive set of rules for steel structures and Part II being a less complete and more performance-based document for composite members and structural systems.

Another important development in seismic design over the last 5 years has been the introduction of performance-based design (PBD) requirements for tall buildings. This development took place essentially because designers did not think that a number of the conventional provisions, particularly those requiring a backup structural system with a capacity to resist 25% of the design base shear, made sense structurally and economically for tall buildings. In the very hot property market that preceded the economic collapse of 2007, there were several dozen tall buildings being planned for high seismic cities such as San Francisco and Los Angeles. Designers for these structures proposed a series of innovative structural systems and connections that were not contemplated by the prescriptive provisions of existing codes. To attempt to provide some basic guidance as to how to demonstrate the validity of these systems, both the cities of San Francisco

and Los Angeles issued guidelines on how to use performance-based design and similar concepts to justify innovative designs (LA 2005, SF 2009).

This paper briefly proposes how the 2010 AISC Specification can be used, in conjunction with existing PBD guidelines, to permit the use of innovative connections without the need to perform extensive full-scale connection qualification tests

2. THE 2010 AISC SEISMIC SPECIFICATION

2.1 Major Changes

As usual with new versions of any specification, the AISC 2010 Seismic Provisions (AISC Seismic 2010) contains a number of new and evolutionary design requirements that reflect the latest in seismic research and practice. In addition, however, there have been two major changes. The first change, which can be considered editorial in nature, is that wherever possible, the provisions now have a consistent set of subsections for all seismic structural systems. These subsections include scope, basis for design, analysis requirements, structural system requirements, member design, and connection provisions. This new organization considerably simplifies the design process and makes possible quick comparisons between alternative structural solutions.

The second change, which is more philosophical in nature, is that the old Part I (Steel Construction) and Part II (Composite Construction) have been completely merged into a single document. For composite structures, this has had two major consequences. First, this approach makes composite design essentially equivalent to traditional steel insofar as expected performance is concerned. This is an important result because composite construction is not considered a viable option in the USA except for tall structures. It is hoped that its inclusion into a single design document with steel structures will make more designers consider composite systems for low- and mid-rise construction. The second consequence is that the old Part II provisions, which were intentionally nebulous in handling many design details, needed to be updated and rendered far more prescriptive in nature. The original NEHRP composite provisions, issued by NEHRP in 1994, were developed as enabling legislation for composite systems, and permitted the use of systems that had neither been tested nor built at the time.

The 2010 AISC main specification for steel structures (AISC 2010) provides much of the background to the seismic provisions and, as its predecessors, contains two important additional statements that are relevant to this paper. First, in its Preface it states that: "*The intention is to provide design criteria for routine use and not to provide specific criteria for infrequently encountered problems, which occur in the full range of structural design."* Second, in its Scope, it states that: *"Where conditions are not covered by the Specification, designs are permitted to be based on tests or analysis, subject to the approval of the authority having jurisdiction. Alternative methods of analysis and design are permitted, provided such alternative methods or criteria are acceptable to the authority having jurisdiction."* (AISC 2010)

Taken together, these two statements provide an escape route for designers wishing to circumvent prescriptive design procedures, but leave the responsibility to accept such approaches to the building officials. The PBD documents from the cities of SFO and LA cited previously aim at providing designers with some guidance on how to fulfill these requirements.

2.2 Member and Connection Design

General requirements for member and connection design are covered in Section D of the new AISC 2010 Specification.

Insofar as member design is concerned (Section D1), the most important change in the new edition is the explicit recognition, and associated requirements, for three types of seismic member categories: conventional, moderately ductile and highly ductile. Conventional members need only comply with the requirements of the main specification (AISC 2010), while the seismic specification gives detailed requirements for moderately and highly ductile members primarily in terms of width-to-thickness ratios, bracing, and protected zone provisions.

Insofar as this paper is concerned, the most important provisions regarding connection design are given in both the general section on connections (Section D2) and on Section E3 (Special Moment Frames). The majority of the important details for this paper are given in Section E3. Connections in special moment frames are required to provide deformation capacity through yielding of beams and panel zone deformations. For steel connections, it is required that (a) the connection shall be capable of accommodating a story drift angle of at least 0.04 rad., and (b) the measured flexural resistance of the connection, determined at the column face, shall equal at least 0.80Mp of the connected beam at a story drift angle of 0.04 rad. Compliance with these requirements can come from:

1. Use of connection prequalified as per AISC 358 (2005). AISC 358 currently prequalifies 7 types of connections based on extensive testing and analysis, primarily from results of the SAC research program (FEMA 2000).
2. Testing as per Appendices K1 and K2 of the seismic specification, which require at least two full-scale connections tests under a stringent displacement history.

It is worthwhile to notice that AISC requires physical testing, and that the testing needs to be supplemented by advanced analyses.

3. PBD GUIDELINES

As noted earlier, there have been two initiatives aimed at promoting the use of performance-based design approaches to seismic design. They include the recommendations of (a) a committee of the Structural Engineers of Northern California, which resulted in a

building ordinance for the city of San Francisco entitled *Requirements and Guidelines for the Seismic Design and Review of New Tall Buildings using Non-Prescriptive Seismic-Design Procedures* (SFO 2007), and (b) the Los Angeles Tall Building Design Council which resulted in a design guideline entitled *An Alternative Procedure for Seismic Analysis and Design of Tall Buildings Located in the Los Angeles Region* (LA 2005).

Only the LA document is truly a PBD document as it states clearly in its scope that its approach "*is based on capacity design principles followed by a series of state-of-the-art performance based design evaluations"* that aims to provide serviceable behavior under frequent events (43 year return period, or 50% probability of exceedance in 30 years) and very low probability of collapse under extreme events (2475 year return period, or 2% probability of exceedance in 50 years). The document provides analyses requirements in terms both of the model and load histories to be used. It focuses on the demand side and as a default, suggests using the member capacities established by ASC 41 (ASCE 41) to check performance. Iit adds an exception that "larger deformation capacities may be used only if substantiated by appropriate laboratory tests and approved by the Peer Review Panel and the Building Official."

The SFO document also utilizes the same two-level approach as the LA one, but intentionally avoids the use of PBD terminology and contains a mix of mandatory and non-mandatory provisions. It focuses on the demand side and is silent on the need for testing to justify the strength and deformation capacity of members and connections.

4.0 INNOVATIVE CONNECTIONS

The previous sections describe the current state of seismic design codes for composite structures in the USA. The rest of this paper describes the how development of an innovative connection can fit within these frameworks without having to carry out extensive physical testing.

The connection under consideration combines the robustness and structural efficiency of concrete-filled tube (CFT) columns with the ductility and recentering capabilities of a partially restrained (PR) connection (Fig. 1). The key innovative part of the connection is the use of a combination of mild steel and shape memory alloy (SMA) through rods as the connecting elements. The mild steel rods provide energy dissipation, while the SMA rods provide recentering capability (Hu and Leon 2010).

This type of connection is applicable in special and intermediate composite moment-resisting frames up to about 10 stories, and combines a number of the advantages associated with composite systems. For CFT columns, these advantages include the fact that the concrete prevents local buckling of the steel tube wall and the confinement action of the steel tube extends the usable strain of the concrete. CFT beam-columns and panel zones provide enhanced ductility and reduced rates of degradation under cycling at large drifts when compared to conventional steel or RC columns.

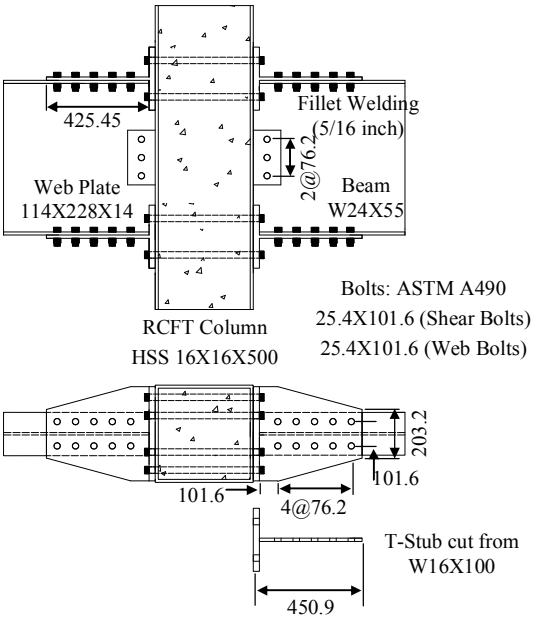

Figure 1 – PR composite connection

In order to utilize these connections in an actual structure, several obstacles need to be overcome as follows:

- The currently available PBD guidelines (see Section 3) will need to be extended to low-rise construction, as currently they are applicable only to structures over 49m in height. As the requirements for taller structures are more restrictive than those for lower ones, acceptance of this approach by progressive building officials is possible.
- The current requirement for full-scale physical testing of composite connections (see Section 2) will need to be waived and replaced by extensive advanced analytical studies. The rest of this paper looks at how this issue can be justified and the level of effort required.
- The use and scope of peer review panels need to be expanded as they need to become the main deciders, as opposed to building coded officials, of the technical merits of an innovative structural solution.

4.1 Connection Modeling and Calibration

The first step in justifying this approach is linked to the development of a simplified connection model whose components' cyclic behavior is well understood. In the case of the connection shown in Fig.1, these components are: (a) the steel beam; (b) the bolted T-stubs that provide the connections to the flanges; (c) the fin plate connection that provides shear transfer; (d) the mild steel and SMA rods that provide axial restraint; (e) the composite panel zone; and (f) the composite CFT column.

Fig. 2 shows a simplified generic model that is suitable to model this connection. In this model, springs C1 and C2 represent the T-stubs in tension and bearing, springs B1 through B4 represent the steel and SMA bars in tension and compression, springs D represent the joint shear deformation, and spring E the shear connection to the beam. Each of these springs can have its own backbone load-deformation

curve, which can represent many forms of deformation. For example, spring C1 includes the deformations due to slippage of the bolts between the beam and T-stub, the axial deformation of the T-stub stem, the flexural and shear deformation of the T-stub flanges, and the ovalization of the bolt holes in bearing. In addition, the cyclic behavior and degradation rules for each spring can be set independently. These models can easily be implemented into a number of existing platforms; OPenSEES was used in this study (Mazzone et al. 2006)

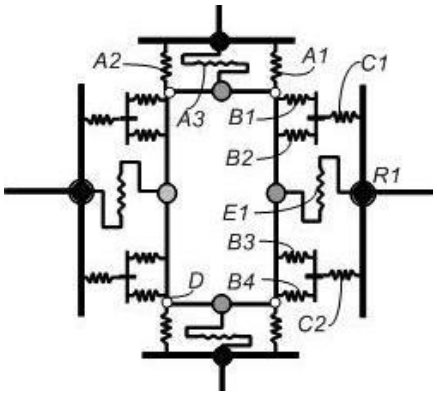

Figure 2 Simplified model of proposed connection

The key question becomes whether the behavior of all of these springs can be accurately predicted. The answer, for this connection, is yes as the individual behavior of (a) T-stubs, including slip, bearing, and ovalization (Swanson 1999,), (b) composite panel zones (Wu et. al. 2007), and (c) SMA materials (Tami and Kitagawa 2002, Song et al. 2006) is well established.. In addition, behavior of both SMA in large connections (Leon et al. 2001, Ocel 2002, Penar 2005) and CFT columns member and panel (Hu et al. 2005, 2007) has been verified by a number of research efforts.

Nevertheless, extensive calibration of the simplified model shown in Fig. 2 to advanced 3D FE models, such as that shown in Fig. 3, is a must. These models need to be very carefully developed to ensure proper meshing and boundary conditions. In addition, smaller detailed models of areas of stress concentrations (Fig. 4) also need to be examined to ensure that no possible failure modes are ignored. ABAQUS (2006) was the FE coded used herein.

The work requires that calibration of each individual mode of deformation be made to well-documented tests. Figs. 5 and 6 show comparisons for the axial deformations of the T-stub stem and slippage of the bolts for a T-stub specimen tested by Swanson (1999). These two deformation modes are built into spring C1 in Fig. 3. The models are capable of reproducing not only the behavior of components but also of entire connections. Fig. 7 shows a comparison between plastic rotations vs. moment for a connection tested by Swanson (1999) and a simplified model in OpenSEES. The model matches well all the observed test behavior both qualitatively and quantitatively.

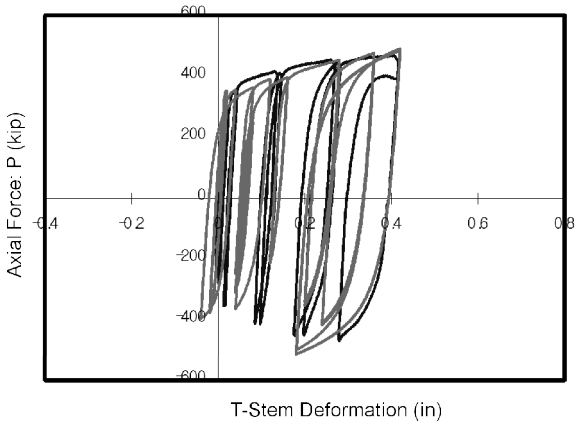

Figure 5 Comparison of T-stub stem deformation from tests and simplified model

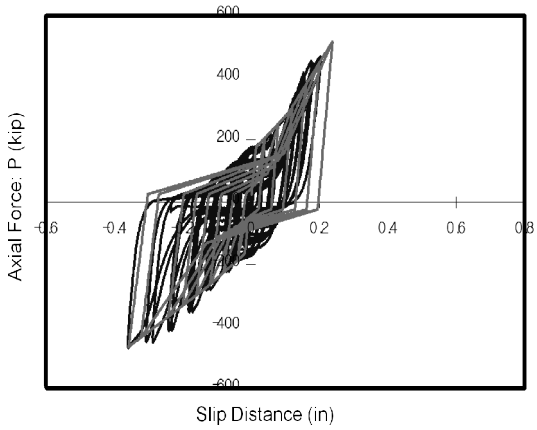

Figure 6 Comparison of T-stub slip from tests and simplified model

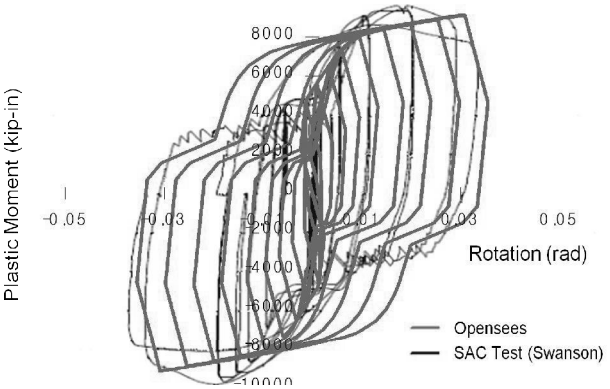

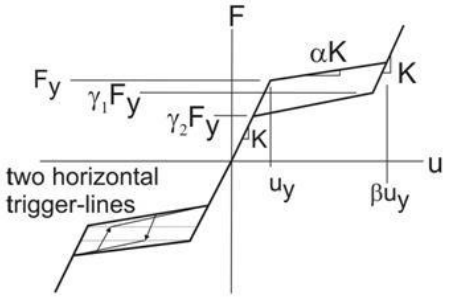

Figure 7 Comparison of measured and predicted moment vs. plastic rotations for a full-scale T-stub connection.

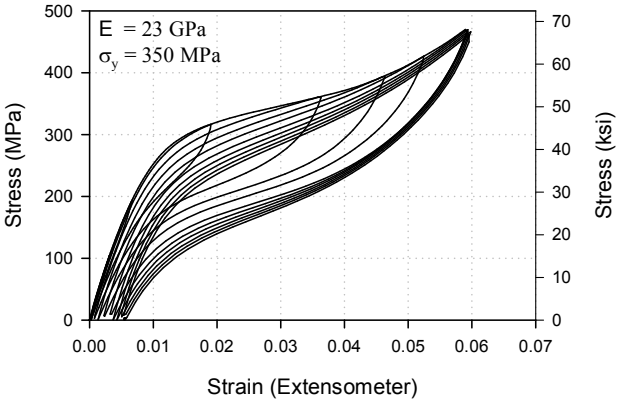
For these connections another complicating factor is the modeling of the shape memory effect, as shown in Fig. 8. Ideally, the material shows a flag-shaped behavior as shown in Fig. 8(a), with a number of break points and trigger lines related to the heat treatment of the material. However, actual data for one quadrant shows (Fig. 8(b)) that these lines and points are not easy to characterize.



4.2 Connection Design Issues

The connection models described in the previous section have only been calibrated to a relatively small number of tests, so it is important that the limitations of the approach be understood. The first important limitation is that the simplified model basically does not consider interactions between failure modes. From the design standpoint this means that failure modes must be carefully separated and that a large number of yielding mechanisms must occur before any fractures or similar failures can take place. This can be accomplished by a well-thought out capacity design approach that clearly recognizes sources of over- and under-strength in the connection. For the connection in Fig. 1, this means that slippage of the bolts will occur first (clearly evident at about 1/3 of the connection strength in Fig. 7, with hole ovalization leading to larger deformations with cycling).

This initial deformation mechanism should be followed by yielding of the beam, tensile yielding of the SMA and mild steel through rods, yielding of the T-stub stem in tension, flexural yielding of the T-stub flanges, and yielding of the panel zone in shear, roughly in that order. These failure modes should provide all the required ductility (on the order of 0.03 to 0.05 rad. of plastic deformation), with local buckling and local crushing of the concrete providing additional deformation capacity should plastic large rotations in excess of 0.05 rad. occurs. Under no circumstance should fracture of the through rods in tension or bolts in shear be permitted at loads less than 150% of those creating yielding mechanisms.

(a) Idealized shape memory behavior

(b) Actual behavior

Figure 8 Comparison of idealized and actual SMA behavior

A second important limitation is that models such as those discussed here can only capture very limited strength and stiffness degradation. In particular, test results such as those shown in Fig. 7 indicate that, at large deformations, there is a gradual reduction of strength and stiffness due to local buckling in the beam flanges. Including this behavior in the connection model will require additional springs and the occurrence of negative stiffnesses from several degrading spring can lead to significant numerical problems for the entire spring assembly. A nice feature of this connection is that the through rods actually behave like buckling restrained braces as they are embedded in a plastic sheath with a diameter slightly larger than the bars itself, and thus their performance in compression is very similar to that

in tension. This is true for the mild steel bars; there is some difference in tension and compression behavior of the SMA that is a function of the material processing. From the design standpoint degradation issues due to local buckling should be dealt with by specifying very compact sections for the beam flange and web, as well as for all other components subjected to yielding in compression. It should be noted that the large amounts of local buckling observed near the end of physical tests are more a creature of the boundary conditions from the test frame (i.e., lack of axial restraint in the beams) than a reflection of actual behavior.

A third important limitation of this approach is that it ignores the effect of the floor slab in redistributing stresses in the connection area. This issue has often been overlooked in seismic codes, but based on the work of Leon et al. (1998) and others, the latest AISC seismic specification explicitly requires that designers either account for this effect in their analysis and design or provide a small opening around in the slab around the column to limit those effects.

An important fourth limitation is the need to arbitrarily impose some strain (or deformation) limitations on the load-deformation curves for the individual springs. Although a large number of tests have been carried out on individual components and these can serve as a basis for establishing such limits, there is little or no statistical work related to the potential for failure when several components show large deformations simultaneously. In a connection such as that under study, where a very large number of deformation mechanism are expected to contribute to the overall connection ductility, this effect may be important.

A final problem that has not received much attention is the robustness of the analytical tools as very large deformations, and consequently very low stiffnesses, are reached. In most cases, it is impossible to ascertain the reasonableness of the results without detailed investigation of the quantitative contribution of each mechanism.

While these limitations are important, it should be recognized that they are not unique to the type of connections of interest here. In general, designers tend to dismiss them as either too difficult to handle in everyday design or as not significant to their design.

The design approach proposed here is based on establishing a prescribed series of yielding mechanisms and capacity design principles. The yielding of the through rods provides an ideal deformation mechanism, as the free length of the rods (around 40cm to 50cm in many cases) provides very large local deformations at reasonable low average strains. However, compliance with this approach is not simple as only a small number of fixed geometries are available for T-stubs cut from rolled sections. More recently, work on T-stubs made from welded plates has considerably eased that problem, and it is expected that in the very near future AISC 358 will sanction this approach.

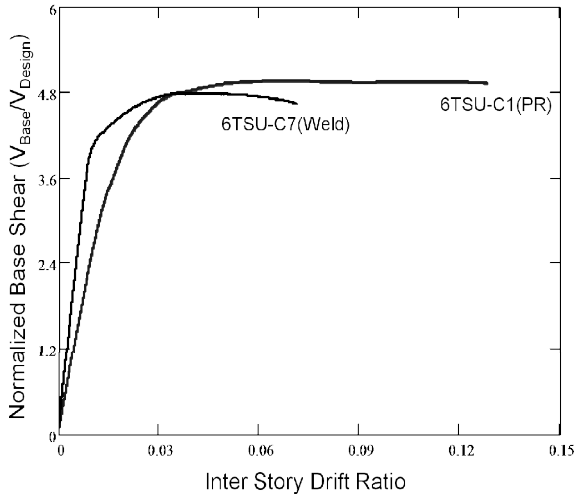
4.3 Frame Performance

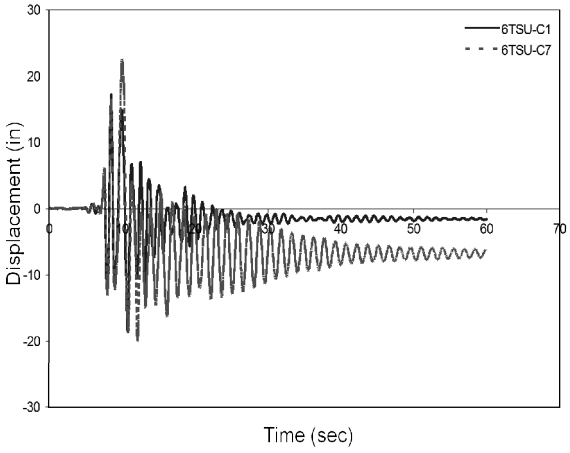
The last step in this design process is to evaluate the seismic performance of the overall structure through both pushover and non-linear dynamic analyses of a set of archetypical frames. This evaluation requires that comparisons be made to similarly designed, all-steel frames that comply with all the requirements present in applicable design codes. Details of these studies have been recently published (Hu and Leon 2010). Figure 8 shows a comparison of the pushover analyses for a 6-story, 5-bay frame for a welded, all-steel special moment frame (6TSU-C7) and two frames using the connections shown in Fig. 1 (6TSU-C1 and C4). Based on initial stiffnesses, the innovative frames fall in the PR category. The welded frame shows less ductility because of weld fractures, which begin around 4% story drift. The frames with innovative connections show almost unlimited ductility and little sensitivity to P-D effects. Both frames show a substantial overstrengthwith respect to the design base shear because these frames are controlled by drift.

The frames were also subjected to the suite of SAC ground motions (SAC 2005). Fig. 9 shows typical results for the LA21 (Kobe 1995) ground motion. The welded frames show very significant residual deformations and a possible collapse at 12 sec. due to fractures in the first story connections. This conclusion is supported by the very large interstory drifts in the first floor at the maximum base shear (Fig. 10(b)). The frames with welded connection show significantly higher drifts, and likely collapses as the drifts exceed 0.1. The average and 84^{TH} percentile interstory drifts for the frame with the innovative connections (Fig. 11), on the other hand, show large but contained deformations.

A large number of frames were designed and studied using data similar to that in Figs. 9 through 11. The results indicate that:

- Overall, the initial stiffness of the frames with welded connections was larger than that of those of the frames with PR connections. However, the strength of welded frames deteriorated very rapidly because the welded connections were susceptible to brittle failure and P-Δ effects. In contrast, the use of flexible tension bars in the innovative connections provided extra deformation capacity, so the composite frames with PR connections showed more gradual strength degradation. As expected, the strength of the taller frames deteriorated more rapidly than that of the shorter frame because of the large P-D effect due to the heavier gravity loads.
- Composite moment frames with PR connections showed smaller residual displacements than those with welded connections due to the recentering effect of the SMA barst. In addition, composite frames with PR connections showed a more gradual strength degradation. For the PR composite frames, the envelope of the cyclic curves corresponded to that of the monotonic curves when the same models were compared.
- Composite moment frames with welded connections showed the largest roof displacements. The outstanding energy dissipation properties of the PR connections resulted in lower drifts.





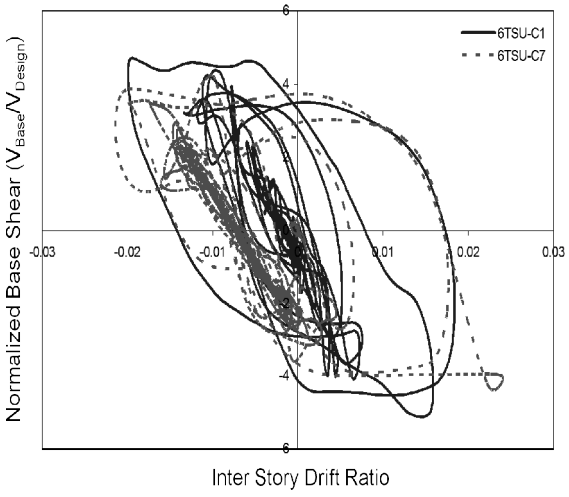


Figure 8 Comparison of pushover behavior between frames with welded and innovative connections

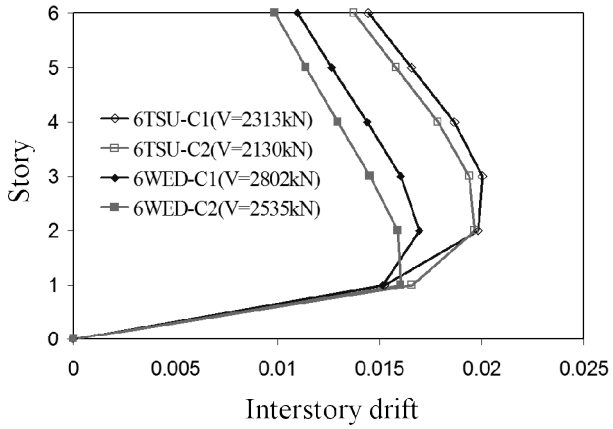
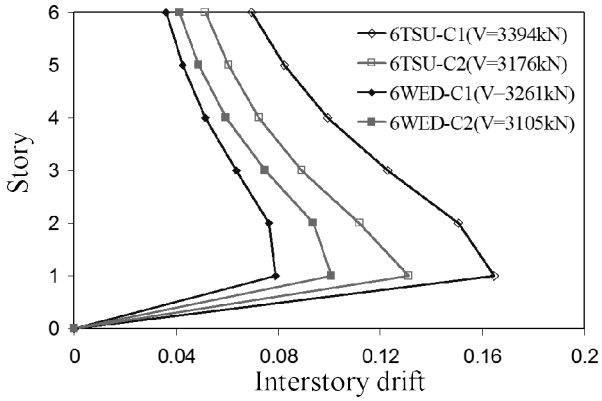


(a) Roof displacement vs. time



(b) Base shear vs. average interstory drift

Figure 9 – Response of welded and innovative frames to the LA 21 ground motion

(a) At initial yield

(b) At ultimate

Figure 10 – Comparison of drifts for welded and innovative frames.

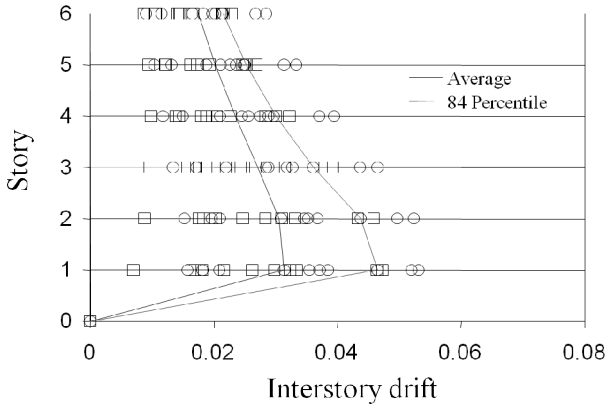


Figure 11 Range of interstory drifts for an innovative frame subjected to a large suite of ground motions.

- Overall, maximum displacement, velocity, and pseudo-acceleration occurred at the roof. The occurrence time for each peak value subjected to the same ground motion was slightly different and trailed the occurrence of the peak ground acceleration (PGA).

- Statistical distributions of the peak interstory drifts were obtained from the dynamic analyses. The peak interstory drifts occurred at the first story level and decreased rapidly as one moved up the structure.

Both the analyses of individual connections and multi-story frames show that these innovative PR frames will display excellent performance when properly designed.

3. CLOSING REMARKS

This paper began with a description of some of the 2010 AISC seismic provisions for composite structures and of the LA and SFO PBD guidelines for tall buildings. It then described the detailed analyses carried out for the development of an innovative PR connection that utilizes a mix of steel and SMA rods as the main yielding mechanism. These analyses were intended to provide enough supporting evidence to convince building officials to waive the requirement for physical testing of full-scale connections present in current codes. The authors believe that careful application of the most advanced analytical tools available coupled with characterization of system response based on a large suite of ground motions provides equal or better justification than physical tests. It should be noted that physical tests have significant shortcomings at the very least with respect to the fact that (a) only two specimens are required (a statistical insignificant number); (b) only a slowly increasing set of deformation cycles are used (very different from what areal earthquake will produce); and (c) boundary conditions are highly idealized and do not correspond to actual designs (slabs and 3D effects are completely ignored in most tests) (Leon and Deierlein 1997). The authors are thus comfortable in concluding that one of the original purposes of the Network for Earthquake Engineering Simulation (NEES), the migration from pure physical testing to full-scale simulation, is well underway and succeeding.

Abstract: In the 1994 Northridge and the 1995 Kobe earthquake, brittle fractures had been occurred at the beam-bottom-flange of welded beam-ends. After these earthquakes, a remarkable number of studies have been made on welded beam-to-column connections. From the research results, plastic rotation capacity of the steel beam ended in the beam-bottom-flange ductile fracture is affected by the presence of a concrete slab. On the other hand, it is known that composite effects of concrete slab have been observed in not only steel beams but also steel panel zones. In Japanese low- and medium-rise steel buildings, columns are designed to have more strength than that of beams to realize beam-yield mechanism. However, the strength of both beams and panel zones is increased by the presence of the concrete slab. Therefore these effects might lead to damage to column to cause story-collapse mechanism. It is very important to consider the composite effects on elasto-plastic behavior of steel beams and panel zones at the stage of seismic design.
Composite effects on elasto-plastic behavior of panel zone are discussed in this paper. Based on equilibrium condition of forces around a panel zone, evaluation models for the composite effects on initial elastic stiffness and yield strength of panel zone were established. And then, cyclic loading tests of four beam-column subassemblies with a concrete slab were carried out. From the test results, composite effects on structural behavior of panel-zone were investigated. Finally, the composite effects obtained from the tests were proven by evaluation models.

1. INTRODUCTION

In the 1994 Northridge and the 1995 Kobe earthquake, brittle fractures had been occurred at the beam-bottom-flange of welded beam-ends. After these earthquakes, a remarkable number of studies have been made on welded beam-to-column connections. From these research results, plastic rotation capacity of the steel beam ended in the beam-bottom-flange ductile fracture is affected by ductility of material, welding condition, geometrical discontinuity (weld access holes), and the presence of a concrete slab. Since most of the fractures were observed at the bottom beam-flange, it was found out that strain concentration caused by a concrete slab was very severe. However, these effects by a concrete slab have been hardly clear in the previous studies.

On the other hand, it is known that composite effects of concrete slab have been observed in not only steel beams but also steel panel zones (Naka et al., 1972, 1973, 1979, Nakao and Osano, 1987, 1988; Kawano et al., 1993; Yamada et al., 2009). In Japanese low- and medium-rise steel buildings, columns are designed to have more strength than that of beams to realize beam-yield mechanism. However, the strength of both beams and panel zones is increased by the presence of the concrete slab. Therefore these effects might lead to damage to column to cause story-collapse mechanism. It is very important to consider the composite effects on elasto-plastic behavior of steel beams and panel zones at the stage of seismic design.

In this paper, composite effects on elasto-plastic behavior of panel zone are discussed. Based on equilibrium condition of forces around a panel zone, evaluation models for the composite effects on initial elastic stiffness and yield strength of panel zone are established. And then, cyclic loading tests of four beam-column subassemblies with a concrete slab are carried out to investigate composite effects on panel-zone.

2. STRUCTURAL BEHAVIOR OF PANEL ZONE CONSIDERING THE PRESENCE OF CONCRETE SLAB

2.1 Evaluation Equation of Composite Effects on Panel Zone based on Equilibrium Condition of Forces

At first, composite effects on structural behavior of panel zone are discussed here. Equilibrium condition of forces around a panel zone without or with a concrete slab is expressed in Figure 1. In case of bare steel structures, as shown in Figure 1(a), bending moments ${}_bM_R$ and ${}_bM_L$ at the both beam-ends divided by effective beam depth d_b are lateral forces at the panel zone. Therefore, column shear force H subtracted from the forces $({}_bM_R + {}_bM_L) / d_b$ is shear force Q at the panel zone. Eq.(1) shows the shear force Q. Note, in Japanese conventional seismic design, the shear

force Q at the panel zone is expressed as panel moment by multiplying beam effective depth d_b.

$$Q = \frac{{}_bM_R - {}_bM_L}{d_b} - H \tag{1}$$

On the other hand, in case of composite structures, the right bending moment ${}_bM_R$ is affected by the presence of a concrete slab. ${}_bM_R$ is decomposed into bending moment ${}_bm_R$ at the bare steel beam section and bending moment $N \cdot z$ caused by axial force N at the concrete slab. z is a length between effective center positions of both a concrete slab and bare steel beam section. ${}_bm_R$ and N at the bare steel beam section are transmitted to panel zone by both upper and lower beam-flanges. Especially in Japan, the Rectangular Hollow Section (RHS) is used for column, and bending moment at the beam-web is decreased by out-of-plane deformation at the RHS column. Bending moment at a concrete slab is neglected in this equation, although a cross section of a concrete slab is thinner than that of bare steel beam. Eq.(2) shows the shear force Q*.

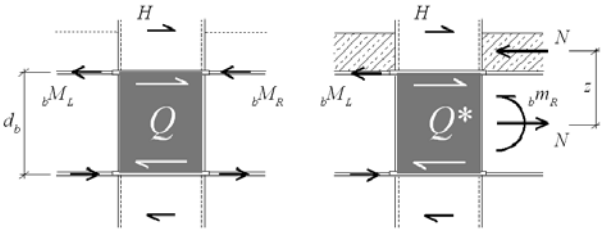
$$Q^* = \frac{{}_bm_R - {}_bM_L}{d_b} - H + \frac{N}{2} \tag{2}$$

Here, parameter α is defined as the ratio between bending moment $N \cdot z$ and the right bending moment ${}_bM_R$. And parameter β is defined as the ratio between the left bending moment ${}_bM_L$ and the right bending moment ${}_bM_R$. Eq.(3), (4) express these parameters.

$$\alpha = \frac{N \cdot z}{{}_bM_R} \tag{3}$$

$$\beta = \frac{{}_bM_L}{{}_bM_R} \tag{4}$$

Column shear force H is obtained from the assumptions: (a)structures have infinite same shapes with beam span l and story height h; (b)increase of story shear between upper and lower story is negligible, and is expressed as Eq.(5).



$$H = \frac{{}_bM_R - {}_bM_L}{h'} \tag{5}$$

Here, h' is effective height of structures and defined as Eq. (6).

$$h' = (1 - \frac{D_c}{l}) \cdot h \tag{6}$$

where, D_c : width of column.

Shear force Q expressed as Eq.(1) is shear force at the panel zone without a concrete slab. On the other hand, shear force Q* expressed as Eq.(2) is "true" shear force at the panel zone considering effects of a concrete slab. Therefore,

(a) (b)

Figure 1 Shear force to panel zone: (a)bare steel structures; (b)considering concrete slab

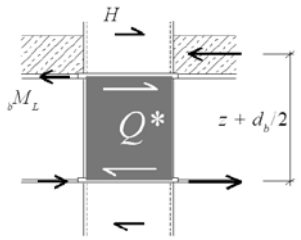


Figure 2 Simple evaluation model for composite effects on structural behavior of panel zone (Nakao and Osano, 1987, 1988; Kawano et al., 1993; Yamada et al., 2009)

increase of stiffness and strength caused by the presence of a concrete slab is expressed as subtraction between Q* and Q. Shear force Q or panel moment $Q \cdot d_b$ is a useful index for seismic design. In other words, increase Q*– Q caused by the presence of a concrete slab is easily applied to current seismic design procedure.

$$Q^* - Q = \left(1 - \frac{d_b}{2\,z}\right) \cdot \alpha \cdot \frac{{}_bM_R}{d_b} \tag{7}$$

z is a length between effective center positions of both a concrete slab and bare steel beam section, and is larger than half of effective beam depth d_b. It indicates that Eq.(7) is always positive. Therefore, shear force Q is underestimation, although panel zone is affected by the presence of a concrete slab.

Here, composite effect is expressed as the ratio between Q and Q* to evaluate parameter effects on the increase of stiffness and strength. Composite effect Q / Q* is expressed as Eq.(8).

$$\frac{Q}{Q^*} = \frac{(1+\beta)(1-\frac{d_b}{h'})}{(1+\beta)(1-\frac{d_b}{h'}) - (1-\frac{d_b}{2\,z})\alpha} \tag{8}$$

On the other hand, the past researches (Nakao and Osano, 1987, 1988; Kawano et al., 1993; Yamada et al., 2009) on composite effects on panel zone presented simple evaluation model, as illustrated in Figure 2. This model considers composite effects of the right beam as increase of

effective beam depth d_b. Mentioned above, the upper beam-flange transmitted ${}_bM/d_b$ and $-N/2$ to panel zone, based on evaluation model in Figure 1. The past model has the assumptions that lateral force at the upper beam-flange is negligible. "True" shear force Q* established by the past researches is expressed as Eq.(9).

$$Q^* = \frac{{}_bM_R}{z + \frac{d_b}{2}} - \frac{{}_bM_L}{d_b} - H \tag{9}$$

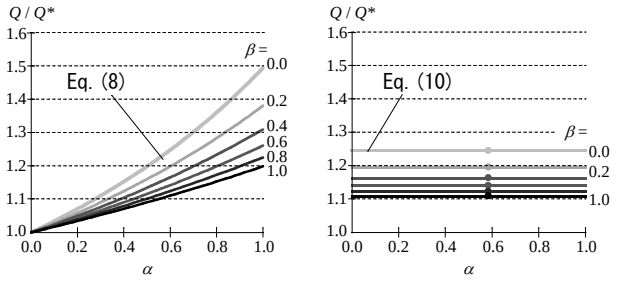
And then, Composite effect Q/Q* is expressed as Eq.(10).

$$\frac{Q}{Q^*} = \frac{(1+\beta)(1-\frac{d_b}{h'})}{(1+\beta)(1-\frac{d_b}{h'}) - (1-\frac{d_b}{2z})(1+\frac{d_b}{2z})^{-1}} \tag{9}$$

2.2 Parameter Study on Composite Effects

Parameter study on indexes α, β, and $d_b/2z$ affecting increase of stiffness and strength is conducted by using evaluation Q / Q* expressed as Eq.(8) and Eq.(10).

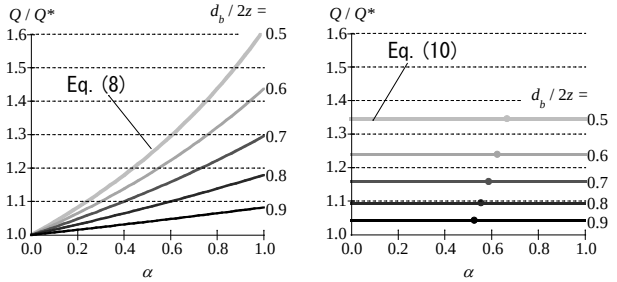
First parameter study with variable index β, the ratio between the left bending moment ${}_bM_L$ and the right bending moment ${}_bM_R$, is showed in Figure 3. Parameter α, the ratio between bending moment $N{\cdot}z$ and the right bending moment ${}_bM_R$, is plotted on the X-axis, and calculated composite effect Q / Q* by $d_b/2z$ (=0.71) of test specimens in Chapter 3 is plotted on the Y-axis.



Increase of parameter α is lead to increase of composite effects Q / Q*, based on evaluation of Eq.(8). Parameter β is calculated from 0.0 (external column) and 1.0. Change of composite effects Q / Q* is strongly affected by parameter α, when parameter β equals to 0.0 (external column). Parameter β is the ratio of bending moment between bare steel beam and composite beam, and composite effects on beam lead increase of stiffness and strength to panel zone. In the previous test (Yamada et al., 2009), elasto-plastic behavior of panel zone in beam to external column with a concrete slab was investigated, and the strong effects caused by the presence of a concrete slab were observed. Evaluation value of composite effects shows the similar trend of the previous test of external column.

On the other hand, composite effects Q / Q* are hardly affected by increase of parameter α, based on evaluation of Eq.(10). Comparing both equations, $1/(1+d_b/2z)$ works as parameter α in Eq.(10). It indicates that parameter α is given as the constant value by geometrical condition d_b and z in Eq.(10), since this simple evaluation model considers composite effects of the right beam as increase of effective beam depth d_b. In case of parameter study shown in Figure 3., parameter α (=$1/(1+d_b/2z)$) equal to 0.58, the cross points of both Figure 3.(a) and (b).

Parameter study with variable index $d_b/2$ is showed in Figure 4. Parameter α is plotted on the X-axis, and calculated composite effect Q / Q* by β (=0.5) of test results in Chapter 3 is plotted on the Y-axis.



Increase of parameter α is lead to increase of composite effects Q / Q*, based on evaluation of Eq.(8). Parameter $d_b/2z$ is calculated from 0.5 and 0.9. Comparing Figure 3 and 4, change of composite effects Q / Q* is more strongly affected by parameter $d_b/2z$, and more than parameter α.

On the other hand, composite effects Q / Q* are hardly affected by increase of parameter α, based on evaluation of Eq.(10). Effects on change of Q / Q* caused by parameter $d_b/2z$ are larger than that of parameter α. It is because that increase of parameter $d_b/2z$ is lead to both α and $d_b/2z$.

3. TEST OF BEAM-COLUMN SUBASSEMBLIES WITH A CONCRETE SLAB

3.1 Test Plan

A constant comparison was used for all specimens to investigate structural behavior of beam-column subassemblies affected by the presence of a concrete slab. Capacity limitations of the testing equipment, as well as constraints on the overall size of the test specimen, dictated that the specimens were approximately half of the actual building bay width and story height. The specimen was cut from the frame with a bay width of 3.5m and a story height of 2.35m. The test set-up is illustrated in Figure 5.

Two series of specimen were tested. In the first series named (F), a rectangular flat section was used for a concrete slab. On the other hand, flat section with deck plates was used for a concrete slab in the second series named (D). Added to this, the first subassemblies (F) was designed as weak panel zone frame by using 9mm of column thickness

and SM490A steel grade for beams. While, the second (D) was designed as weak beam frame by using 12mm of column thickness and SN400B steel grade for beams. Overall details are complied in Table 1.

A detail of the test specimen is shown in Figure 6.

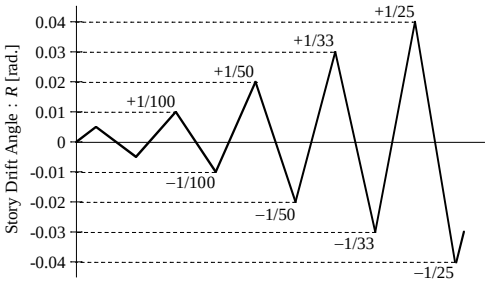

Figure 7 Loading Program

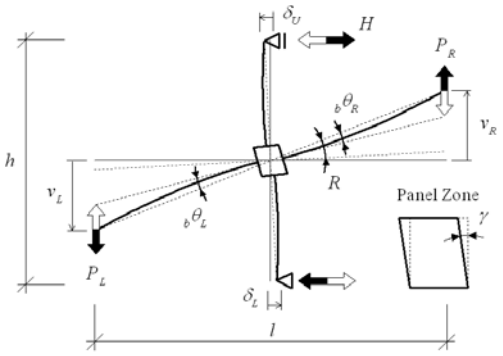

Figure 8 Loading Program

Quasi-static loading was carried out following to a simple loading program shown in Figure 7. The loading program was based on story drift angles *R* of the specimen, which were 1/200, 1/100, 1/50, 1/33, and 1/25 radian. The beam-column subassemblies had a height *h* from the top and bottom pin joints. The total tip deflection was due to elastic

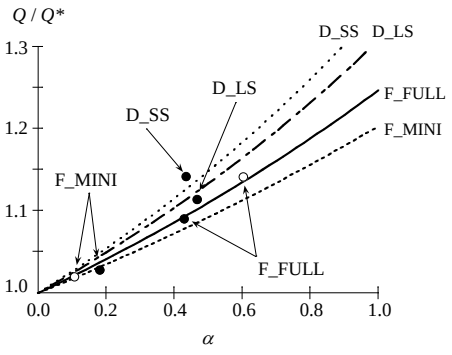
and plastic flexural deformation of the column and beams, and shear deformation of panel zone. A story drift angle R of test specimen can be found out by dividing the total tip deformation by h. Definitions of deformations and loads in this test are illustrated in Figure 8.

3.2 Test Results

Relation between shear force Q and shear deformation angle γ of each specimen are shown in Figure 9. Monotonic behavior of bare panel zone expressed in red line is calculated based on coupon test of steel used for column panel zone.

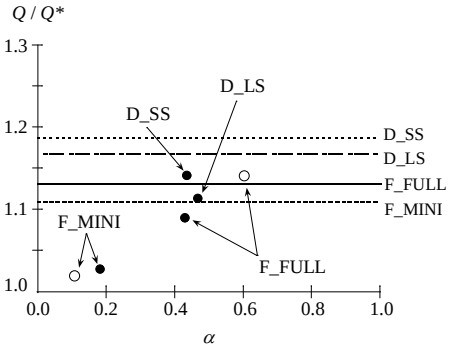
Test specimen shows stable hysteresis loop and sufficient plastic deformation capacity until 5%. The increases of stiffness and yield strength are as follows: Specimen F_FULL: 10 to 20% increase in stiffness and 10 to 15% increase in yield strength is observed, respectively. F_MINI: 5% increases in stiffness and yield strength are observed. D_LS: 15 to 25% increase in stiffness and 10% increase in yield strength is observed, respectively. D_LL: 15% increase in stiffness and 10% increase in yield strength is observed, respectively.

Quasi-static loading was carried out following to a simple loading program shown in Figure 7. The loading program was based



3.3 Evaluation of Composite Effects

Experimental values of composite effects on increase of stiffness and yield strength of panel zone are plotted in Figure 10. The experimental values are defined as a position in X-axis, with evaluation of parameter α from the test results. And four lines shows calculated values of composite effects Q / Q* obtained from Eq.(8) and Eq.(10). Geometrical conditions d_b and z are based on test specimen, and parameters α and β are obtained from the test results.



Calculated values by Eq.(8) shows good corresponding with experimental values of increase in stiffness and yield strength. Meanwhile, calculated values by Eq.(10) shows overestimation to experimental values. It is indicating that parameter α, the ratio between bending moment $N{\cdot}z$ and the right bending moment ${}_bM_R$, is important index for evaluating composite effects on panel zone.

4. CONCLUSIONS

It is known that composite effects of concrete slab have been observed in not only steel beams but also steel panel zones. Though effects might lead to damage to column to cause story-collapse mechanism, it is very important to consider the composite effects on steel beams and panel zones at the stage of seismic design. In this paper, composite effects on elasto-plastic behavior of panel zone were discussed. Based on equilibrium condition of forces around a panel zone, evaluation models for the composite effects on initial elastic stiffness and yield strength of panel zone were established. And then, cyclic loading tests of four beam-column subassemblies with a concrete slab were carried out to investigate composite effects on panel-zone. Finally, the composite effects obtained from the tests were proven by evaluation models.

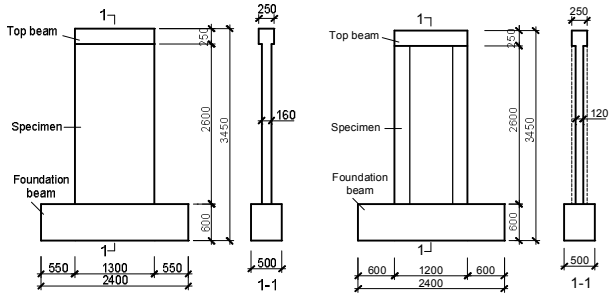
Abstract: Reinforced concrete (RC) shear walls have been widely used as the major lateral force-resistant member in high-rise buildings. However, the RC walls with high axial force ratios are less ductile. This paper proposed an innovative composite wall, named the steel tube-reinforced concrete (ST-RC) composite wall. Steel tubes were embedded at the wall's boundary elements and fully anchored within the foundation, which could enhance the seismic performance of the wall. A series of quasi-static tests were conducted to examine the proposed walls subjected to high axial force and lateral cyclic loads. The effects of the area ratio of steel tubes/CFSTs, axial force ratio, and cross-sectional shape of wall were investigated. The test results indicated that the ST-RC composite walls had both larger load-carrying and deformation capacities than the RC walls. The deformation capacity of the composite walls increased with an increase in the area ratio of steel tubes/CFSTs and decreased with an increase in the axial force ratio. The barbell-shaped composite wall had remarkably larger deformation and energy dissipation capacities than the rectangular-shaped composite walls. Simplified formulation was proposed for evaluating the strength of the composite walls, and some recommendations were proposed for seismic design of the composite walls.

1. INTRODUCTION

Reinforced concrete (RC) shear walls have been widely used as the major lateral force-resistant components in high-rise buildings because of their large lateral stiffness and strength. However, RC walls are less ductile when subjected to both considerable large axial forces exerted from gravity loads and cyclic lateral seismic loads (Paulay and Priestly 1992, Qian et al. 1999). Such poor performance is reflected in seismic codes (for example, UBC 1997, EuroCode8 2003, GB 50011-2001, ACI 318-05 and NZS 3101:2006), which specify the upper limits of the axial force ratio. As a result of the code requirements, the RC walls in lower stories of earthquake-resistant high-rise buildings are often assigned with rather thick sections, occupying usable floor areas. On the other hand, these codes require the amount of transverse reinforcements in the confined boundary element. To satisfy the code provisions, dense stirrups are assigned at the wall boundaries, causing serious difficulties in construction. It is thus crucial to develop innovative shear walls with excellent earthquake-resistant performance even under a high axial force ratio and with less transverse reinforcement at the wall boundary elements.

In recent years, a variety of steel-concrete composite walls have been developed (for example, Hajjar 2002, Hossain and Wright 2004, Zhao and Abolhassan 2004, Qian et al. 2008, and Eom et al. 2009). These walls combine the beauty of two construction materials, steel and concrete, and provide a promising alternative to conventional RC walls. In this paper, an innovative shear wall called steel tube-reinforced concrete (ST-RC) composite wall is proposed by embedding circular steel tubes at the wall boundary elements. The steel tubes are fully anchored within the foundation. The embedded steel tubes act compositely with their concrete cores to form concrete-filled steel tubes (CFSTs), which can enhance both strength and deformation capacities of the wall. In addition, the proposed composite wall takes advantages of ease of construction, since no special elements (e.g., shear studs) are needed for the connection between the embedded steel tubes and their surrounding concrete.

This paper presents a series of quasi-static tests of the ST-RC composite walls under high axial force ratios and cyclic lateral loading conditions, and examines their seismic behavior (i.e., failure mode, lateral load-carrying capacity, deformation capacity, and energy dissipation). The effects of the area ratio of steel tubes/CFSTs, the axial force ratio, and the cross-sectional shape of wall on the seismic behavior are investigated, and the possibility of loosening the code requirements on the axial force ratio and the amount of transverse reinforcement at the boundary elements which are adopted for RC walls is explored. Based on test observations and data analysis, some recommendations are proposed for seismic design of the

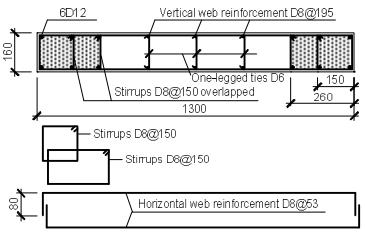


ST-RC composite walls.

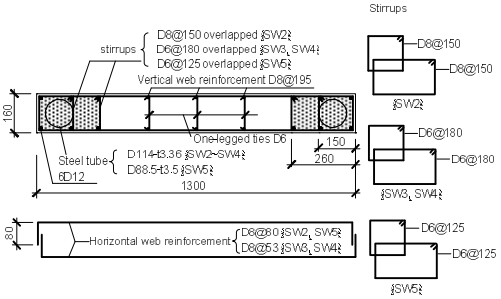
2. EXPERIMENTAL PROGRAM

2.1 Test Specimens

2.1.1 Specimens Design



The test specimens were designed to represent the lower stories of structural walls in high-rise buildings, and were fabricated at approximately 1/3 scale. Seven walls labeled Specimens SW1 to SW7 were examined. Specimen SW1 was a RC wall, and the others were ST-RC composite walls. The overall geometries of the specimens are shown in Fig. 1. A foundation beam and a top beam were cast together with the wall. The wall was 2600 mm tall, and had an aspect ratio (height-to-width ratio) of around 2.0.



(a) (b)

Figure 1. Elevation view of shear wall specimens (Unit: mm): (a) SW1 through SW6, and (b) SW7

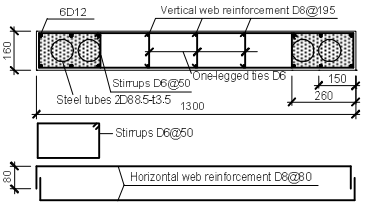


Fig.2 shows the sectional dimensions of the specimens. Specimens SW1 through SW6 had a rectangular-shaped cross section. They were classified into three pairs. The first pair consisted of Specimens SW1 and SW2, where the former was a RC wall and the latter was a ST-RC composite wall. The second pair included Specimens SW3 and SW4, which were different only at the applied axial force during tests. The third pair involved Specimens SW5 and SW6, where one had an embedded steel tube at each boundary element and the other had two tubes. Specimen SW7 was a ST-RC composite wall with a barbell-shaped cross section which included a wall web and two square edge columns.

(d)

(e)

Figure 2. Section dimensions and reinforcing details (Unit: mm): (a) SW1, (b) SW2 through SW5, (c) SW6, (d) SW7, and (e) Elevation drawing of steel tubes and reinforcement for SW2

Fig. 2 shows the confined boundary elements by shadowing. The boundary elements were determined according to the Chinese code for seismic design of buildings (GB 50011-2001), which stipulates that the extent of the confined boundary element for the walls constructed at severe earthquake-prone regions (seismic fortification intensity of 8, PGA=0.2 g) shall be not less than 0.2 times the wall's sectional depth for the rectangular-shaped walls and not less than the edge column depth for the

barbell-shaped walls.

Fig. 2 also presents the reinforcing details of the specimens. Note that the assignment of reinforcing bars could secure the "strong shear and weak bending" mechanism of the specimens. All walls were designated with D8 (Diameter=8 mm) vertical and horizontal web reinforcement. Six D12 (Diameter=12 mm) steel rebars were placed as the vertical reinforcement at the boundary elements for Specimens SW1 through SW6, which corresponded to a 1.63% reinforcement ratio (i.e., the ratio of cross-sectional areas between the vertical rebars and the boundary element). Four D12 vertical rebars were placed in each edge column for Specimen SW7, which corresponded to a reinforcement ratio of 0.72%. The transverse reinforcement at the confined boundary elements was made in the form of rectangular hoops. Further details on the transverse reinforcement at the boundary elements are described in Subsection 2.1.3.

Fig. 2(e) shows an elevation drawing of steel tubes and reinforcement for Specimen SW2. The steel tubes and vertical reinforcement were extended into the foundation beam and top beam to achieve the full anchorage. The anchorage depth of the steel tubes within the foundation beams was not less than three times the tube's diameter. In addition, a steel cover plate was welded at the tube bottom, which could also contribute to the secure anchorage. Note that no special elements (e.g., shear studs) were used for the bond between the steel tubes and their surrounding concrete.

2.1.2 Material Properties

The walls were constructed with the concrete that had a strength grade of C40 (the nominal cubic compressive strength, $f_{cu,d}$=40 MPa, and the design value of axial compressive strength, $f_{c,d}$=19.1 MPa). The means values of the measured cubic compressive strengths $f_{cu,t}$ of the wall concrete at the time of testing were 40.2, 44.3, 40.5, 40.1, 46.7, 49.8 and 47.3 MPa for Specimens SW1 through SW7, respectively. The tested cubes had the dimension of 150 mm×150 mm×150 mm. The higher strength grade concrete, C50 (the nominal cubic compressive strength, $f_{cu,d}$=50 MPa, and the design value of axial compressive strength, $f_{c,d}$=23.1 MPa), was used to fill in steel tubes. The measured cubic compressive strength $f_{cu,t}$ was 57.5 MPa. Note that the actual value of axial compressive strength of concrete $f_{c,t}$ was taken as $0.76f_{cu,t}$ according to the Chinese code for design of concrete structures (GB 50010-2002).

The steel grade of D12 rebar was HRB335 (the nominal yield stress, f_y=335 MPa) and the other rebars were HPB235 (f_y=235 MPa). The measured yield strengths of steel were 382, 344 and 409 MPa for the rebars D12, D8 and D6, respectively. Steel tubes were fabricated by Grade Q235 steel (fy=235 MPa). The yield strengths of steel measured by coupon tests were 369 and 356 MPa for the steel tubes with the diameter of 114 and 88.5 mm, respectively.

2.1.3 Transverse reinforcement at boundary elements

The transverse reinforcement at wall boundary elements is essential for confining concrete when the compressive strain exceeds a critical value (Thomsen and Wallace 2004). The amount of transverse reinforcement is expressed in terms of the volumetric transverse reinforcement ratio ρ_v (i.e., the ratio of volumes between the stirrups and the concrete core confined by stirrups) or the stirrup characteristic value ($\lambda = \rho_v f_{yv} / f_c$,where f_{yv} and f_c denote the yield strength of transverse reinforcement and the axial compressive strength of concrete, respectively).

A discrepancy exists in the treatment of transverse reinforcement at the confined boundary elements among different codes. In the codes of United States and elsewhere, a uniform amount of transverse reinforcement is adopted for the entire confined boundary element. In Chinese codes, the boundary element is divided into two regions, as shown in Fig. 3. Varying amounts of transverse reinforcement are allowed for different regions. Region I is specified to have double the amount of transverse reinforcement as Region II, which is attributed to larger compressive strains developing in Region I by the combination of actions of the axial compression and bending. Region I had an extent of 150 mm from the wall edge for the tested rectangular-shaped walls. The Chinese seismic design code requires that the stirrup characteristic value for Region I should be no less than 0.2 for the walls used in severe earthquake-prone regions (GB 50011-2001).

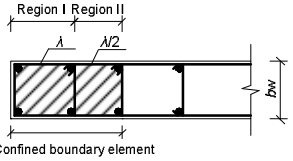

Figure 3. Chinese code requirement on transverse reinforcement at confined boundary element

Table 1 Transverse reinforcement at confined boundary elements

Specimen no.	Stirrup		ρ_v/%	λ
	Region I	Region II		
SW1	D8@75	D8@150	1.86	0.21
SW2	D8@75	D8@150	3.88	0.43
SW3	D6@90	D6@180	1.83	0.20
SW4	D6@90	D6@180	1.83	0.20
SW5	D6@63	D6@125	1.86	0.20
SW6	D6@50	D6@50	1.91	0.21
SW7	D8@50		1.91	0.21

Notes: ρ_v and λ in Table above indicate the amount of transverse reinforcement in Region I for the rectangular wall specimens and in the edge column for Specimen SW7.

The transverse reinforcement at the confined boundary elements of the test specimens is summarized in Table 1. When calculating the volumetric transverse reinforcement ratio and the corresponding stirrup characteristic value, the CFST volume was excluded in calculating the volume of concrete confined by stirrups, since the concrete core of CFST could be well confined by a steel tube. The stirrup

characteristic value of each specimen was no less than 0.2, which satisfied the code provision. Table 1 indicates that the stirrup characteristic value of each specimen was no less than 0.2, which satisfied the code provision. Note that the stirrup characteristic values shown in Table 1 were calculated through the use of the design value of material strengths.

2.2 Primary variables

Three primary variables were considered in the tests: the area ratio of steel tubes/CFSTs, the axial force ratio, and the cross-sectional shape of wall. As shown in Fig. 2, two types of wall cross sections (i.e. the rectangle-shaped and barbell-shaped sections) were considered in the tests. Details of other two variables are described as follows.

2.2.1 Area ratio of steel tubes/CFSTs

Two sizes of circular steel tubes were included, of which one was used for Specimens SW2 through SW4 and the other for Specimens SW5 through SW7. The former steel tube was denoted as ST-114-3.36 and the latter was denoted as ST-88.5-3.5. In the nomenclature for identifying steel tubes, the first number represented the outer diameter and the second number represented the thickness in mm. ST-114-3.36 had a diameter-to-thickness ratio of 31.7, and ST-88.5-3.5 had a smaller diameter-to-thickness ratio of 25.3. Only one steel tube was encased at each boundary element for ST-RC composite wall specimens except Specimen SW6 which had two steel tubes embedded at each boundary element. The steel tube and concrete core acted compositely as a CFST. CFST-114-3.36 and CFST-88.5-3.5 were used to represent the CFSTs that consisted of the corresponding steel tubes.

In order to investigate the effect of steel tubes and CFSTs, two indices were defined: the steel tube ratio and CFST ratio. The steel tube ratio, ρ, represents the ratio of the cross-sectional areas between the steel tube and the boundary element. The CFST ratio, ξ, represents the ratio of the cross-sectional areas between the CFST and the boundary element. Fig. 4 shows these indices for all test specimens. Specimen SW6 had the highest steel tube ratio and CFST ratio, whereas Specimen SW7 had the lowest steel tube ratio and CFST ratio because of its larger cross-sectional area covered by the edge column.

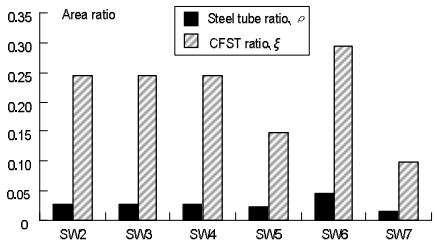

Figure 4. Area ratios of steel tubes and of CFSTs

2.2.2 Axial force ratio

The increase of the axial compressive force increases the depth of the compression zone and consequently decreases the ultimate deformation capacity for the lateral force-resistant elements (Paulay and Priestly 1992). The axial force ratio was thus considered as one of the critical concerns for the design of ductile structural walls. For ST-RC composite walls, the axial force ratio was defined as follows:

$$n_{\mathrm{d}} = \frac{N_{\mathrm{d}}}{f_{\mathrm{c,d}}(A - A_{\mathrm{CFST}}) + f_{\mathrm{cc,d}} A_{\mathrm{CFST}}} \tag{1-a}$$

$$n_{\mathrm{t}} = \frac{N_{\mathrm{t}}}{f_{\mathrm{c,t}}(A - A_{\mathrm{CFST}}) + f_{\mathrm{cc,t}} A_{\mathrm{CFST}}} \tag{1-b}$$

in which, n denotes the axial force ratio; N denotes the axial load applied on the specimen; f_{c} and f_{cc} denote the axial compressive strength of wall concrete and core concrete in the steel tube, respectively; A represents the gross cross-sectional area of the wall; A_{CFST} represents the gross cross-sectional area of the CFSTs; and subscripts d and t represent the design and test values, respectively. In the code GB 50011-2001, the design axial load is defined as N_{d}=1.2(D+0.5L), where D and L represent the dead and live loads, respectively. The specified load factor is taken as 1.2, and the live load has a reduction factor of 0.5. Thus, the design value of axial loads of the walls was 1.2 times the test value of axial loads applied on the specimens. The Chinese design code specifies that the design value of the axial compressive strength of concrete is equal to its test value of the strength multiplied by the reduction factor, to allow for the under-strength probability due to material variations and reliability. For instance, the design and test values of the axial compressive strength of concrete C40 were equal to 19.1 and 30.4 MPa, respectively, which corresponded to a material strength reduction factor of 0.63. An overall ratio between the design and the test values of the axial force ratios combines the load factor and material strength reduction factor, which accordingly equals to 1.2/0.63=1.9, rounded up to 2.

Table 2 shows the axial loads applied in the test specimens and the corresponding axial force ratios. The first pair, Specimens SW1 and SW2, had the same design axial force ratio of 0.55. For the second pair, Specimen SW3 was assigned a design axial force ratio of 0.60, while Specimen SW4 had a higher ratio of 0.72. The third pair, Specimens SW5 and SW6, had a design axial force ratio of approximately 0.70. Specimen SW7 had the largest design axial force ratio of 0.76. Note that the design axial force ratios for the specimens were larger than 0.5, i.e., the limit value for the ductile RC walls specified in the Chinese seismic design code.

Table 2 Applied axial force and axial force ratio

Specimen no.	Axial force N_t (kN)	Axial force ratio n	
		n_d	n_t
SW1	1821	0.55	0.29
SW2	1873	0.55	0.26
SW3	2042	0.60	0.31
SW4	2462	0.72	0.38
SW5	2346	0.70	0.32
SW6	2495	0.73	0.31
SW7	2570	0.76	0.34

2.3 Test setup and loading program

The test specimen was placed in a loading frame, as shown in Fig. 5. A vertical load was initially applied to the specimen by the vertical jack and it was maintained constantly for the duration of the test. Afterwards, cyclic lateral loads were applied quasi-statically by the actuator mounted horizontally to the reaction wall. The horizontal loading point was 2690 mm high above the wall bottom. The shear span ratios were 2.1 for Specimens SW1 through SW6, and 2.3 for Specimen SW7.

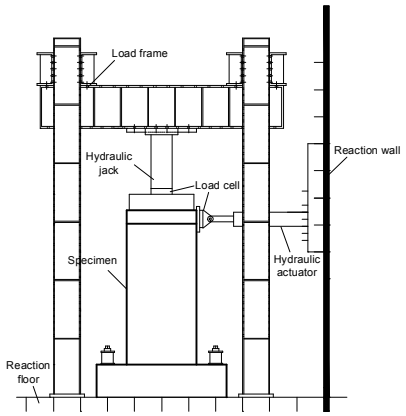

Figure 5. Test setup

Fig. 6 shows the loading history for the tests. Before the specimen yielded, the lateral loading was force-controlled and a cycle was performed at each force level. Four levels were considered in this phase: 0.25, 0.5, 0.75, and 1.0 times the predicted yield load. The loading was changed to displacement control after the specimen yielded. The displacement was expressed in terms of the drift ratio θ, which was defined as the ratio of the lateral displacement at the loading point over the height of the loading point from the wall bottom. The drift ratios increased in sequence of 1/200, 1/150, 1/100, 1/75 and 1/50, and two cycles were repeated at each drift level. In each cycle, a push was exerted and then followed by a pull, where the push was defined as the positive loading and the pull as the negative loading. The test was terminated at a complete failure due to concrete crushing developed at the wall bottom.

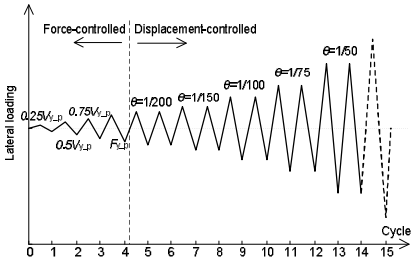

Figure 6. Loading history

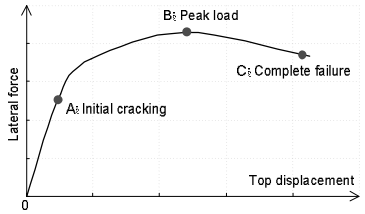
2.4 Instrumentation

Instrumentation was used to measure loads, displacements and strains for each specimen. Load cells measured the vertical and lateral loads applied to the specimen. Five linear variable differential transformers (LVDTs) were mounted to measure the lateral displacements at 520 mm intervals over the wall height. A LVDT was mounted horizontally on the foundation beam to monitor any horizontal slip of the foundation beam along the reaction floor. The strains in the reinforcing steel were measured through the use of strain gauges. The strains of the vertical boundary steel rebars and vertical web steel rebars were monitored. The longitudinal and hoop strains of the steel tubes were measured. All gauges were located approximately 20 mm above the wall bottom. All measurements were recorded by a computer data acquisition system. During the tests, cracks and failures were observed carefully and were recorded by hand.

3. EXPERIMENTAL RESULTS

3.1 Damage and failure mode

The walls behaved in a similar manner for each test. Specimen SW5 was selected to show a typical envelope curve of the measured lateral force versus the top displacement in Fig. 7. In general, the damage of the specimen could be characterized into three stages: initial cracking stage, crack developing and yield stage, and failure stage. These stages correspond to Points A, B and C in Fig. 7, respectively. Fig. 8 shows the concrete cracking and crushing patterns for Specimens SW1 and SW5 after the tests. The cracking and crushing patterns for other composite walls were similar to that for Specimen SW5. The damage observed at each stage is summarized as follows.



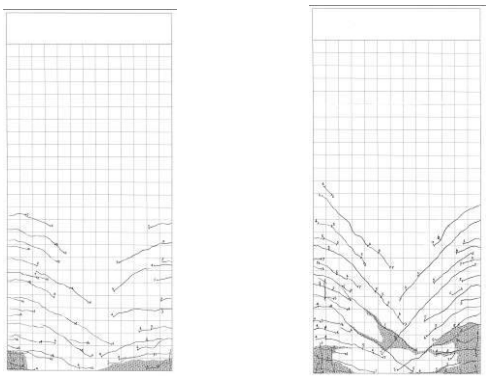


Figure 7. Typical envelope curve of lateral force versus top displacement

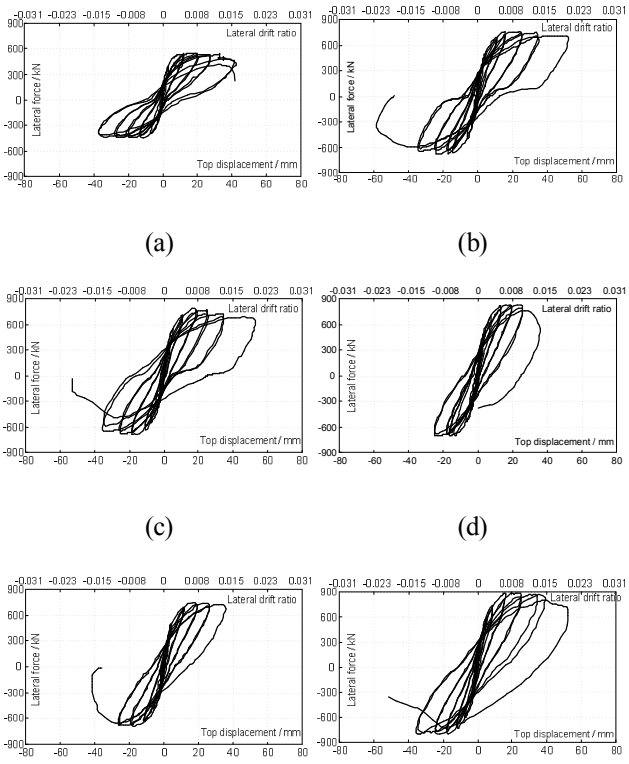
Initial cracking stage: This stage began from the onset

of testing to the occurrence of the initial crack. When the drift ratio reached 0.14% on the average (varied from 0.11% to 0.16% for different specimens), a horizontal flexure crack was observed initially at the wall bottom. A higher axial force ratio could delay the onset of flexure cracking. For instance, Specimen SW3 (n_d=0.60) cracked initially at a 0.13% drift ratio, whereas Specimen SW4 (n_d=0.72) cracked initially at a 0.16% drift ratio. On the other hand, a higher axial force ratio could expedite the compressive yield of vertical boundary reinforcement. For Specimen SW4 (i.e., the one subjected to the highest actual axial force ratio), the vertical boundary rebars yielded in compression nearly at the same time as the initial cracking. For other Specimens, the vertical boundary rebars experienced compressive yield after the cracks developed horizontally along the wall bottom. The specimens behaved almost linearly before cracking, and the initial cracking caused an obvious loss of stiffness as indicated in Fig. 7.

Crack developing and yield stage: This stage began from the initial cracking to the point when the specimen reached its peak load. Following the initial cracking, both the occurrences of new cracks and the extension and widening of existing cracks were observed upon further loading. The cracks were distributed in the region from the wall bottom up to an approximate height equal to the wall's sectional depth. The horizontal cracks extended from the boundary elements to the wall web, and then developed along the diagonal directions. The diagonal cracks were at an approximately 45° angle. Fig. 8 shows that the cracks in the RC wall were sparser and wider relative to those developed in the ST-RC composite walls. The measured strains indicated that the reinforcing bars and steel tubes sustained compressive yielding at an average drift ratio of 0.23%, and then experienced tensile yielding at an average drift ratio of 0.44%. Following the rapid development of the post-yield strains in rebars and steel tubes, the specimen reached the peak load at an average drift ratio of 0.58%.

Failure stage: This stage started from the peak load point to a complete failure of the specimen. After the lateral peak load was attained, vertical cracks caused by extremely large compressive strain occurred at the bottom corners of the wall. Concrete spalling and crushing occurred at further cycles, along with gradual strength deterioration. In the end, concrete crushing significantly reduced the wall's vertical load-carrying capacity, and consequently resulted in a complete failure. Concrete crushing was concentrated in the region from the wall bottom up to above 400 mm height. At the end of the tests, significant local buckling was observed at the bottom of CFSTs after removing the loose concrete.



(a) (b)

Figure 8. Cracking and crushing patterns after tests: (a) SW1, and (b) SW5.

3.2 Force-Displacement Relationship

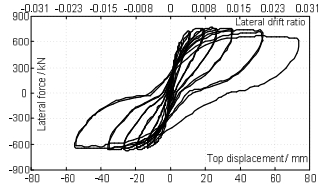


Fig. 9 shows the measured lateral force versus top displacement relationships for all seven specimens. In view of the hysteretic loops, the following observations were evident. The hysteresis loops of all specimens were fat and not significantly pinched, showing the characteristics of the flexure failure mode. When loading and unloading within a small drift (prior to the concrete cracking), the hysteretic curves cycled almost linearly with no residual displacement. After cracking, the stiffness clearly degraded and the strength steadily increased. Residual deformation was observed in unloading. After the peak load, the hysteretic curves showed a pinching effect, and the residual deformation became noticeable.

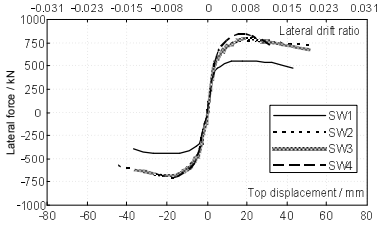
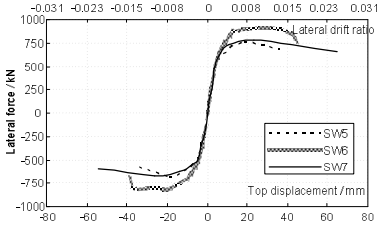
(a) (b)

(c) (d)



(e) (f)



(g)

Figure 9. Hysteretic loops of lateral force versus top displacement relationships of specimens: (a) SW1, (b) SW2, (c) SW3, (d) SW4, (e) SW5, (f) SW6, and (g) SW7.

Fig. 10 plots the envelope curves of the lateral force versus top displacement relationships. All specimens had nearly identical initial stiffness. For the first pair of specimens, Specimen SW2 exhibited both larger lateral load-carrying and deformation capacities than Specimen SW1, due to the contribution of embedded CFSTs. Note that Specimen SW1 was over-loaded in the positive loading at its last loading cycle with the drift ratio θ=1/75 (i.e., 1.33%) due to loading error, which could affect its measured maximum deformation. For the second pair, Specimens SW3 and SW4 showed similar strengths, while Specimen SW4, which was under a higher axial force ratio, had a far smaller ultimate deformation than Specimen SW3. For the third pair, Specimens SW6, which had larger steel tube and CFST ratios, exhibited both larger lateral load-carrying and deformation capacities relative to Specimen SW5. Specimen SW7, the barbell-shaped wall, had the largest deformation capacity among all specimens due to the enhancement of edge columns. Quantitative discussions on the load-carrying and deformation capacities of the specimens are stated in the following subsections.

(a)

(b)

Figure 10. Envelope curves of lateral force versus top displacement of specimens: (a) SW1 through SW4, and (b) SW5 through SW7

3.3 Lateral load-Carrying Capacity

Table 3 illustrates the measured crack load V_{cr_m}, yield load V_{y_m} and peak load V_{p_m} of the specimens. The crack load V_{cr_m} corresponded to the load measured at initial cracking. The values of crack load and corresponding crack displacement could have some degree of uncertainty, since the naked-eye observation of cracks was affected by inspectors. The yield load V_{y_m} was defined by using the concept of equal plastic energy (Choi and Park 2008) so that the area enclosed by the idealized elastic-perfectly plastic envelope curve was the same as the measured envelope curve. The comparison between Specimen SW1 and SW2 indicated that the presence of CFSTs at the boundary elements evidently increased the crack load and yield load, and enlarged the peak load by 44%. The peak load of Specimen SW6 was 18% greater than Specimen SW5, indicating that larger steel tube/CFST ratios could improve the lateral load-carrying capacity.

Table 3 Lateral load-carrying capacity of specimens

Specimen no.	V_{cr_m} (kN)	V_{y_m} (kN)	Peak load		
			V_{p_m}(kN)	V_{p_e}(kN)	V_{p_m}/V_{p_e}
SW1	335	422	503	424.8	1.18
SW2	410	601	718	639.2	1.12
SW3	445	617	738	642.8	1.15
SW4	515	647	771	669.4	1.15
SW5	445	598	719	636.8	1.13
SW6	490	697	851	771.6	1.10
SW7	475	602	721	663.5	1.09

Since the specimens displayed a flexure-dominated behavior, the lateral load-carrying capacity could be estimated from the flexural strength at the wall bottom section. The following assumptions were made in assessing flexural strength. (1) Initially plane sections remained plane after bending. (2) The unconfined compression strengths of concrete f_c were utilized, ignoring the increased influence of compression strengths of the concrete that was confined by steel tubes and by stirrups at the boundary elements. Tension strength of concrete was ignored. (3) The steel's stress-strain relationship was idealized by an elastic-perfectly plastic approximation, ignoring the strain hardening and the effect of buckling of steel tubes and rebars. (4) The internal compression force of concrete were calculated by using the equivalent rectangular stress block of average stress αf_c and of the extent x from the extreme compression fiber. (5) The steel tubes were conservatively treated as vertical steel rebars. The steel tubes and vertical rebars in the boundary elements of two edges yielded in tension and in compression, respectively, which was evidenced by the measured strain data. (6) The contribution of the vertical web rebars that were placed within the extent of 1.5x from the extreme compression fiber were neglected, since they were close to the neural axis and their stress did not developed fully. Whereas the other vertical web rebars were assumed to yield in tension (JGJ 3−2002). Fig. 11 illustrates the mechanism principle of simplified evaluation for the flexure strength of wall section.

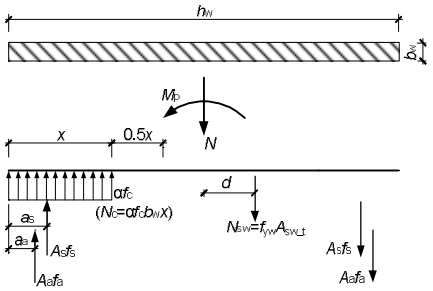


Figure 11. Flexure strength evaluation of wall cross section

According to the force equilibrium and moment equilibrium with respected to the wall's centroid, the following equations were derived:

$$N = N_c - N_{sw} \tag{2-a}$$

$$M_p = 0.5N_c\left(h_w - x\right) + A_s f_y\left(h_w - 2a_s\right) + A_a f_a\left(h_w - 2a_a\right) + N_{sw} d \tag{2-b}$$

$$N_c = \alpha f_c b_w x \tag{2-c}$$

$$N_{sw} = f_{yw} A_{sw_t} \tag{2-d}$$

where N denotes the axial load applied at the top of the wall; M_p denotes the flexure strength at the wall bottom section under the axial compressive force N; N_c and N_{sw} denote the reaction forces provided by the concrete in compression and by the vertical web rebars in tension, respectively; h_w and b_w denote the depth and thickness of the wall section, respectively; A_s and A_a denote the gross cross-sectional areas of the vertical rebars and steel tubes in one boundary element, respectively; A_{sw_t} denotes the gross cross-sectional areas of the vertical web rebars that were in tension; f_y, f_a, and f_{yw} represent the yield strengths of the vertical boundary rebars, steel tubes and vertical web rebars, respectively; f_c represents the axial compressive strength of concrete; a_s and a_a represent the distances of the vertical boundary rebar centroid and of steel tube centroid to the nearest wall edge, respectively; d denotes the distance between the centroid of the vertical web rebars that were in tension and the centroid of the wall section; x represents the extent of the equivalent rectangular stress block; and αf_c denotes the average stress of equivalent rectangular stress block, and the value for α factor is taken to be 1.0 for the concrete of which the cubic compressive strength is not higher than C50 (JGJ 3−2002). Note that the strength variety of the concretes inside and outside steel tubes were considered in the evaluation.

After assessing the flexural strength at the wall bottom section, M_p, the lateral load-carrying capacity was calculated by Equation (3) which included the P-Δ effect (Park and Eom 2007).

$$V_{p_e} = \frac{M_p - N\Delta_p}{H} \tag{3}$$

Where V_{p_e} denotes the evaluated lateral load-carrying capacity, Δ_p denotes the measured lateral displacement of the lateral loading point at the peak load, and H denotes the height of the lateral loading point relative to the wall base. Table 3 shows the values of V_{p_e} for all specimens and the comparison with the measured peak lateral load V_{p_m} in the tests. The evaluated results for ST-RC composite walls correlated well with the corresponding test results, with no more than 15% errors.

3.4 Deformation Capacity

Table 4 presents the crack displacement Δ_{cr}, yield displacement Δ_y, ultimate displacement Δ_u, displacement ductility ratio μ_Δ, and ultimate drift ratio θ_u of the specimens. The yield displacement Δ_y was the displacement at the yield load V_{y_m}. The ultimate displacement Δ_u was defined as the post-peak displacement at the instant when the lateral load decreased to 85% of the peak lateral load. If the lateral load did not drop to 85%, then the maximum displacement at the last loading cycle was taken as the ultimate displacement. Note that the displacement in the push direction was considered for analyzing the deformation capacity because the pull displacement at failure could not exceed the displacement at the previous cycle due to significant damage caused by prior push loading. The displacement ductility ratio μ_Δ was calculated as $\mu_\Delta = \Delta_u/\Delta_y$, and the ultimate drift ratio was calculated as $\theta_u = \Delta_u/H$.

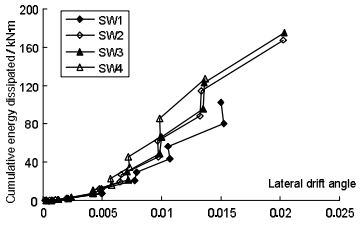

Table 4 Deformation capacity and ductility ratio of specimens

Specimen no.	Δ_{cr} (mm)	Δ_y (mm)	Δ_u (mm)	μ_Δ	θ_u
SW1	3.23	5.24	42.70	8.15	0.016
SW2	3.09	8.36	51.93	6.21	0.020
SW3	3.43	8.16	51.60	6.32	0.020
SW4	4.22	7.49	31.90	4.26	0.012
SW5	3.62	7.89	35.73	4.53	0.014
SW6	3.65	8.79	44.96	5.11	0.017
SW7	3.72	6.88	64.61	9.39	0.025

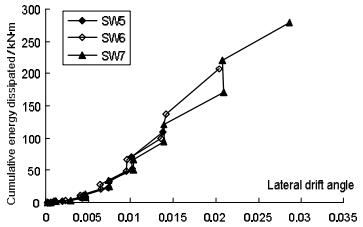

Table 4 indicates the following observations. The ultimate drift ratio of Specimen SW2 was 22% greater than the corresponding RC wall, Specimen SW1. For the two identical walls, Specimens SW3 and SW4, the ultimate drift ratio decreased to 60% when the test axial force ratio increased from 0.31 to 0.38. The ultimate drift ratio of Specimen SW6 was 26% greater than Specimen SW5, which indicated that having larger steel tube/CFST ratios could improve the ultimate deformation capacity. Specimen SW7, the barbell-shaped wall, exhibited a much larger deformation capacity relative to the rectangular-shaped walls, with an ultimate drift ratio of 0.025. It should be pointed out that because the presence of CFSTs at the boundary elements increased both the yield displacement and ultimate displacement, the displacement ductility ratio of ST-RC composite walls was smaller than the corresponding RC wall.

3.5 Energy Dissipation Capacity

Fig. 12 shows the energy dissipation curves for the specimens. The energy dissipation capacity of rectangular walls increased with an increase in steel tube/CFST ratios, and decreased with an increase in the axial force ratio. The total energy dissipated by Specimen SW2 was 63% greater than the corresponding RC wall, Specimen SW1. Due to the presence of edge columns, Specimen SW7 exhibited the largest energy dissipation capacity. It is notable that the ST-RC composite walls under design axial force ratios of up to 0.7 (e.g., Specimens SW4 through SW6) showed greater hysteretic energy dissipation capacities than the RC shear wall under a design axial force ratio of 0.55.

4 CONCLUSIONS AND RECOMMENDATIONS

This paper presented an innovative composite wall, named the ST-RC composite wall. A series of quasi-static tests were conducted to investigate the lateral load-carrying capacity, deformation capacity, and energy dissipation of the walls under the condition of high axial force ratios and cyclic lateral loading. The primary test variables included the steel tubes/CFSTs ratios, the axial force ratio, and the cross-sectional shape of wall. Key observations obtained from this study were as follows:

(1) The ST-RC composite wall specimens showed a flexure failure mode, characterized by tensile yield of the vertical reinforcement and steel tubes in the boundary elements and compressive crushing of concrete at the wall bottom.

(2) With the addition of embedded steel tubes, the ST-RC composite walls showed a larger crack load, yield load, peak load, and ultimate deformation capacity relative to the RC wall. The deformation capacities of the ST-RC composite walls increased with an increase in the steel tube/CFST ratios, and decreased with an increase in the axial force ratio.

(3) The barbell-shaped ST-RC composite wall that was configured with edge columns showed remarkably larger deformation and energy dissipation capacities relative to the rectangular-shaped composite walls.

(4) Simplified formulation was developed to evaluate the lateral load-carrying capacity of the composite walls, in which the steel tubes were taken as vertical steel rebars. The evaluated results for the ST-RC composite walls showed no more than 15% errors compared with the corresponding test results.

Based on tests observation and data analysis, the following recommendations were proposed for seismic design of the ST-RC composite walls.

(1) Under the design axial force ratio of 0.73 and the confined boundary element's stirrup characteristic value of 0.20, the rectangular-shaped ST-RC wall had an ultimate drift ratio of 0.012, which was larger than the story drift requirement (i.e., 1/120=0.0083 drift ratio) for RC wall structures under the action of maximum considered earthquakes specified in the Chinese code for seismic design of buildings (GB 50011-2001). Considering the reliability of the design, rectangular-shaped ST-RC composite walls that were adopted in severe earthquake-prone regions were suggested under a design axial force ratio no greater than 0.65 and a confined boundary element's stirrup characteristic value no less than 0.2. Note that the CFST volume could be excluded from the concrete volume when calculating the volumetric transverse reinforcement ratio of the boundary elements.

(2) The barbell-shaped ST-RC composite wall that was configured with edge columns had an ultimate drift ratio of 0.025 under the design axial force ratio of up to 0.76 and an edge column's stirrup characteristic value of approximately 0.2. The barbell-shaped ST-RC composite walls used in severe earthquake-prone regions were suggested under a design axial force ratio no greater than 0.70 and an edge column's stirrup characteristic value no less than 0.2. Similarly, the CFST volume could be excluded from the concrete volume when calculating the volumetric transverse reinforcement ratio of the boundary elements.

Abstract: In order to adapt to anchor bolts of exposed bases in steel moment frames, we have devised a hysteretic damper of tubular shaped steel for use in a bolt joint. The damper is expected to deform stably over a large plastic deformation range after local buckling occurs in the tubular part. The present paper describes basic experiments conducted during the development of the. Cyclic axial loading tests of the damper are conducted in order to investigate the deformation capacity of the damper. The length and diameter-thickness ratio of the damper are adopted as the experiment parameters. The test results reveal that the local buckling mode and the deformation capacity depend on the length and the diameter-to-thickness ratio.

1. INTRODUCTION

A variety of seismic dampers are used to reduce the structural response to seismic loading. Although viscoelastic or hysteretic dampers can reduce structural and nonstructural damage from seismic events, it is difficult to design a steel moment frame that will not be damaged at column bottoms of the first story by a severe earthquake. In order to adapt to the anchor bolts of exposed-type column bases in steel moment frames, we have devised a hysteretic damper of tubular shaped steel for use in a bolt joint, as shown in Fig. 1 (Mukaide). In the proposed device, one end of the damper is in contact with the nut, and the other is in contact with the base plate. When the column bottom is subjected to a large bending moment, the damper is expected to ensure that the other parts remain elastic by absorbing seismic input energy.

The proposed device consists of a bolt joint and a tubular damper. In this device, one end of the damper is in contact with the nut, and the other is in contact with the base plate. Figure 2 shows examples of the configuration detail. The welded damper in Fig. 2(a) is welded to the nut via the flange and the base plate. The screw-on damper in Fig. 2(b) is machined from extremely thick tube, and the ends of the damper have external screws on the outer circumferences. The damper is screwed onto the base plate and the lock nut. Thus, the

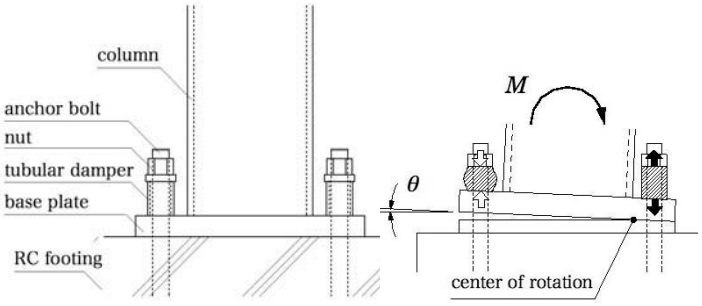

Fig. 1 Proposed device

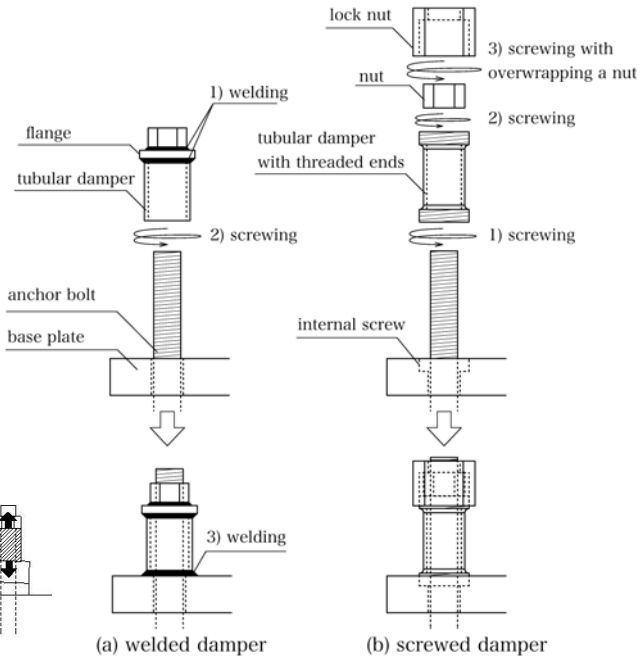

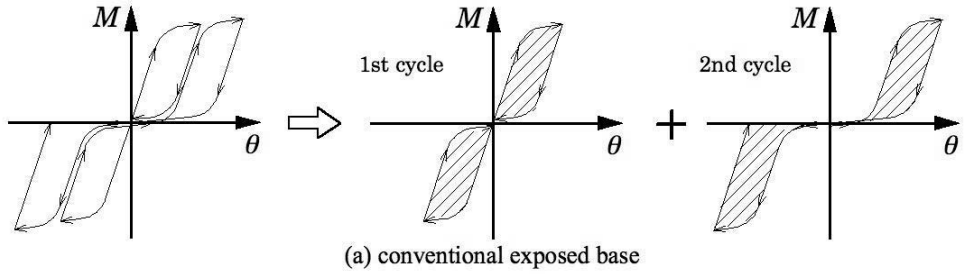

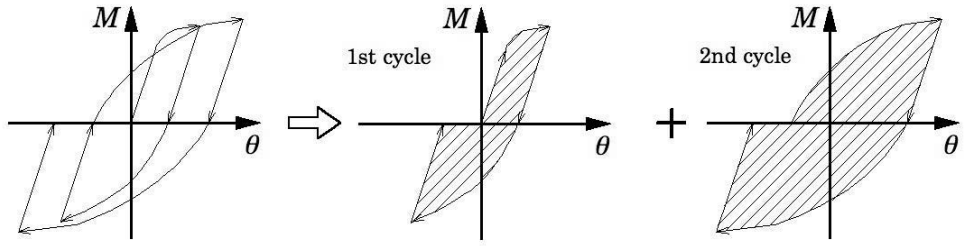

Fig. 2 Damper configuration

(a) conventional exposed base

(b) exposed base with the proposed device

Fig. 3 Hysteresis loops

damper is subjected to not only compressive stress but also tensile stress.

Since the center of rotation of the base is generally near the compressive flange of the column, the axial deformation of the damper is much larger in the compressive direction than in the tensile direction. Therefore, the damper must deform stably over a large plastic deformation range after local buckling occurs in the tubular part.

Figure 3(a) shows the hysteretic behavior of a conventional exposed base, in which the anchor bolts yield first. The restoring force characteristics shift to a slip-type behavior after the anchor bolts yield. The area of the hysteresis loops is much smaller than spindle-shaped hysteresis loops. However, in the proposed device, the exposed base is predicted to exhibit a pattern of a roughly spindle-shaped hysteresis loops, as shown in Fig. 3(b). Therefore, the proposed device will be able to absorb seismic input energy as a hysteretic damper.

A number of the present authors have conducted monotonic and cyclic loading tests during the development of the proposed system (Mukaide). Monotonic tests revealed high deformation performance of steel tubes with low diameter-to-thickness ratios, and cyclic loading tests of the welded damper (Fig. 2(a)) revealed that the deformation capacity was low because of fracturing at welded joints.

The present paper reports the data obtained in our latest fundamental tests. In these tests, screw-on dampers (Fig. 2(b)) are considered with the hope of improving deformation capacity. The purpose of the present study is to clarify the potential performance of the proposed system.

2. EXPERIMENT

For the case in which the damper is applied to exposed-type column bases, an axial load acts dominantly on the damper. In order to investigate the deformation capacities, cyclic axial loading tests of the dampers are conducted.

The tubular damper must fracture over a large deformation range with local buckling so that the damper may absorb a great deal of energy. Therefore, the diameter-to-thickness ratio and the length of the damper are used as experimental parameters because these factors may influence the local buckling characteristics.

A schematic diagram of the specimens is shown in Fig. 4. Table 1 lists the dimensions and materials of the specimens. The specimens are characterized by low diameter-to-thickness ratios *D/t*. The specimens are constructed from carbon steel tubes for machine structural purposes (JIS STKM13A). The mechanical properties obtained by a tension test are shown in Table 2.

The loading set-up is shown in Fig. 5. The joints of specimens are connected to loading plates by screws. One end of the specimen is fixed, and the other is connected to an oil-jack. The center of rotation of an exposed base is generally near the compressive flange of

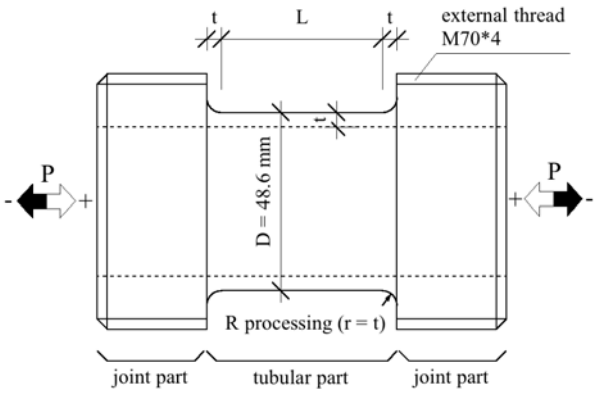

Fig. 4 Schematic diagram of the specimens

the column. Assuming that ratio of compressive deformation to tensile deformation is 8, the specimens are loaded cyclically according to the history shown in Fig. 6. The calculated length of one local buckling, ${}_cl$ is used as the reference value of the target deformation. Based on the classical theory (Timoshenko), ${}_cl$ is expressed by

$$ {}_cl = 2\pi \cdot \sqrt[4]{\frac{(D \cdot t)^2}{48(1-\nu^2)}} \qquad (1) $$

3. EXPERIMENTAL RESULTS

3.1 Axial Strength

The test results and some of the hysteresis curves are shown in Table 1 and Fig. 7, respectively. The yield strength is calculated based on the tensile test results.

The greater the diameter-thickness ratio *D/t* of the damper, the greater the maximum strength. The maximum strengths of the damper with *D/t* = 16.8 (G15 series) and D/t = 8.1 (G8 series) are increased approximately 1.7- and 2.1-fold, respectively. The maximum strength of the damper with *D/t* = 8.1 (G8 series) is increased approximately 2.1-fold.

The maximum strength tends to decrease slightly as the tubular part becomes longer, although there the length did not significantly affect the hysteresis curve (shown in Fig. 7). This strength decrease is influenced by the local buckling mode explained later.

Fig. 7 Hysteresis curves

In Table 3, ${}_cP_{max}$ is the maximum strength, which is expressed as

$$ {}_cP_{max} = {}_cP_y \left(0.0163 \frac{E \cdot t}{\sigma_{yc} \cdot D} + 0.929 \right) \qquad (2) $$

where E is Young's modulus and σ_{yc} is the compressive yield stress (tensile yield stress is used in the present paper). The strength ${}_eP_{max}$ must be calculated in order to design the other parts so that they will remain elastic. Equation (2) is an empirical formula based on the monotonic compressive loading test (Suzuki) with a thinner tube (for which D/t is from 20 to 80) than the specimens in this test. Although this test is out of the applicable range of the formula, ${}_cP_{max}$ is in good agreement with ${}_eP_{max}$, except for G8 series.

After the maximum strengths, the restoring forces of the G15 series degrade rapidly. Hence, tubes thinner than the G15 series appear to be in appropriate for hysteretic dampers.

3.2 Local Buckling Mode

Examples of the deformation state after loading are shown in Photo. 1. Even for the same diameter-to-thickness ratio, these results are grouped roughly into three local buckling modes according to $L/{}_cl$. These three modes, as shown in Fig. 8, are a mode with a buckling wave at the center of the tubular part (mode-Is), a mode with an asymmetrical buckling (mode-Ia), and a mode with two buckling waves (mode-II) in ascending order of length. Table 3 indicates that the boundary of $L/{}_cl$ between mode-Is and mode-Ia is somewhere between 1.2 and 1.3 and that the boundary of $L/{}_cl$ between mode-Ia and mode-II is somewhere between 1.4 and 1.6.

3.3 Deformation Capacity

The deformation capacity to fracture is

Photo. 1 Deformation state after loading

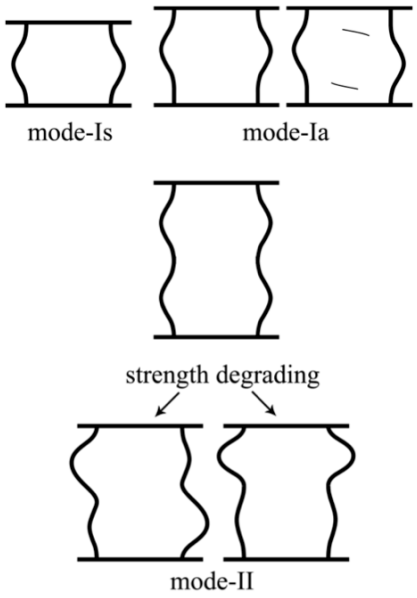

Fig.8 Local buckling modes

evaluated based on v_{max} and $\Sigma E/P_y$ in Table 3. The deformation capacities of respective local buckling modes exhibit different trends.

In the case of mode-Is and mode-Ia, specimens for which length L is shorter than ${}_cl$ fracture during the fourth loading cycle, whereas specimens for which L is longer than ${}_cl$ fracture during the fifth loading cycle. The shorter specimens have shorter buckling waves. Therefore, the premature fracturing of the shorter specimens is caused by larger out-of-plane bending deformation. The longer specimens have subequal buckling wavelengths and similar deformation capacities.

In the case of mode-II, specimens of the G10, G12, and G15 series have comparable deformation capacities to the mode-Is and mode-Ia specimens. This is because only one of the two local buckling waves deforms and the other is unloaded after the strength degrades. On the other hand, the specimens of the G8 series have a higher deformation capacity. Both of the local buckling waves deform significantly because these specimens maintain their ultimate strength without degradation until fracture. The longer specimens of mode-II have higher deformation capacities than the shorter specimens, which is also the case for mode-Is and mode-Ia.

Compared with the welded dampers, the screw-on dampers, which have the same form, exhibit a 1.2- to 3.1-fold increase in $\Sigma E/P_y$. This is because the fractures occurred in the base rather than ay the weld.

In the case of the proposed dampers, design decisions such as the section size of the column and the layout of anchor bolts affect the deformation capacity of the exposed base. Assuming that distance from the dampers to the center of rotation of the base is 400 mm, the maximum rotation angle to fracture for specimen G8-2.2 exceeds 0.04 rad. This is believed to be sufficient for hysteretic dampers.

4. CONCLUSIONS

In order to develop a new hysteretic damper for bolted joints, we have investigated experimentally the fundamental properties of a damper under axial load. The main conclusions are summarized as follows:

1) The local buckling mode of the tubular part varies

according to the diameter-to-thickness ratio and the length.

2) The specimens exhibiting mode-Ia or mode-Is buckling have similar deformation capacities (v_{max} = 0.3 $_{c}l$). The specimens of the G8 series exhibiting mode-II buckling have good performance. These results suggest the efficacy of the dampers when they are adapted to the anchor bolts of exposed-type column bases.

In the next series of experiments, the exposed base with the proposed dampers will be loaded in order to investigate the deformation capacities

Abstract: High-strength bolts used in Special Bolted Moment Frame (SBMF) are in snug-tight conditions. AISI S110 Standard provides a design table with values that are based on 75.6 kN bolt tension force for 25.4 mm diameter high-strength bolts with a slip coefficient 0.19. To evaluate the effect of bolt over-tightening or under-tightening on the seismic response of SBMF including story drift ratio and maximum moment in the bolted connection, a sensitivity study was conducted. Additionally, the effect of the variation of bolt tension on the collapse margin was evaluated per the FEMA P695 Methodology. It was concluded that the over-tightening or over-tightening of the bolts is not a major concern.

1. INTRODUCTION

The American Iron and Steel Institute (AISI) recently published S110 "*Standard for Seismic Design of Cold-Formed Steel Structural Systems–Special Bolted Moment Frames*" (AISI 2007). Special Bolted Moment Frame (SBMF) is intended for use as free-standing light storage mezzanines, elevated office support platforms, equivalent support platform, and small buildings in all seismic areas. It is composed of cold-formed Hollow Structural Sections (HSS) columns and double C-section beams connected by snug-tight high-strength bolts (see Figure 1). If needed, bearing plate can be welded to the connection region to increase the bearing strength of the bolted moment connection. Based on the cyclic test results of 9 full-scale beam-column subassemblies (Hong and Uang 2004), it was shown that using a 75.6 kN bolt tension for 25.4 mm diameter high-strength bolts with a slip coefficient k=0.19 would provide a satisfactory correlation of the test results in the slip range (Uang et al. 2010). Therefore, this bolt tension force and slip coefficient were adopted in the AISI S110 Standard (2009) to compute the slip resistance of the bolt group.

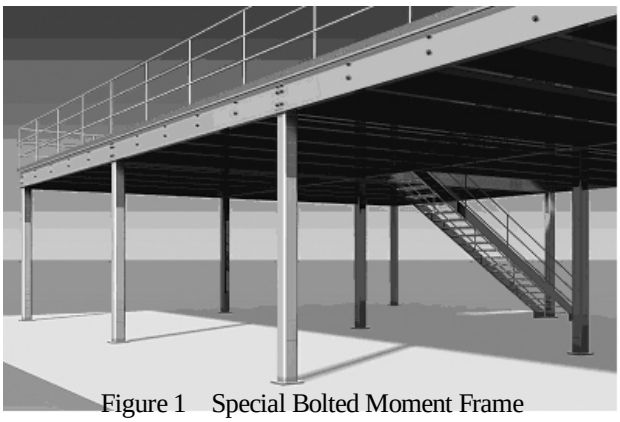

Figure 1 Special Bolted Moment Frame

Since bolts are to be tensioned to a snug-tight condition (RCSC 2004), a concern was raised on whether over-tightening or under-tightening will affect the maximum moment that can be developed in the bolted connection. Since the inelastic action in a SBMF is to be developed in the bolted moment connection during a seismic event, a high moment in the bolted connection may over-load the beams and columns and cause the frame to failure in a non-ductile manner.

To evaluate the effect of bolt over-tightening or under-tightening on the seismic response of SBMF, a sensitivity study was conducted. A series of nonlinear time-history analyses of sample SBMFs by using a suite of 44 earthquake ground motions were conducted to evaluate statistically effect of the variation of bolt tension on the seismic response including the story drift and the maximum moment in the bolted connection. The effect of the variation of bolt tension on the collapse margin was also evaluated per FEMA P695 Methodology (2009).

2. STRUCTURAL MODEL

2.1 Archetype Structural Design

Figure 2 shows the two-dimensional frame geometry that was used to model the one-story SBMF structures; Table 1 shows the design data of each archetype design. The archetypes were designed for Site Class D condition (soft soil) with S_{DS} = 1.0g as well as S_{D1} = 0.6g. The

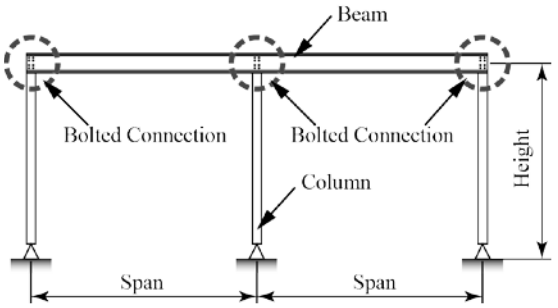

Figure 2 Archetype Analysis Model for SBMF

corresponding Maximum Considered Earthquake (MCE) hazard spectral values were equal to 1.5 times of these design spectral values (ASCE 2005). Following the P695 Methodology, the archetype models were designed based on the following seismic load combinations:

$$(1.2 + 0.2S_{DS})D + \rho Q_E + L \quad (1)$$

$$(0.9 - 0.2S_{DS})D + \rho Q_E \quad (2)$$

where D is the structural self-weight and superimposed dead loads, and L is the design live load (see Table 2). Q_E is the effect of horizontal seismic forces resulting from the base shear, V. Following P695, the redundancy factor, ρ, was conservatively assumed to be 1.0 in all cases.

The structural design was in accordance with S110; Response Modification Coefficient, R, is equal to 3.5. The beams were specified to be ASTM A653 galvanized cold-formed steel C-section members with nominal yield stress (F_y) and ultimate strength (F_u) of 345 and 483 N/mm^2, respectively. ASTM A500 Grade B HSS members with F_y and F_u values of 317 and 483 N/mm^2, respectively, were used for the columns. Tables 2 and 3 summarize the member and connection designs based on the seismic load combinations in Eqs. 1 and 2.

2.2 Development of Nonlinear Structural Model

The nonlinear analyses were performed by using the software OpenSees (PEER 2006). The model shown in Figure 2 included beam and column elements as well as a zero-length rotational spring to simulate the nonlinear behavior of the bolted beam-to-column connections (Uang et al. 2010). Fiber element was used to model the yielding of the beams and columns; no buckling was considered in the analysis.

The expected yield stress (= R_yF_y) was used to compute the strength for the beam and column, where R_y is equal to 1.1 and 1.4 for the beam and column, respectively (AISI 2007). To model the hardening range of the bolted moment connection response, the bearing strength at bolt holes is a function of the expected tensile strength (= R_tF_u). The following R_t values were used: 1.1 for the beam and 1.3 for the column (AISI 2007).

For either nonlinear static or dynamic analysis, P695 requires that the following gravity loads be imposed to the model structure:

Table 1 Archetype Structural Design Parameters

ID	No. of Span	Span (m)	Bay (m)	Height (m)	T (sec)	$S_{MT}(T)$ (g)

25.4mm diameter snug-tight high strength bolts are used.

$$1.05D + 0.25L \quad (3)$$

A 5% damping ratio was assumed for the models. The P-Delta effect was also included in the analysis.

For each archetype, 3 models were considered. The "Standard" (ST) model assumes that the bolts were properly tightened to the snug-tight condition such that the bolt tension is the same as that assumed (T = 75.6 kN). The "over-tightened" (OT) model assumes that all the bolts were over-tightened such that the bolt tension is 50% larger (i.e., T = 133 kN). The "under-tightened" (UT) model assumes that the bolt tension is 70% of that assumed in the standard model (i.e., T = 52.9 kN).

3. ANALYSES RESULTS

3.1 Static Pushover Analysis

A comparison of the static pushover results can be made in Figure 3. The variation in the bolt tension mainly affects the response in the slip range, but not too much in the bearing range.

3.2 Dynamic Analysis at DBE Level

A sample comparison of the global responses of Archetype 3 for three bolt tension models at Design Basis Earthquake (DBE) Level is shown in Figure 4. Figure 5 summarizes the maximum story drift ratio produced by all

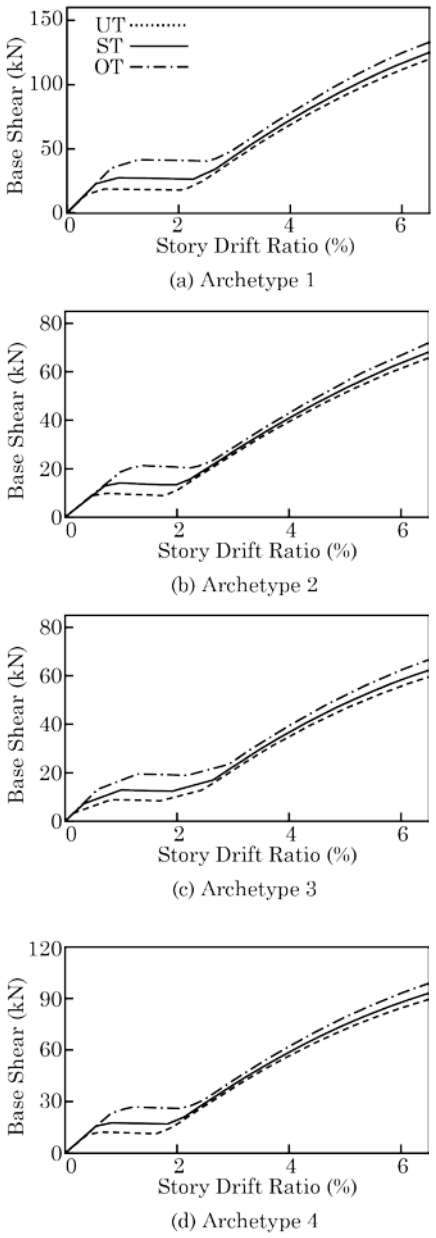

Figure 3 Sensitivity of Bolt Tension on Pushover Analysis

44 ground motions per P695. Figure 6 shows a summary of the based shear. (The maximum moment in a bolted connection is proportional to the base shear). The average value and the standard deviation of both the story drift and base shear are summarized in Table 4.

Even with the assumption that the bolt tension would be increased by 50% due to over-tightening, it is observed from Table 4 that both the story drift ratio and base shear (or moment in the bolted connection) are not very sensitive to the variation of bolt tension. In this case, over-tightening reduces the story drift by 2.7% to 3.4%, although the maximum moment in the bolted connection is increased by 4.4% to 18%. If the bolt tension was reduced by 30% due to under-tightening, it is also observed from Table 4 that both the story drift ratio and base shear are not very sensitive to the variation of bolt tension. In this case, under-tightening

increases the story drift by 3.3% to 10%, and maximum moment in the bolted connection is reduced by up to 5.7%. Therefore, this sensitivity study concludes that the over-tightening or under-tightening is not a major concern.

3.3 Evaluation of Collapse Margin

For each archetype model, the spectral acceleration at collapse, S_{CT}, was computed for each of the 44 ground motion, from which the median collapse intensity, $\hat{S}_{CT}$, was computed. $\hat{S}_{CT}$ was obtained by scaling all the records in the record set to the MCE intensity, S_{MT}, and then by increasing the intensity until one-half of the scaled ground motion records caused collapse. The ration between the median collapse intensity, $\hat{S}_{CT}$, and MCE intensity, S_{MT}, is the Collapse Margin Ratio (*CMR*).

$$CMR = \hat{S}_{CT} / S_{MT} \tag{4}$$

The value of $\hat{S}_{CT}$ depends on how the collapse is defined. Using a very large story drift ratio to define $\hat{S}_{CT}$ gives a nonconservative estimation of *CMR*. On the other hand, using the code specified story drift limits (ASCE 2005) to define $\hat{S}_{CT}$ is too conservative because the actual story drift capacity is generally higher. Since the beam and column of all the archetypes satisfied the S110 seismic compactness requirements, it is judged that a story drift capacity of 0.06 radians was a reasonable value to define the lower bound collapse limit state (Uang et al. 2010). Figure 7 shows the Incremental Dynamic Analysis (IDA) results for calculating the lower bound $\hat{S}_{CT}$ and *CMR* values for "Standard" (ST) model of Archetype 3. Figure 8 shows the collapse probability obtained from the IDA with bolt tensions varied, i.e., Standard (ST), over-tightened (OT), and under-tightened (UT). The lower bound $\hat{S}_{CT}$ and *CMR* values for all archetypes are summarized in Table 5.

According to P695, Spectral Shape Factor, *SSF*, is considered to remove the conservatism from using the

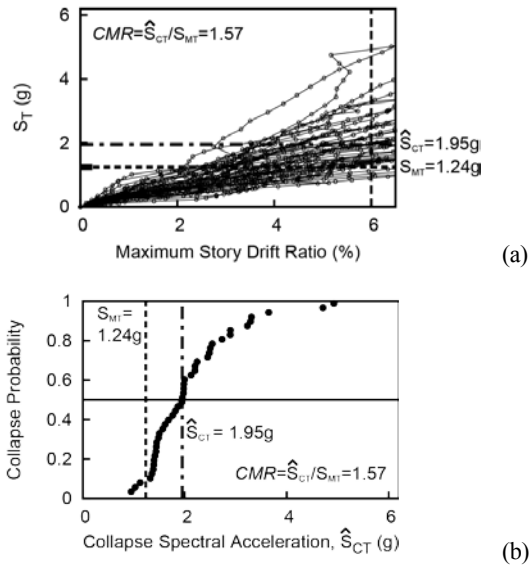

Figure 7 Sample IDA results and Collapse Probability (Archetype 3)

ground motion record set and the Adjusted Collapse Margin Ratio, *ACMR*, is used to compare with the acceptable values.

$$ACMR = SSF \times CMR \tag{5}$$

The Acceptable *ACMR* values are also provided in P695. For each archetype, the following criterion has to be satisfied.

$$ACMR_i \geq ACMR_{20\%} \tag{6}$$

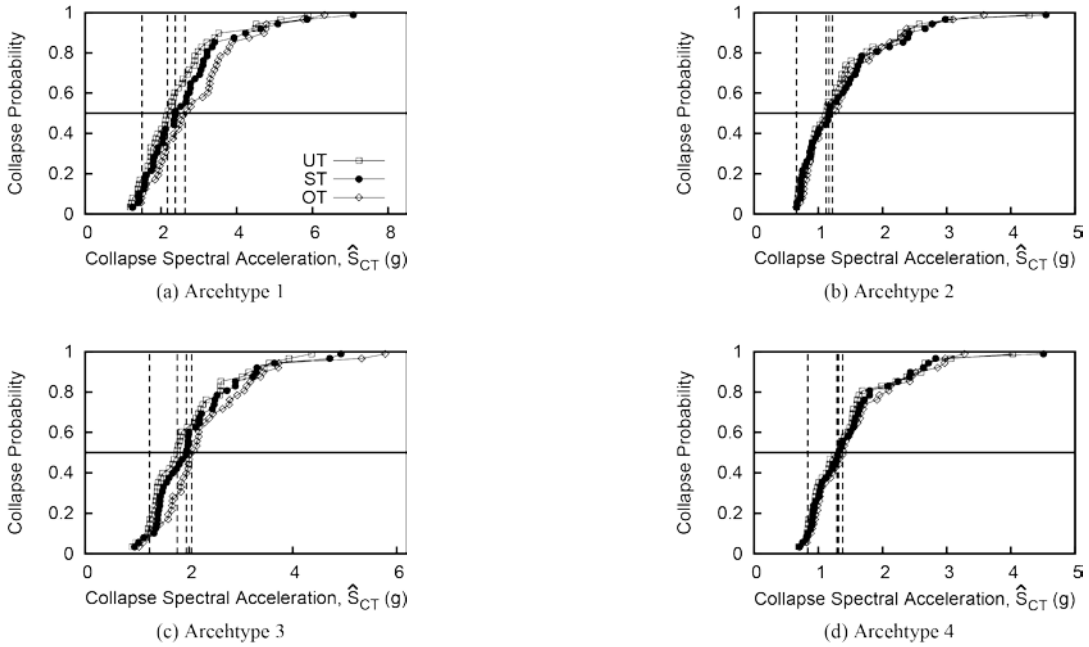

Figure 8 Sensitivity of Bolt Tension on Collapse Probability

$ACRM_{20\%}$ is the acceptable value with a collapse probability of 20%. This value is a function of the total system collapse uncertainty, β_{TOT}. This parameter reflects the fact that systems that have more robust design requirements, more comprehensive test data, and more detailed nonlinear analysis models, have less collapse uncertainty. In this study, a value of 0.60 for β_{TOT} is used per P695. As the result, a value of 1.66 is used for $ACRM_{20\%}$. A comparison of the calculated and acceptable *ACMR* values in Table 5 shows that Eq. (6) is satisfied. These results also showed that bolt tension force is not a major concern and a sufficient margin against collapse due to Maximum Considered Earthquake ground motions is provided.

4. CONCLUSIONS

A sensitivity study of the bolt tension force on the story drift ratio, maximum moment in the bolted connection, and the collapse margins of Special Bolted Moment Frame (SBMF) was presented in this paper. Over-tightening of the bolts reduced the story drift ratio by up to 3.4%, although the maximum moment in the bolted connection was increased by 4.4% to 18%. On the other hand, under-tightening of the bolts increased the story drift ratio by 3.3% to 10%, and the maximum moment in the bolted connection was reduced by up to 5.7%. Evaluating the collapse margin, the effect of bolt tension was not significant and the acceptance criteria provided by FEMA P695 were met. Therefore, it can be concluded that over-tightening or under-tightening of the bolts in SBMF is not a major concern.

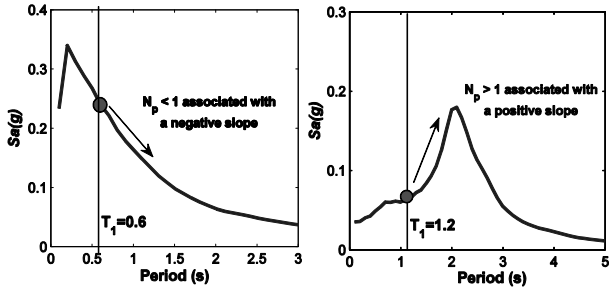
Abstract: In this paper, several vector-valued ground motion intensity measures based on a parameter to characterize the spectral shape named N_p are analyzed. The parameter N_p is commonly used to represent the spectral acceleration response spectra in a range of periods, and in the present study this parameters was used to discuss which spectral shape is more related with a specific performance parameter corresponding to maximum and energy demands. For this aim, vector-valued ground motion intensity measures based on N_p through different type of response spectra such as: pseudo-acceleration, pseudo-velocity and input energy are analyzed. The efficiency of the vectors to predict the nonlinear response of several steel frames subjected to narrow-band motions from the soft soil of Mexico City is compared. Finally, an approach to predict the nonlinear response of structures dominated by higher modes of vibrations is proposed.

1. INTRODUCTION

In the last years, parameters to represent the ground motion potential of an earthquake named intensity measures (IMs) have been proposed (Housner 1952, Arias 1970, Von-Thun et al. 1988, Cordova et al. 2001, Baker and Cornell 2005, Tothong and Luco 2007, Baker and Cornell 2008, Bojórquez and Iervolino 2010). One of the desirable features of an IM must be the ability to predict the response of structures subjected to earthquakes (small variability of structural response given the IM). This ability is known as *efficiency* (Bazzurro 1998, Shome 1999, Luco 2002). The efficiency is crucial in records selection for nonlinear structural response with seismic design purposes as well as for reliability-based analysis. Due to this, many efforts have been oriented to propose ground motion intensity measures. Most of these parameters have the peculiar characteristic of representing the spectral shape in a range of periods, which is strongly related with the structural response as suggested in many studies (Cordova et al. 2001, Baker and Cornell 2005, Tothong and Luco 2007, Baker and Cornell 2008, Bojórquez and Iervolino 2010). In particular, vector and scalar ground motion intensity measures based on N_p which is representative of the spectral shape have resulted very well correlated with the nonlinear structural response (Bojórquez and Iervolino 2010, Bojórquez et al. 2010a). However, the studies regarding the parameter N_p have been developed considering only the spectral pseudo-acceleration shape, and it is important to observe which spectral shape is more related with a specific performance parameters as in the case of maximum interstory drift, hysteretic energy, etc. It is the main objective of this paper to analyze the efficiency of several vector-valued ground motion intensity measures, based on N_p and considering different types of response spectra, to predict the structural response of steel frames.

2. THE PARAMETER N_p



2.1 Definition

It has been mentioned that IMs often try to capture the structural response via the spectral shape with different degrees of accuracy. For example, $Sa(T_1)$, is the perfect predictor for the response of elastic single degree of freedom systems, and a good predictor for elastic multi-degree of freedom systems dominated by the first mode of vibration (associated to the T_1 period). Moreover, studies have found the sufficiency of $Sa(T_1)$ with respect to magnitude and distance (Shome 1999, Iervolino and Cornell 2005). Nevertheless, $Sa(T_1)$ does not provide information about the spectral shape in other regions of the spectrum, which may be important for the nonlinear behavior (beyond T_1) or for structures dominated by higher modes (before T_1). In the case of structures with nonlinear behavior, the structural response may be sensitive to different spectral values associated to the whole range of periods, from the fundamental period until a specific period of the structure beyond of T_1 to account for nonlinear behavior here named T_N. This calls for intensity measures providing information

about the spectral shape in different regions of the spectrum (Baker and Cornell 2008). The parameter N_p is inspired and focused in the featuring of the spectral acceleration shape and it can be obtained by the ratio between the geometrical mean in the range of periods from T_1 until T_N $Sa_{avg}(T_1,...,T_N)$ divided by $Sa(T_1)$. It is mathematically represented as:

$$Np = \frac{Sa_{avg}(T_1,...,T_N)}{Sa(T_1)} \quad (1)$$

According to this equation, if we have one or *n* records with a mean N_p value close to one, it is expected that the average spectrum be about flat in the range of periods between T_1 and T_N. For a N_p value lower than one, an average spectrum with negative slope is expected. As an example, the mean value of N_p for a group of ordinary records in the period T_1 = 0.6s is 0.39. In Figure 1a, the average spectrum of this set is illustrated. In the case of N_p values larger than one, the spectra tend to increase beyond T_1. As it can be appreciated for a set of narrow-band records, where the mean value of N_p=1.9 for T_1=1.2s, the average spectrum shows an increasing accelerations zone (see Figure 1b). Finally, the normalization of $Sa(T_1)$ let N_p be independent of the scaling level of the records based on $Sa(T_1)$, but most importantly it helps to improve the knowledge of the path of the spectrum from period T_1 until T_N, which is related with the nonlinear structural response. In the present study, for all the cases analyzed T_N equals to 2.2 times T_1 was used, as suggested by Bojórquez and Iervolino (2010).

Figure 1 Mean elastic response spectra for a set of records with: (a) N_p=0.39, and (b) N_p=1.9

3. FEATURING DIFFERENT TYPES OF SPECTRAL SHAPE, AND VECTOR-VALUED GROUND MOTION IMs CONSIDERED

The efficiency to predict the nonlinear response of moment-resisting steel frames subjected to ground motion records is compared by means of different alternatives vector-valued ground motion intensity measures IMs with two parameters. An efficient IM can help to considerably reduce the number of analyses required to estimate the response of structures subjected to earthquakes with accuracy. Because most of the seismic hazard maps around the world were developed for the spectral acceleration at first mode of vibration $Sa(T_1)$, all the vectors here considered are based in $Sa(T_1)$ as the first parameter; however, other parameters as pseudo-velocity or nonlinear parameters can be used. In the second parameter of the vector, N_p was considered but using different types of response spectra. In total three different response spectra were considered to feature N_p as the second parameter. The first vector considered is $<Sa(T_1),N_{pSa}>$ which originally was proposed by Bojórquez and Iervolino (2010). It can be obtained by using Equation 1. The second vector is $<Sa(T_1),N_{pSv}>$, where N_{pSv} is obtained from Equation 1, but using the pseudo-velocity response spectrum instead of the pseudo-acceleration response spectrum. Finally, the last vector-valued ground motion intensity measure considered was $<Sa(T_1), N_{pEI}>$, where N_{pEI} is based on the input energy response spectrum. The input energy can be defined from the equation of motion of a single degree of freedom system as follows:

$$m\,\ddot{x}(t) + c\,\dot{x}(t) + f_s(x,\dot{x}) = -m\ddot{x}_g(t) \quad (2)$$

In equation 2, m is the mass of the system; c, the viscous damping coefficient; $f_s(x,\dot{x})$, the non-linear force; $\ddot{x}$, the ground acceleration; and x, the displacement with respect to the base of the system. A dot above x indicates a derivative with respect to time. In case of an elastic linear system, $f_s(x,\dot{x}) = k\,x$, where k is the stiffness of the system.

Integrating each member of Equation 2 with respects to x, yields:

$$\int m\,\ddot{x}(t)\,dx + \int c\,\dot{x}(t)\,dx + \int f_s(x,\dot{x})\,dx = -\int m\,\ddot{x}_g(t)\,dx \quad (3)$$

Equation 3 can be written as energy balanced equation as follows:

$$E_K + E_D + E_S + E_H = E_I \quad (4)$$

where E_K, E_D, E_S and E_H represent the kinetic (k), viscous damping (D), deformation (S) and dissipated hysteretic (H) energies, respectively; and E_I is the relative input energy, which will be used to obtain the vector $<Sa(T_1), N_{pEI}>$. Note that all the vectors were selected to represent maximum and cumulative potential of a ground motion shaking.

4. STRUCTURAL STEEL FRAME MODELS, SEISMIC RECORDS AND PERFORMANCE PARAMETERS

4.1 Structural steel frame models

Four moment-resisting steel frames having 4, 6, 8 and 10 stories, were considered for the studies reported herein. The frames are denoted as F4, F6, F8 and F10, respectively. As shown in Figure 2, the frames, designed according to the Mexico City Building Code (MCBC), have three eight-meter bays and inter-story heights of 3.5 meters. Each frame was provided with ductile detailing and its lateral strength was established according to the MCBC. A36 steel was used for the beams and columns of the frames. Relevant characteristics for each frame, such as the fundamental period of vibration (T_1), and the seismic coefficient and

displacement at yielding (*Cy* and *Dy*) are shown in Table 1 (the latter two values were established from static nonlinear analyses).

A two dimensional, lumped plasticity nonlinear model of each frame was prepared and analyzed. For this purpose, an elasto-plastic model with 3% strain-hardening was used to represent the cyclic behavior (in terms of bending moment and rotation) of the transverse sections located at both ends of the steel beams and columns. As discussed by Bojórquez and Rivera (2008), this model provides a good approximation to the actual hysteretic behavior of steel members. The frames were analyzed considering 3% of critical damping.

Table 1 Relevant characteristics of the steel frames

Frame	Number of Stories	T_1 (s)	C_y	D_y (m)
F4	4	0.90	0.45	0.136
F6	6	1.07	0.42	0.174
F8	8	1.20	0.38	0.192
F10	10	1.37	0.36	0.226

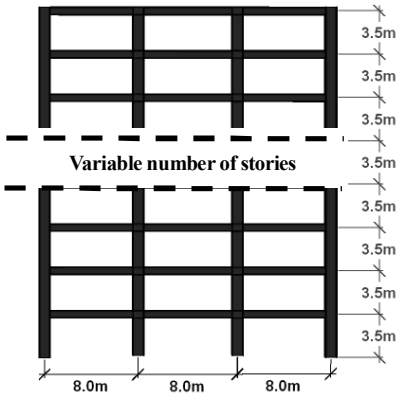

Figure 2 Geometrical characteristics of the steel frames considered

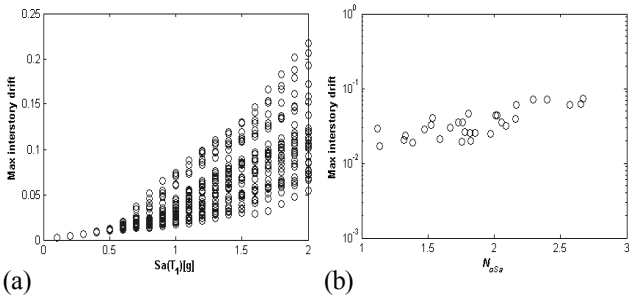
4.2 Seismic records

A set of 30 narrow-banded ground motions recorded at Lake Zone sites of Mexico City was considered. Particularly, all motions were recorded at sites having soil periods of two seconds, during seismic events with magnitudes near of seven or larger and having epicenters located at distances of 300 km or more from Mexico City. Some important characteristics of the records are summarized in Table 2. In this table, *PGA* and *PGV* denote the peak ground acceleration and velocity, respectively. It should be mentioned that sites having soil periods of two seconds are fairly common within the Lake Zone, and that the higher levels of shaking (in terms of peak ground acceleration) have been consistently observed at these sites.

4.3 Performance parameters

Two performance parameters were considered. The maximum interstory drift ratio, due to its relevance for design purposes, and the normalized dissipated hysteretic energy (E_N) by yielding displacement (D_y) and strength (F_y), see Equation 5. E_N was selected here as a performance parameter because its direct relationship with the cumulative demands (Iervolino et al. 2006). In fact, currently various damage indexes have been proposed based on hysteretic energy (Terán and Jirsa 2005, Rodriguez and Padilla 2008, Bojórquez et al. 2010b). It is important to say, that F_y and D_y were obtained from a push-over analysis, and E_H corresponds to the total plastic energy dissipated by the structure (the plastic energy dissipated by all the elements).



$$N_{EH} = \frac{E_H}{F_y D_y} \tag{5}$$

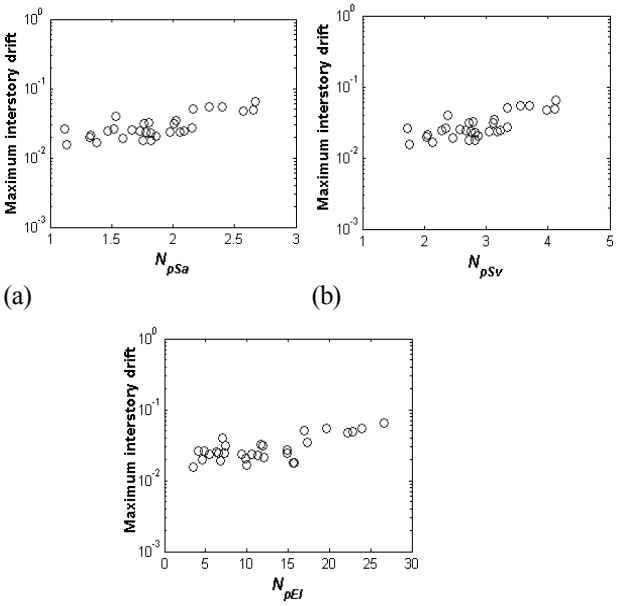
5 RELATION BETWEEN VECTOR-VALUED IMs AND THE STRUCTURAL DEMAND OF STEEL FRAMES

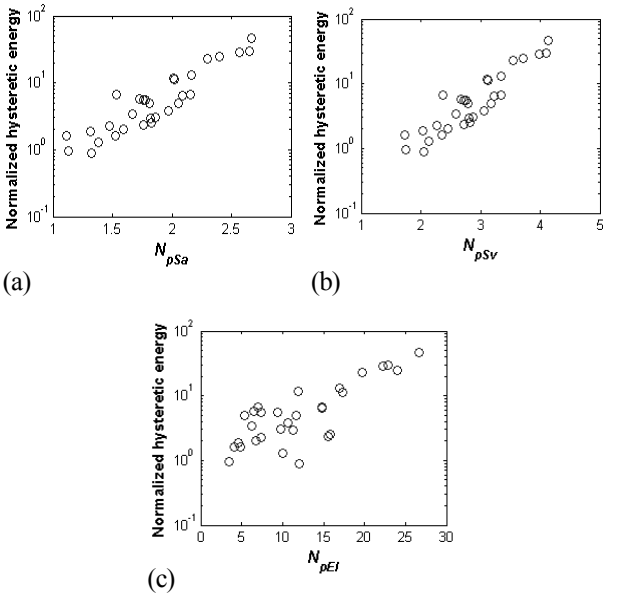
Baker and Cornell (2005) and Bojórquez and Iervolino (2010) showed the advantages of using vector-valued ground motion intensity measures instead of scalars. The main advantage is the increment in the efficiency to predict the structural response. Herein with the aim to obtain the relation between the structural response of steel frames and the vectors selected; nonlinear incremental dynamic analysis of the frames subjected to the 30 records by using the first parameter of the vector, in this case $Sa(T_1)$ was perform, and then the relation between the structural response of the steel frames and the second parameter of the vector based on N_p is obtained. Note that it must be developed for a specific level of spectral acceleration and for all the intensity levels considered. While Figure 3a shows and example of the incremental dynamic analysis for $Sa(T_1)$, Figure 3b illustrates the relation obtained for $<Sa(T_1),N_{pSa}>$ and the maximum interstory drift demand when $Sa(T_1)$=1g. Note the good relation between N_{pSa} and the maximum interstory drift reflecting the advantage of the vector-valued ground motion intensity measure.



(a) (b)

Figure 3 (a) incremental dynamic analysis scaling for $Sa(T_1)$; (b) relation between N_{pSa} and the maximum interstory drift for $Sa(T_1)$=1g

5.1 Prediction of maximum interstory drift and normalized hysteretic energy via vector-valued ground motion intensity measures: Analyses results



The relation between maximum interstory drift and normalized hysteretic energy demand of the frames analyzed is discussed. Figure 4 compares N_{pSa}, N_{pSv} and N_{pEI} with the maximum interstoy drift for frame F6, and for the records scaled at $Sa(T_1)$=0.9g. This scaling level corresponds to the point where the median value of the maximum interstory drift achieves 0.03 (structural collapse according to the MCBC). However, other scaling levels are considered as will be illustrated below. A good correlation can be observed between maximum interstory drift and all the parameters based on the spectral shape considered. This observation is valid also to predict the normalized hysteretic energy, see Figure 5; except that in this case, the parameter based on the input energy spectral shape is less effectiveness to predict normalized hysteretic energy demands, which is an important observation since this vector take into account structural damage potential. All these conclusions are valid also for the other frames under considerations. An important issue fall in the fact that the variation of the N_p based on spectral acceleration is in the range from 1 to 3 while in the other cases this variation is larger; particularly for the input energy the interval is between 0 and 30 which is quite large. Finally, the trend observed for the N_p based on pseudo-acceleration and pseudo-velocity response spectra is very similar due to the dependence of these parameters through the circular frequency.

(a) (b)

(c)

Figure 4 Maximum interstory drift prediction for the steel frame F6 with T_1=1.07s ($Sa(T_1)$=0.9g) for: (a) N_{pSa}, (b) N_{pSv} and (c) N_{pEI}

(a) (b)

(c)

Figure 5 Normalized hysteretic energy prediction for the steel frame F6 with T_1=1.07s (Sa=0.9g) for: (a) N_{pSa}; (b) N_{pSv} and (c) N_{pEI}

To demonstrate that all the conclusions obtained before are valid for a wider range of intensity levels. Figure 6 compares the standard deviation of the natural logarithm of maximum interstory drift for frame F4 and for all the IMs: $Sa(T_1)$ and the vectors $<Sa,N_{pSa}>$, $<Sa, N_{pSv}>$ and $<Sa,N_{pEI}>$. As Figure 6 suggests, the vector-valued ground motion intensity measures results in less dispersion for all the scaling level of the records compared with the scaling criteria based on spectral acceleration. Note that the vectors based on pseudo-acceleration and pseudo-velocity results in similar standard deviation. As it has been mentioned before, this is due to the relationship between both parameters, which suggest that there is no significant difference when using spectral acceleration shape or pseudo-velocity spectral shape as the type of vector here presented. The same conclusion is valid for frame F6 illustrated in Figure 7.

The results for normalized dissipated hysteretic energy and all the frames under consideration are presented in Figure 8. It is observed that, the vectors $<Sa,N_{pSa}>$ and $<Sa, N_{pSv}>$ are similar for frames F4 and F6, but in the case of frames F8 and F10 they results with minimum difference. The figure suggests that $<Sa,N_{pSa}>$ is the best correlated with nonlinear structural response of the steel frames subjected to narrow-band motions, and for this reason, it suggests that the spectral acceleration shape is a good indicator to predict maximum and cumulative demands. Regarding the question of which spectral shape really matter to predict nonlinear structural response?, the study conclude that both pseudo-acceleration and pseudo-velocity response spectra really matter; in particular, the spectral pseudo-acceleration shape.

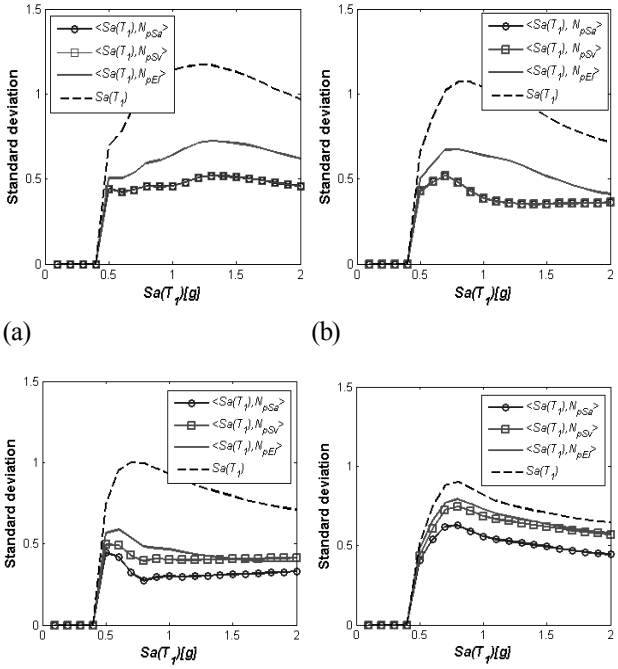

Figure 8 Standard deviation of the natural logarithm of normalized hysteretic energy given $S_a(T_1)$ and the vectors $<Sa, N_{pSa}>$, $<Sa,N_{pSv}>$ and $<Sa,N_{pEI}>$ at different intensity levels for frames (a) F4, (b) F6, (c) F8 and (d) F10

6. INCORPORING THE EFFECT OF HIGHER MODES OF VIBRATION AND FUTURE STUDIES

The work presented here was limited to predict the nonlinear seismic response of structural steel frames. Nevertheless, an efficient ground motion intensity measure should also be able to predict the nonlinear seismic response of structures dominated by higher modes as in the case of tall buildings. This is out of the scope of this paper; however,

some ideas to incorporate the effect of higher modes are given herein.

The influence of higher modes of vibration in structural response can be developed through a simple modification in the intervals of periods delimiting the parameter N_p. This is, instead assessing N_p between the range of T_1 (initial period) and T_N (final period), one possibility is to evaluate this parameter from the period of the interest mode (e.g. T_{2modo}) until T_N. Note that seismic ground motions selection in FEMA is based on a very similar approach. Moreover, the N_p parameter can be an alternative in record selection for nonlinear dynamic analysis. Furthermore, the inclusion of higher modes can be realized via vector with three parameters, as example: $<Sa, R_{T1,T2}, R_{T1,T2modo}>$, $<Sa, N_{pT1,TN}, R_{T1,T2modo}>$ or, $<Sa, N_{pT1,TN}, N_{pT1,T2modo}>$ (where $R_{T1,T2}$ proposed by Cordoba et al. 2001, is the ratio of the spectral acceleration at period T_2 and the spectral acceleration at period T_1; T_2 represents a period longer than T_1, the same is valid for other modes).

Another alternative is by giving a specific weighted to the contribution of the elastic response, nonlinear response or that dominated by higher modes of vibrations.

It would be of interest to develop a similar study but evaluating N_p non as the relation between the geometrical means divided by $Sa(T_1)$, if not by the relation of the weighted geometrical mean divided by $Sa(T_1)$. This can improve considerably the efficiency of the vectors here proposed. As can be observed, there are an ample possible alternatives to be incorporated in similar studies with the aim of increasing the efficiency of ground motion intensity measures to predict the seismic response of structures under earthquakes. Further, although it is necessary to compare other ground motion intensity measure commonly used with no dependence of the spectral shape, a recent study developed by Bojórquez et al. (2010a) showed that fragility assessment of steel buildings results more benefic if spectral shape ground motion intensity measure are used, compared with the traditional IMs as Arias intensity (Arias 1970), peak ground acceleration, peak ground velocity, ground motions durations an others.

7. CONCLUSIONS

A study to observe which spectral shape is more related with the structural response was developed. The study considers spectral shape ground motion intensity measures based on maximum and cumulative damage potential of an earthquake. The results suggest that the use of vector-valued ground motion IMs considerably predict with better approximation the structural response compared with the most commonly scalar IM (spectral acceleration at first mode of vibration). The study concludes that spectral shape ground motion IMs based on the pseudo-acceleration or pseudo-velocity spectra are more effective than those based on input energy; either to predict maximum interstory drift of steel frames under narrow-band motions, or hysteretic energy demands. In general, the work here presented recommends the use of the vector $<Sa, N_{pSa}>$ for prediction of nonlinear seismic response of structures.

Abstract: In the field of energy based seismic design, the structural performance of steel structures is determined by the energy dissipation capacity, which depends greatly on the plastic deformation capacity of the structural components that form the whole system. The plastic strain capacity of the structural steel is one of the primary factors that determine the components' plastic deformation capacity. Most of the cyclic loadings employed in the structural steel tests are the recommended standard (typically incremental or constant amplitude) loading protocols, which is insufficient to study the deformation capacity under random loadings such as earthquake effects. This paper focuses on the evaluation of the plastic strain capacity of structural steel under various axial strain histories till ductile fracture. A series of element specimens made of SS400 and SN400 steel were tested under diverse cyclic axial strain loadings. The deformation capacity of the structural steel under cyclic axial loading till fracture was evaluated by studying the experimental strain capacity/energy dissipation capacity of the skeleton curve and the Bauschinger part. The error range of this method was proved smaller than that of the Miner's rules.

1. INTRODUCTION

In energy-based seismic design, the seismic performances of buildings which are subjected to random lateral loading histories such as earthquakes are evaluated by regarding the energy input to the structures as the seismic demand and the energy dissipation capacity of structures as the structural seismic performance (Akiyama 1985). In this design method, it is necessary to accurately reflect the energy dissipation capacity, i.e., the ultimate cumulative plastic deformation capacity, of the structural components constituting the whole system.

Seismic effects applied on the steel components during earthquakes depend on the configuration, strength, stiffness, etc. of the structure. Fracture is one of the typical ultimate states of steel components under earthquakes. Many researchers have been paying attention to the plastic deformation capacity of steel components till fracture. In case of component fracture, it is also important to clarify the relationship between the local strain history at the fracture area and the plastic strain capacity of the material (structural steel). Consequently, in addition to the evaluation of plastic deformation capacity of different structural components, it is necessary to carry out fundamental research focusing on the plastic strain capacity of structural steel under various loading (strain) histories. Moreover, it is also important to clarify the relationship between the energy dissipation capacity of steel components and the material. Unfortunately, this kind of work has not been fully understood.

There are several conventional evaluation methods of the plastic deformation capacity of structural steel suffering ductile fracture under axial strain histories, such as the experimental Manson-Coffin relation (fatigue life) of structural steel under constant amplitude cyclic strain histories. Among them, the most popular method is the combination of Manson-Coffin relation (Manson 1954, Coffin et al 1954) and Miner's rule (Miner et al1945). However, it is reported when the structures are subjected to seismic effects, the amplitudes of the strain history at the fracture area are usually quite large and the material fracture under several cycles. In these cases, the above mentioned method always gives obvious error which should not be neglected.

Other than the Manson-Coffin & Miner method, it is possible to evaluate the plastic deformation capacity of steel components or material through the plastic deformation capacity of the skeleton curves, which can be extracted from the hysteresis curves. This method is developed based on empirical law (Kato 1970) of the stress-strain relation of steel material under cyclic loadings, which has been employed to evaluate the plastic deformation capacity of steel components. The analytical results of Yamada et al (Yamada et al 2006) indicate that there is a correspondence between the skeleton curve of the steel components and the structural steel. It is possible to obtain the relationship between the plastic deformation capacities of steel

components and structural steel as long as the deformation capacity of steel is known.

Therefore, in this study, a series of plate element specimens made of SS400 and SN400 steel were tested under diverse cyclic axial strain loadings. The hysteresis loops of the specimens are divided into the skeleton curves and Bauschinger parts. The plastic strain capacity of structural steel SS400 and SN400 under cyclic axial strain histories is evaluated by studying the plastic deformation capacity of each parts of the hysteresis loops

2. CYCLIC LOADING TESTS OF STEEL PLATE ELEMENTS

2.1 Details of the Specimens

The shape of the steel plate specimen is shown in Figure 1. The parameters of this experiment are the different lots of steel and the strain histories, the details of which are shown in Table 1. Twenty-eight specimens were made from 4 different steel/lots (1~4) of SS400 steel and eighteen specimens were made from the same steel/lot (5) of SN400 steel. The size of the testing part is 40mm 100mm (the lengths of specimens FF01, 02 and 03 are 80mm). In order to avoid stress concentration, both sides of the testing part are designed to have a corner R. Here, R=10mm for SS400 steel 1~4 while R=20mm for SN400 steel 5.

Tensile coupon test was conducted using the JIS-1A standard coupon. The results of the tensile test (material stress-strain relation) are shown in Figure 2.

2.2 Test Setup

Figure 3 shows the setup details of the experiment. A testing machine with its loading capacity of 500kN was

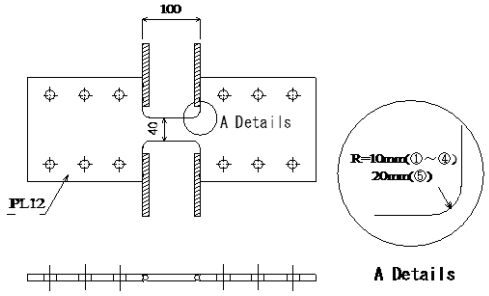

Figure 1 Shape of the specimen

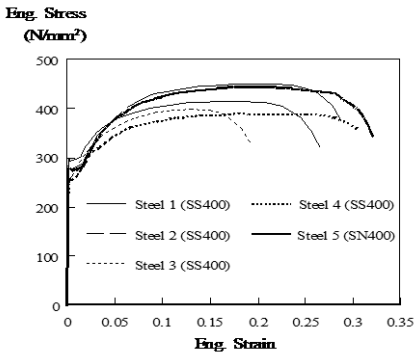

Figure 2 Results of the coupon tests (Engineering values)

employed to offer axial load. In order to prevent buckling, several buckling restraining jigs were set around the specimen. Teflon sheets were attached to the jigs to avoid the friction between the jigs and the specimen. The load was recorded by the load cell of the testing machine. Four displacement transducers were set to the end of the testing area. The deformation of the specimens was calculated through the results of these four transducers.

2.3 Strain histories

The main parameter of this experiment is the strain histories. The details of each strain history in this study are listed in Table 1. Six basic patterns of loading histories were applied to the specimens during testing (Figure 4).

1) Constant amplitude cyclic loading till fracture (Con. Amp.)

2) Constant amplitude cyclic loading followed by tension till fracture (Con. Amp.→Ten.)

3) Incremental amplitude cyclic loading followed by tension till fracture (Inc. Amp.→Ten.)

4) Constant amplitude cyclic loading followed by same constant amplitude cyclic loading with the neutral axis offset to tension side till fracture (Off.)

Note: 1) In this table, the loading histories are expressed as
"Full amplitude ε_t (Neutral axis ε_0)"×Number of cycles N

5) Random strain histories followed by tension till fracture (Ran.→Ten.)
6) Monotonic tension loading till fracture (Mono. Ten.)

2.4 Experimental results

The experimental results are shown in Table 1. The engineering stress-strain relations were obtained during testing. This study focuses on the fracture of structural steel, therefore, the true stress-true strain relations (${}_t\sigma_t\varepsilon$) were calculated from the direct engineering stress-strain results (${}_n\sigma_n\varepsilon$). Under the assumption of constant volume of the testing area, the following equations can be used for conversion.

$$ {}_t\sigma = (1+{}_n\varepsilon)\cdot {}_n\sigma \quad (1) $$

$$ {}_t\varepsilon = \ln(1+{}_n\varepsilon) \quad (2) $$

Note that in this study, fracture point is defined as the point when the slope of the true stress-strain turns from positive to negative. It is reasonable to use this definition, in other word, to study the deformation behavior of steel till its uniform elongation, when discussing the relation between components and material from a macro perspective.

Some typical true stress-strain relations of each loading pattern are shown in Figure 5 as examples. The true stress-strain hysteresis loops of this experiment were divided in to 3 parts of the skeleton curve, Bauschinger part as well as the elastic unloading part, as shown in Figure 6. The skeleton curve is obtained by connecting parts of the true stress-strain relation of both tension and compression sides sequentially, when the steel experienced its highest loading for the first time. The cumulative plastic strain of both tension and compression side in the skeleton curve and

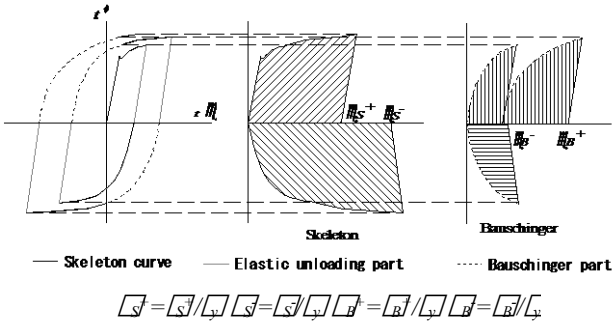

Figure 6 Decomposition of the hysteresis loops

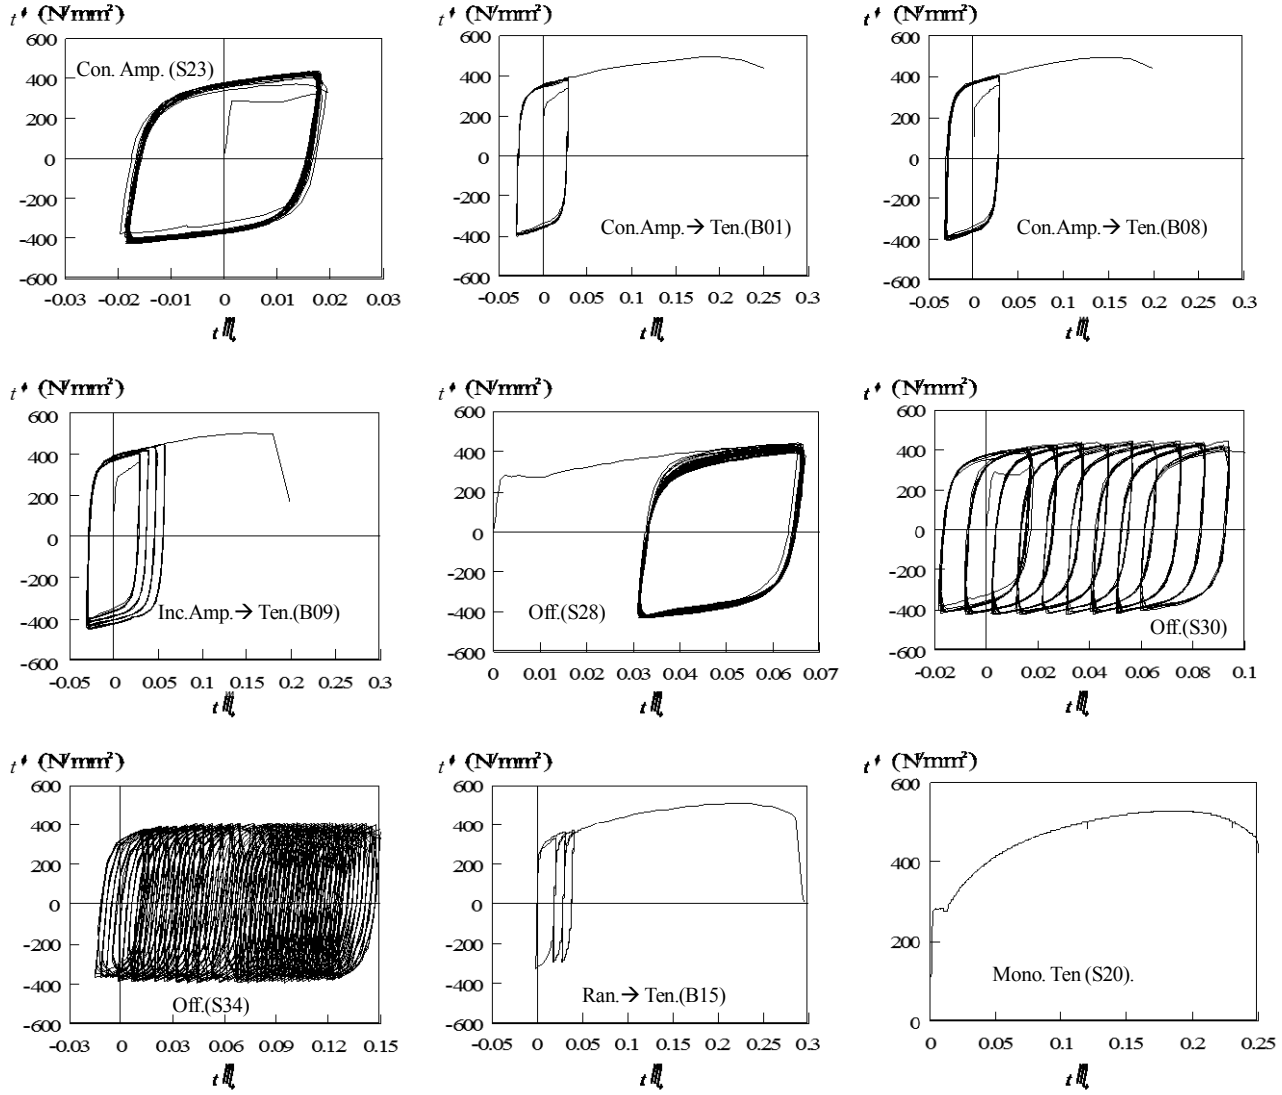

Figure 5 True stress-true strain relation (examples)

Bauschinger part is expressed as ($\varepsilon_S^+, \varepsilon_S^-, \varepsilon_B^+, \varepsilon_B^-$) respectively. The cumulative plastic strain ratio ($\eta_S^+, \eta_S^-, \eta_B^+, \eta_B^-$) is defined as ($\varepsilon_S^+, \varepsilon_S^-, \varepsilon_B^+, \varepsilon_B^-$) divided by yield strain ε_y (refer to the equations in Figure 6). The cumulative plastic strain ratio is the index that evaluates the plastic strain capacity of the steel. The $\eta_S^+, \eta_S^-, \eta_B^+, \eta_B^-$ of all specimens were calculated and shown in Table 1.

3. EVALUATION OF THE PLASTIC DEFORMATION CAPACITY OF STRUCTURAL STEEL THROUGH THE SKELETON METHOD

In this section, the plastic deformation capacity of steel suffering ductile fracture is evaluated by studying the cumulative plastic strain ratio ($\eta_S^+, \eta_S^-, \eta_B^+, \eta_B^-$) of the specimen. This method is called skeleton method in short from now on. The total plastic deformation capacity is the sum of that obtained from each part of the hysteresis loops, which can be written as $\eta_T = \eta_S^+ + \eta_S^- + \eta_B^+ + \eta_B^-$. The relation between η_T and η_S^+ of all specimens are plotted in Figure 7. Here, all the values are normalized by dividing η_0, which is the cumulative plastic strain ratio, in order to eliminate the effect of different material. A linear relation can be seen in Figure 7. Equation 3 can be used to express this linear relationship.

$$\eta_T / \eta_0 = 70 \cdot (1 - \eta_S^+ / \eta_0) + 1 \qquad (3)$$
$$(0.17 \le \eta_T / \eta_0 \le 1.0)$$

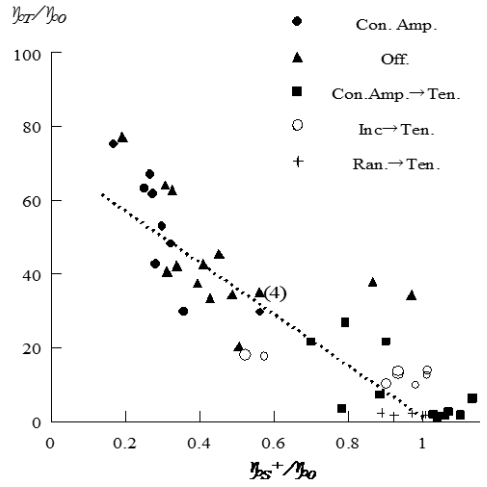

Figure 7 Relation between η_T / η_0 and η_S^+ / η_0

4. EVALUATION OF THE PLASTIC DEFORMATION CAPACITY OF STRUCTURAL STEEL THROUGH THE M-M METHOD

The combination of Manson-Coffin relation and the Miner's rule (M-M method in short) is commonly used to predict the fatigue life of steel. Manson-Coffin relation is the relation between S (amplitude) and N (number of loading cycles till fracture) of steel subjected to constant amplitude cyclic loading history, which is also the foundation of using the Miner's.

The Manson coffin relation of the steel in this research (SS400 and SN400) can be obtained through the experimental results of the specimens subjected to constant amplitude loadings. Equation 4 and Figure 8 show the Manson-Coffin relation of these specimens.

$$\Delta\varepsilon_P = 0.6 \cdot N_f^{-0.57} \qquad (4)$$

The Miner's rule is often used in the evaluation of the accumulated damage of steel under various amplitude cyclic loadings, shown in Equation 5. The material fractures when D equals to 1.

$$D = \sum (n_i / N_i) \qquad (5)$$

where n_i is the number of loading cycles under a certain loading amplitude A, and N_i is the number of loading cycles till fracture if the material is subject to the constant amplitude A cyclic loading.

Using the M-M method, the accumulated damage of all specimens was calculated. The results are shown in Figure 9. Here, the rainflow counting algorithm (Endo et al 1974) was introduced into the study to count the number of loading cycles.

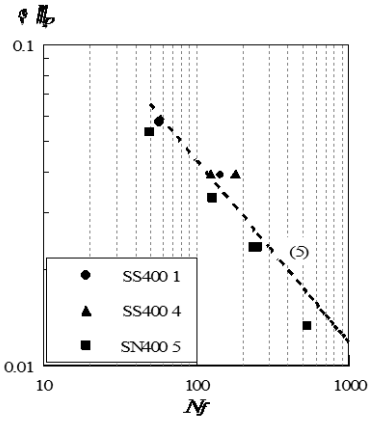

Figure 8 Manson-Coffin relation obtained from the specimens subjected to Con. Amp. loadings

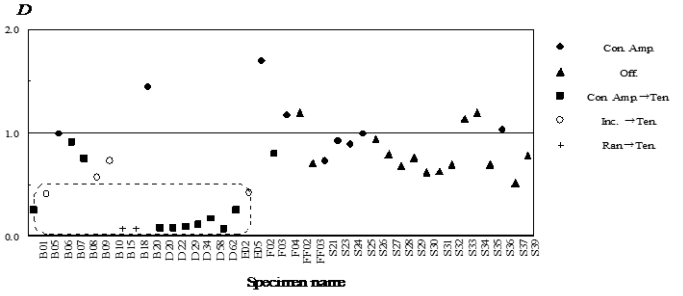

Figure 9 Evaluation of accumulative damage through the Miner's rule

Using the M-M method, the accumulated damage of all specimens was calculated. The results are shown in Figure 9. Here, the rainflow counting algorithm (Endo et al 1974) was introduced into the study to count the number of loading cycles. It is observed that the M-M method tends to give too small evaluation to those specimens that fractured within fewer loading cycles (especially the specimens in the dash square). According to the characteristics of seismic effects and the steel structures, structural steel is very likely to be subjected to the cyclic loadings with relatively large amplitudes, and fractures after several loading cycles.

5. COMPARISON OF THE EVALUATION METHODS

In this section, the evaluation method explained in Section 3 which focuses on the skeleton curve is compared to the evaluation method based on the Manson-Coffin equation and Miner's Rule in Section 4. As the error in the skeleton method is expressed by the accumulated plastic strain, and the error in the method based on the Mason-Coffin relation and Minor's Rule is expressed as the accumulated damage, these two cannot be compared directly. Therefore, in this research, in order to do the comparison, the errors was converted in to a same index—the number of loading cycles under a certain amplitude. The plastic strain amplitude of 2% was chose in this study.

First, in the skeleton evaluation method, the experimental error ${}_{err}\eta_T$ of cumulative plastic strain ratio can be obtained from equation 4. Then ${}_{err}\eta_T \cdot \varepsilon_y$ is the cumulative plastic strain error, where ε_y is the yield strain. Consequently the error in form of the number of loading cycles with plastic amplitude of 2% can be expressed as follow:

$$ {}_{err}N_{skl} = {}_{err}\eta_T \cdot \varepsilon_y / (2 \cdot 0.02) \qquad (6) $$

On the other hand, the error ${}_{err}N_{mcm}$ for the evaluation method based on the Mason-Coffin relation and Miner's Rule was obtained through the following steps: The error of the accumulated damage can be obtained through Equation 5. This value times the number of loading cycles that the specimen would fracture under the constant amplitude loading of 2% is the ${}_{err}N_{mcm}$.

The comparison of these two evaluation methods is illustrated in Figure 10. The errors of the skeleton method are plotted on Y-axis and those of the M-M method are plotted on X-axis. It is obvious that the error level of the skeleton method is smaller than that of the other's. Moreover, the M-M method tends to give smaller evaluation than the real value, while the skeleton method appears to have symmetric errors.

The M-M method is valid from the fatigue region to the low cycle fatigue region, while the skeleton method can only

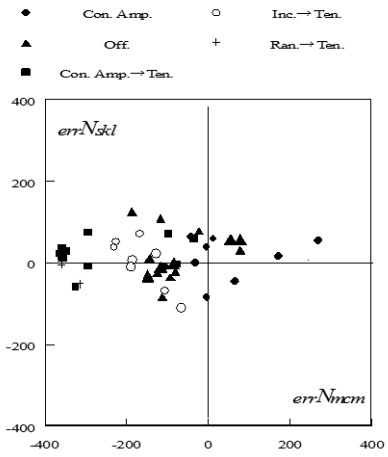

Figure 10 Comparison of two evaluation methods

be used in the low cycle fatigue region since the condition of using this method is the plastification of the material. However, the advantage of the skeleton method is its accuracy when evaluating the plastic deformation capacity of the steel subjected to relatively large amplitude loadings, which is close to the seismic effects.

6. CONCLUSIONS

In order to evaluate the plastic strain capacity of structural steel under various axial strain histories till ductile fracture, a series of element specimens made of SS400 and SN400 steel were tested under diverse cyclic axial strain loadings. The deformation capacity of the structural steel under cyclic axial loading till fracture was evaluated by studying the experimental strain capacity of the skeleton curve and the Bauschinger part. The error range of this method was proved smaller than that of the Miner's rules.

Abstract: This paper describes elasto-plastic behavior of RHS columns under bi-axial bending moments. First, the monotonic loading test of RHS columns by a simple beam-style without an axial force was conducted in order to obtain the strength, stiffness, and deteriorate behaviors. Secondly, shear stress distribution in RHS columns with a bi-axial bending moment was expressed based on the proposed equations from previous studies which have only considered mono-axial bending moments. From these examinations, the fundamental performance in RHS columns affected by both a bi-axial bending moment and the axial force is clarified.

1. INTRODUCTION

RHS columns are usually used in steel buildings in Japan because it has no distinction between its strong axis and its weak axis. Because this feature and its closed section undergo, RHS columns hardly twist. Under earthquake motions, the structures receive three-dimensional forces and the columns experience not only an axial force but also a bi-axial bending moment. A lot of studies of RHS columns under mono-axial bending moments have been conducted, from the elastic region to the elasto-plastic region. Viewing previous studies, it has been pointed out that strength under bi-axial bending moments decreases faster than under mono-axial bending moments. However, there are very few of these studies, and enough researches were not done. Also, very few studies about the deterioration region of RHS columns with local buckling, therefore, how RHS columns under bi-axial bending moment deteriorate, compared to under mono-axial bending moments, is unclear.

In order to clarify the elasto-plastic behavior of RHS columns under bi-axial bending moment, experiment on RHS columns were conducted and evaluations of stress were made. First, the strength, stiffness, and deteriorate behavior under monotonic loading without the axial force were obtained by the simple beam-style test. Secondly, shear stress distribution in RHS columns considering bi-axial bending moment was expressed based on the proposed equations from previous studies. From these examinations, the fundamental performance in RHS columns, affected by both bi-axial bending moments and an axial force is clarified.

2. EXPERIMENT PROCEDURE

2.1 Specimen and Setup

Specimens are four type of simple-beam as shown in Figure 1. All specimen consists of RHS column; □-200×8 (BCR295) and a steel plate; PL28 (SN400). Parameter is angle between loading direction and RHS column surface α; 0[deg], 15[deg], 30[deg], 45[deg]. Each specimen has made with different angle.

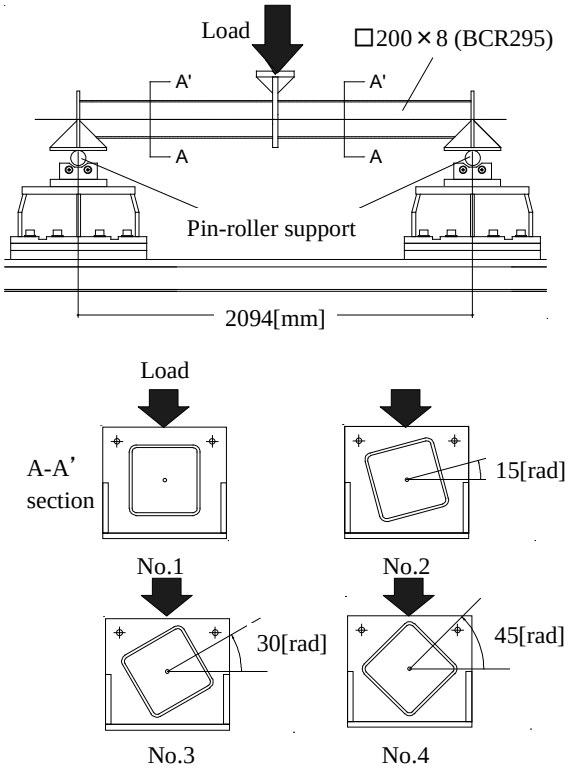

Figure 1 Specimen and Setup

Setup is also shows in Figure 1. Both edges of specimen support by pin-roller systems. Monotonic Load added at the center of specimen by knife-edge which is attached to the testing machine.

Table 1 shows results of coupon test by JIS-1A type test piece.

Table 1 Steel Characteristics

σ_y [N/mm^2]	σ_u [N/mm^2]	yield ratio [%]
374	443	84

2.2 Measurement

Rotation angles and bending moments around the center of each specimen calculated by measured values of displacement transducers as shown in Figure 2. Displacement transducers are settled at both sides above specimen, each measured value is average of displacement at both sides. The equations show below based on displacements as shown in Figure 2 and 3.

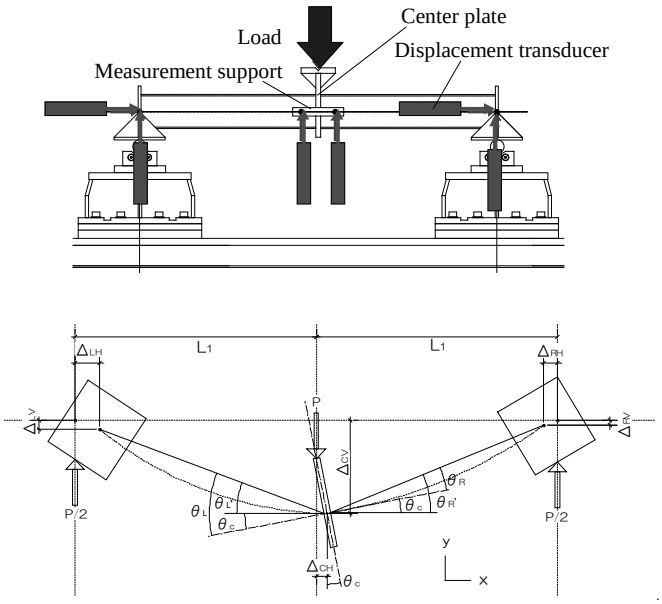

Figure 2 Measurement system

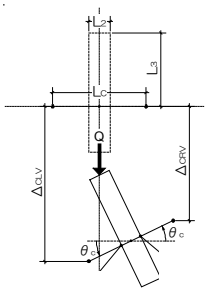

Figure 3 Measurement system (close-up)

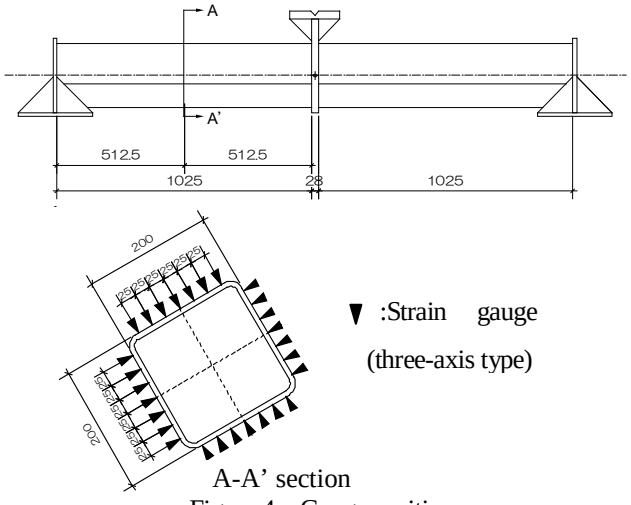
$$\theta_C = \tan^{-1}\frac{\Delta_{CLv}-\Delta_{CRv}}{\sqrt{{L_C}^2-\left(\Delta_{CLv}-\Delta_{CRv}\right)^2}}$$

$$\Delta_{Cv}=\frac{\Delta_{CLv}+\Delta_{CRv}}{2} \qquad \Delta_{Ch}=-L_3\cdot\sin\theta_c$$

$$\theta_L{}'=\tan^{-1}\frac{-\Delta_{Cv}+\Delta_{Lv}+\frac{1}{2}L_2\cdot\sin\theta_c}{L_1+\Delta_{Ch}-\Delta_{Lh}-\frac{1}{2}L_2\cdot\cos\theta_c} \qquad \theta_L=\theta_L{}'-\theta_C$$



$$\theta_R{}'=\tan^{-1}\frac{\Delta_{Cv}-\Delta_{Rv}-\frac{1}{2}L_2\cdot\sin\theta_c}{L_1-\Delta_{Ch}+\Delta_{Rh}-\frac{1}{2}L_2\cdot\cos\theta_c} \qquad \theta_R=\theta_R{}'-\theta_C$$

$$M_L=\frac{1}{2}P\left(L_1+\Delta_{Ch}-\frac{1}{2}L_2\cdot\cos\theta_c\right)$$

$$M_R=-\frac{1}{2}P\left(L_1-\Delta_{Ch}-\frac{1}{2}L_2\cdot\cos\theta_c\right)$$

Where, θ_C is rotation angle of the center plate, Δ_{Cv} is vertical displacement in the center, Δ_{Ch} is horizontal displacement in the center, Δ_{CLv} is vertical displacement in the center (left side of the center plate), Δ_{CRv} is vertical displacement in the center (right side of the center plate), L_3 is height between the top of the center plate and measurement support, $\theta_L{}'$ is angle between RHS column and measurement support (left side of the center plate), θ_L is rotation angle of RHS column (left side of the center plate), $\theta_R{}'$ is angle between RHS column and measurement support (right side of the center plate), θ_R is rotation angle of RHS column (right side of the center plate), L_2 is thickness of the center plate, L_1 is length of the RHS column.

In order to measure the distinction of shear stress of RHS member, strain gauges (three-axis type) glued at the section shown in Figure 4.

A-A' section

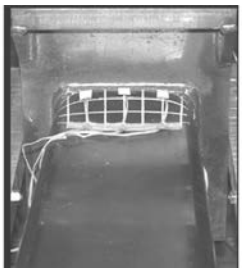


Figure 4 Gauge position

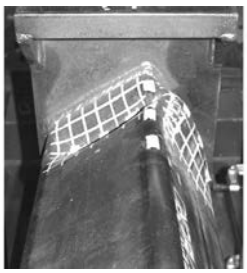
3. EXPRIMENTAL RESULTS

Figure 5 shows the local buckling after the loading ended. Table 2 shows bending moments and rotation angles at the half span which occurred local buckling in each specimen. Figure 6 is bending moment versus rotation angle relationship of each specimen and these four relationships gathered and shows in Figure 7.

The bending moment at the time which local buckling occurred slightly decrease accompanying that the angle between loading direction and RHS surface increased step by step from 0[deg] to 45[deg]. Whereas, the rotation angle at the same time increased. This difference in bending moments and rotation angle is considered as the effect that each specimen has different from bending stress distribution. It is based that elastic buckling of a plate element is affected by stress distribution. The bending stress distribution of each specimen under bi-axial bending moment shows in Figure 8. Therefore, this method is applied to the buckling at elasto-plastic region.



The maximum values of bending moment slightly decrease accompanied byθload increased step by step from 0[deg] to 45[deg]. Whereas, the rotation angle at the time of the maximum values of bending moment occurred is increased. As shown in Figure 7, bending moment versus rotation angle relationship before it reached the maximum values of bending moment in each specimen is observed almost same hysteresis.

4. SHEAR STRESS DISTRIBUTION

The shear flow theory has proposed as shear stress distribution in the cross section consists of some thin plates. In this theory, shear stress in the direction for thickness of plate is supposed zero, therefore, shear stress can be expressed as shown below;

$$\tau = \frac{Q}{I_x t_1} \cdot \int_0^s ytds$$

For example, shear stress distributions of opened section and closed symmetrical section based on the shear flow theory are shown in Figure 9. Based on the theory, all force in the section balances if shear force loads at the end of the opened section or the center of the closed symmetry section. However, the cross section of RHS member under bi-axial bending is closed nonsymmetrical. In case of closed nonsymmetrical section, all force in the section doesn't balance if shear force loads the center of the section and equations have not proposed.

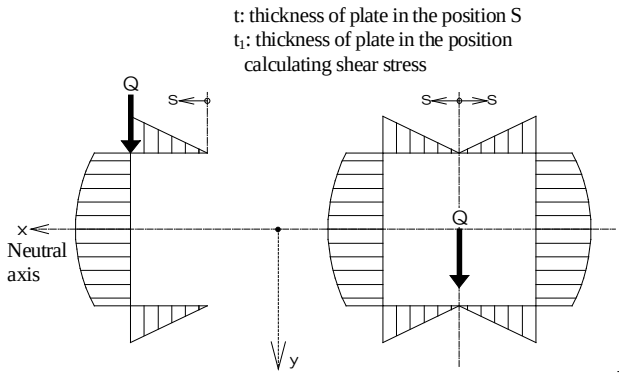

Figure 9 Shear stress distribution of symmetrical section

In this study, the equations which calculate shear stress distribution present based on the shear flow theory to closed nonsymmetrical section as shown below equation (1)~(4). Figure 10 shows the diagram to obtain the shear stress distribution. As shown this figure, cross section is replaced to wires and all corners are neglected roundness.

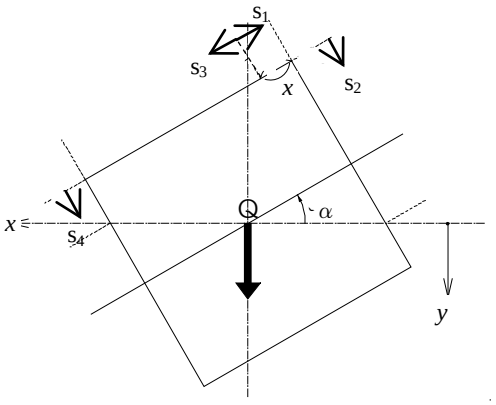

Figure 10 The diagram to obtain shear stress distribution

Where;

$$x = \frac{d(\cos\alpha + \sin\alpha) - d\sqrt{1 + 2\sin^2\alpha}}{2\sin\alpha}$$

In case of $0 \le s_1 \le x$,

$$\tau_1 = \frac{Q}{I_x}\left[\left\{\frac{\sqrt{2}}{2}d\sin(45° + \alpha) - x\sin\alpha\right\}s_1 + \frac{1}{2}s_1^2\sin\alpha\right] \quad (1)$$

In case of $0 \le s_2 \le \left\{\sqrt{2}d\sin(45° + \alpha)\right\}/2\cos\alpha$

$$\tau_2 = \frac{Q}{I_x}\left\{\frac{\sqrt{2}}{2}dx\sin(45° + \alpha) - \frac{1}{2}x^2\sin\alpha + \frac{\sqrt{2}}{2}ds_2\sin(45° + \alpha) - \frac{1}{2}s_2^2\cos\alpha\right\} \quad (2)$$

In case of $0 \le s_3 \le d - x$

$$\tau_3 = \frac{Q}{I_x}\left[\left\{\frac{\sqrt{2}}{2}d\sin(45° + \alpha) - x\sin\alpha\right\}s_3 - \frac{1}{2}s_3^2\sin\alpha\right] \quad (3)$$

In case of $0 \le s_4 \le \left\{\sqrt{2}d\sin(45° - \alpha)\right\}/2\cos\alpha$

$$\tau_4 = \frac{Q}{I_x}\left\{-\frac{1}{2}dx(\sin\alpha + \cos\alpha) + \frac{1}{2}x^2\sin\alpha + \frac{\sqrt{2}}{2}ds_4\sin(45° - \alpha) - \frac{1}{2}s_4^2\cos\alpha\right\} \quad (4)$$

Figure 11 shows the comparisons of the shear stress distributions between obtained by equation (1)~(4) and obtained by experiment results at the time that the maximum values of bending moment occurred. As shown in this figure, equations presented this study and experiment results almost correspond.

5. SUMMARY

In this study, the fundamental consideration is conducted about elasto-plastic behavior of RHS column under bi-axial bending.

The important findings are follows;

1. The strength of the RHS-column under bi-axial bending moment without any axial force slightly decreased than under mono-axial bending moment.

2. M- θ relationships before RHS-column yielded are similar in all specimens.

3. The hysterisys after local buckling occurred changes as the angle α increases.

4. The formulas used to calculate shear stress distribution in a closed nonsymmetrical section, such as the RHS-column under the bi-axial bending moment, were shown to be true.

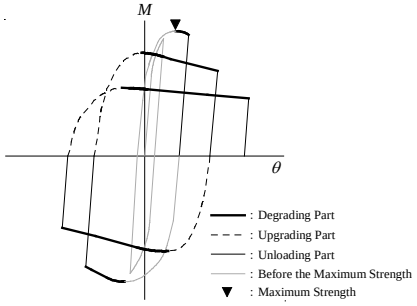
Abstract: In Japan, RHS (Rectangular Hollow Section)-columns are generally used in steel building structures. In the evaluation of earthquake-resistant limit-state capacity of building structures, it is important to clarify the ultimate behavior of columns. In this paper, the post-buckling and deterioration behavior of RHS-columns under cyclic loadings are investigated based on the database built from previous cyclic loading test results.

1. INTRODUCTION



In Japan, RHS-columns are generally used in steel building structures. In the evaluation of earthquake-resistant limit-state capacity of building structures, it is important to clarify the ultimate behavior of columns. According to the previous studies, under cyclic loading, before the steel member reaches its maximum strength, the hysteresis loop can be decomposed into the skeleton part, Bauschinger part and the elastic unloading part. Moreover, it is also known that the skeleton part corresponds to the load-deformation relation of steel member under monotonic loading and the Bauschinger part can be modeled through the bilinear model [1]. On the other hand, the post-buckling and deterioration behavior of RHS-columns were studied analytically under monotonic loading [2]. Nevertheless, although many experiments focusing on the deterioration behavior of RHS-columns under cyclic loadings have been carried out, the general restoring force characteristics including the deterioration behavior of RHS-columns have not been modelled yet. In this paper, the post-buckling and deterioration behavior of RHS-columns under cyclic loadings are investigated based on the database built from previous cyclic loading test results.

2. DECOMPOSITION OF HYSTERESIS LOOP

Before the steel member reaches its maximum strength, the load-deformation relation under cyclic loading (hysteresis loop) can be decomposed into three parts: skeleton curve, Bauschinger part and the elastic unloading part (Figure 1(a)). The load-deformation relation of both positive and negative loading directions in the post-buckling and deterioration range can also be divided into three parts, which are defined as degrading part, upgrading part and

(a) Until the Maximum Strength

(b) After the Maximum Strength

Figure 1 Restoring Force Characteristics of Steel Columns under Cyclic Loading

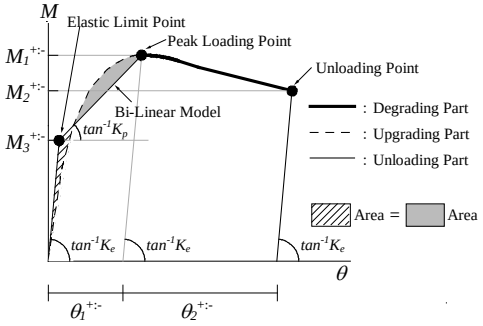


Figure 2 Load-Deformation Relations of Half Cycles

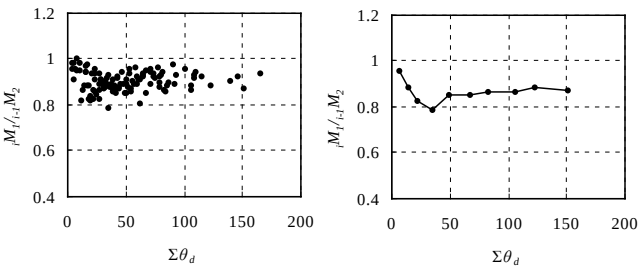
unloading part (Figure 1(b)). The degrading part can be assumed as skeleton part, and the upgrading part as Bauschinger part. A half cycle of the hysteresis loop in the deterioration range is shown in Figure 2. The degrading part is from the peak loading point to the unloading point, while the unloading part is from the unloading point to the point that the load reaches 0. The segment left is the upgrading part. Furthermore, the upgrading part is simplified to a bilinear model which dissipates equivalent amount of plastic energy as the original one does. Here, $M_1^{+,-}$ is the moment of peak loading point, $M_2^{+,-}$ and $M_3^{+,-}$ are the moment of unloading point and the elastic limit point respectively. $\theta_1^{+,-}$ is the maximum deformation of upgrading part, and $\theta_2^{+,-}$ is the deformation of degrading part. K_e and K_p are the elastic and inelastic stiffness. Superscript + and – denote the positive and negative loading domains.

3. INVESTIGATION OF CYCLIC DETERIORATION BEHAVIOR BASED ON THE DATABASE

3.1 Extraction of the Parameters

In order to clarify the post-bucking and deterioration behavior of RHS-columns under cyclic loadings, the database is built based on previous cyclic loading test results.

The load-deformation relations of previous test results are normalized to the dimensionless moment-rotation relations (M/M_p-θ/θ_p relations) so that $M_1^{+,-}$, $\theta_1^{+,-}$, $M_2^{+,-}$, $\theta_2^{+,-}$, and $M_3^{+,-}$ can be obtained. These parameters ($M_1^{+,-}$, $\theta_1^{+,-}$, $M_2^{+,-}$, $\theta_2^{+,-}$, and $M_3^{+,-}$) are the characteristics of the hysteresis loops in the deterioration range, as shown in Figure 1, where M_p is the full-plastic moment of each specimen, and θ_p is the elastic rotation corresponding to M_p. However, in case of the half cycles where the specimens were unloaded within the upgrading part, the data of these half cycles are eliminated from the database. As for the elastic stiffness K_e, the calculated value is used ($K_e = M_p/\theta_p$). If the experimental elastic stiffness of the specimen shows bad correspondence to the calculated value, the unloading stiffness of the first cycle is used as elastic stiffness.



3.2 Strength Restoration Ratio

In both positive and negative loading directions, it is possible to obtain the ratio of the peak load of arbitrary cycle ($_iM_1^+$, $_iM_1^-$) to the load of unloading point in the previous cycle ($_{i-1}M_2^+$, $_{i-1}M_2^-$) $_iM_1^+/_{i-1}M_2^+$ and $_iM_1^-/_{i-1}M_2^-$, which are defined as the strength restoration ratio $_iM_1/_{i-1}M_2$, where the subscript i is the number of cycles. Furthermore, the cumulative plastic deformation $\Sigma\theta_d$ ($\Sigma\theta_d = \Sigma\theta_d^+ + \Sigma|\theta_d^-|$) is obtained by eliminating the elastic deformation from the cumulative deformation after reaching the maximum strength. The relations between the strength restoration ratios $_iM_1/_{i-1}M_2$ and the cumulative plastic deformation $\Sigma\theta_d$ from every half cycle of each specimen are shown in Figure 3. The results of one specimen of each axial force ratio are also exemplified in Figure 3. The strength restoration ratio is almost a constant despite the increase of cumulative plastic deformation after the maximum strength. This trend has been seen in all specimens. Consequently, it is reasonable to study the relation between the average values of strength restoration ratio and the multiplicative inverse of normalized equivalent width to thickness ratio $1/\alpha_e$, which is shown in Figure 4. Here, the normalized equivalent width to thickness ratio α_e, which governs the post-buckling and deterioration behavior of RHS members, is obtained by equation (1) [2]. The strength restoration ratio is almost a constant 0.9.

3.3 Maximum Deformation of Upgrading Part

The maximum deformations of the upgrading parts that correspond to Bauschinger parts, $\theta_1^+$and $|\theta_1^-|$, are expressed by θ_1. The cumulative plastic deformation of skeleton part is denoted by $\Sigma|\theta_s|$. The cumulative plastic deformation of the degrading part that corresponds to the skeleton part is denoted by $\Sigma|\theta_2|$. The relation between θ_1 and $\Sigma|\theta_s|+\Sigma|\theta_2|$ of each specimen is shown in Figure 5. The results of one specimen of each axial force ratio are also exemplified in Figure 5. The maximum deformation of upgrading part becomes smaller as axial force ratio increase.

3.4 Elastic Limit Point of Upgrading Part

The ratio of the load of elastic limit point M_3^+, M_3^- and the load of peak loading point M_1^+, M_1^- in each half cycle, M_3^+/M_1^+ and M_3^-/M_1^- are denoted by M_3/M_1. The relations between the ratio M_3/M_1 of each specimen from each half cycle and the cumulative plastic deformation $\Sigma\theta_d$ after reaching the maximum strength are shown in Figure 6. The results of one specimen of each axial force ratio are also exemplified in Figure 6. The ratio M_3/M_1 is approximately constant in spite of the increase of the cumulative plastic deformation after the peak loading point. This trend has been seen in all specimens. Therefore, the average M_3/M_1 of each specimen is calculated. The relation between average M_3/M_1 of each specimen and $1/\alpha_e$ is shown in Figure 7. M_3/M_1 and $1/\alpha_e$ has an approximately linear relation.

3.5 Envelope Curve of Deterioration Range

Based on the observation from section 3.2-3.4, the bilinear model of the upgrading part can be modeled by formulating the strength restoration ratio, the maximum deformation of upgrading part, and elastic limit point. Therefore, the restoring force characteristics in the deterioration range under cyclic loading can be modeled by clarifying the slope of load degrading part. The envelope curve of the steel member in the deterioration range is obtained by connecting hysteresis loops in each cycle of positive or negative loading direction sequentially. Empirical rule shows that the envelope curve corresponds to the load-deformation relation under monotonic loading [14]. The slope of the degrading part is denoted by K_d, and the slope of the segment between the peak loading point of a certain cycle and the unloading point of the previous cycle is denoted by K_d', as shown in Figure 8. The relation of K_d-$\Sigma\theta_d$ is shown in Figure 9, the relation of K_d'-$\Sigma\theta_d$ is also shown in Figure 9. Notice here, the specimens with their calculated elastic stiffness different from the experimental results were eliminated from the database. It is noted that K_d almost corresponds to K_d'. Therefore, the envelope curve is approximately continuous.

4. CONCLUSIONS

Post-buckling and deterioration behavior of the RHS-columns under cyclic loading was investigated based on the database built based on previous cyclic loading test results. In this paper, the hysteresis loop of deterioration range is decomposed into three parts: the degrading part that corresponds to skeleton part, the upgrading part that corresponds to Bauschinger part and the elastic unloading part. Main conclusions can be drawn as follows:

1) The strength restoration ratio is almost constant despite the increase of the cumulative plastic deformation after reaching the maximum strength. Moreover, the relation between the average strength restoration ratio of each specimen and the multiplicative inverse of normalized equivalent width to thickness ratio shows that the average of strength restoration ratio of each specimen is approximate 0.9.

2) Although within the axial force ratio range of 0~0.1, the maximum deformation of upgrading part increases linearly

with the increase of $\Sigma|\theta_s| + \Sigma|\theta_2|$. In case of axial force ratio more than 0.14, the maximum deformation of upgrading part is almost constant. In summary, the maximum deformation of upgrading part becomes smaller as axial force ratio increase.

3) The ratio M_3/M_1 is approximately constant in spite of the changing cumulative plastic deformation after reaching the maximum strength. The relation between the average M_3/M_1 in each specimen and $1/\alpha_e$ shows an approximately liner relation.

4) It is noted that K_d almost corresponds to K_d'. Therefore, the envelope curve is approximately continuous.

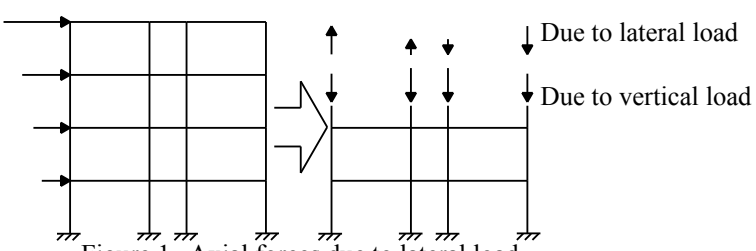
Abstract: The elastic buckling strength of columns in steel moment resisting frames had been investigated extensively for regular vertical loads. However, in Japan, where seismic loads are significant, the axial forces corresponding to the overturning moment due to seismic loads should be considered in design. Under such load conditions, a column that is subjected to a larger compressive force can be supported laterally by other columns, which sustain moderate or tensile axial forces. This present paper proposes a method by which to estimate the elastic buckling strength of columns in moment resisting frames under anti-symmetric vertical loads on beam-to-column nodes. The accuracy of estimation is confirmed through comparison to the results of obtained by geometrical non-linear analyses or eigenvalue analyses for portal frames.

1. INTRODUCTION

In the design of a steel structural building, it is necessary to consider the flexural buckling of the column. The calculation method used to determine the buckling length of the column in a regular moment frame in which the lateral displacement is not restrained is given in, for example, the "Design Standard for Steel Structures" (AIJ, 2002) etc. Moreover, Mitani et al. (2002) and Morino et al. (1993) reported the accuracy of applying the calculation method to irregular frames. In addition, an improved method was proposed by Tsuda (2001, 2003) and Shibata (2003). The above studies investigated vertical loads. However, in Japan, where seismic loads are predominant, it is also necessary to consider the column-buckling by the compressive force generated by the overturning moment due to the horizontal load (Figure 1). In this case, the column that receives a larger compressive force is laterally restrained by other columns which receive smaller compressive or tensile forces. Therefore, the buckling length is thought to be shorter than the case in which vertical loads act on the column.

The present paper proposes formulas by which to estimate the elastic buckling strength of columns under arbitrary boundary conditions. The proposed formulas are explicit expressions in which numerical analyses are not necessary. The calculation results confirm the results of the eigenvalue analysis and the increment analysis of the equilibrium path for the entire frame, and the error margins are small. The proposed formulas assume anti-symmetry vertical loads on the beam-to-column nodes (Figure 2). This load assumes an axial force distribution in the column due to the horizontal loads.



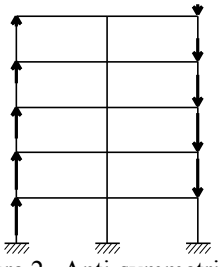


Figure 1. Axial forces due to lateral load

Figure 2. Anti-symmetric load

2. PROPOSED FORMULA

2.1 Previous Study

Inoue and Tada (2007) proposed simple formulas of elastic buckling strength of columns in a moment frame by considering the lateral restraint of adjacent columns. They first modeled the column as shown in Figure 3 and then divided the model into two models according to the buckling mode, as shown in Figures 4(a) and 4(b). Each model was applied according to the magnitude of rigidity of the horizontal spring, K_H. The respective buckling strengths were formulated as follows:

Mode 1 : $$ {}_1P_{cr} = \frac{\pi^2 EI_c}{h^2} \quad (1) $$

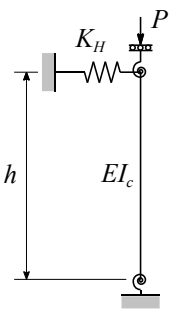
Mode 2 : $$ {}_2P_{cr} = K_H h \quad (2) $$

In the present study, two buckling modes are assumed also as shown by Inoue and Tada (2007). The mode in which the capital does not sway, as shown in Figure 5(a), is referred to as the *member-buckling* mode, and the mode in which the capital sways laterally, as shown in Figure 5(b), is referred to as the *sway buckling* mode. In the following sections, the mechanical model shown in Figure 3 will be used.

2.2 Member-buckling mode

The formula for elastic buckling strength for an arbitrary supported column corresponding to the *member-buckling* mode will be derived in this section. As shown in Figure 5(a), the horizontal spring at the capital elongates only slightly in this mode. The postulated conditions are illustrated in Figure 6(a), and they are as follows. The lateral displacement of the capital is ignored. The deflection of the column is approximated by two cubic functions for the upper part u_2 and the lower part u_1, respectively. The boundary conditions are expressed by the following nine equations:

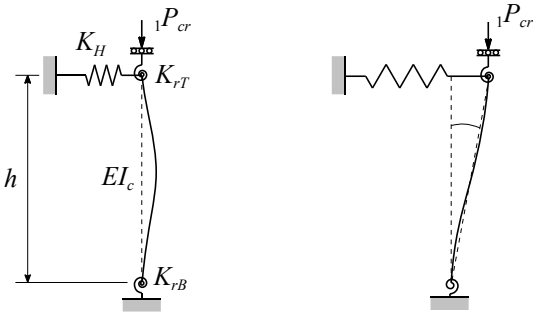
$$ u_1(0) = 0, \quad \left.\frac{du_1}{dz}\right|_{z=0} = \theta_B, \quad u_1\left(\frac{h}{2}\right) = u_2\left(\frac{h}{2}\right) $$



$$ u_2(h) = 0, \quad \left.\frac{du_2}{dz}\right|_{z=h} = -\theta_T, \quad \left.\frac{du_1}{dz}\right|_{z=\frac{h}{2}} = \left.\frac{du_2}{dz}\right|_{z=\frac{h}{2}} $$

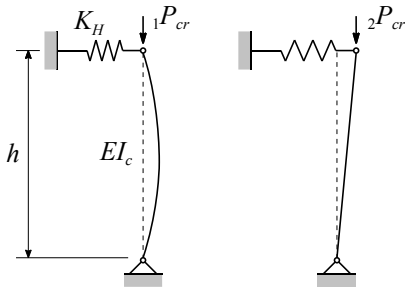
$$ \left.\frac{d^2u_1}{dz^2}\right|_{z=0} = \frac{K_{rB}\theta_B}{EI_c} = k_{rB}\theta_B\frac{1}{h} $$

$$ \left.\frac{d^2u_2}{dz^2}\right|_{z=h} = \frac{K_{rT}\theta_T}{EI_c} = k_{rT}\theta_T\frac{1}{h} $$



$$ -EI_c\left.\frac{d^3u_1}{dz^3}\right|_{z=0} = -EI_c\left.\frac{d^3u_2}{dz^3}\right|_{z=h} \quad (3a \sim i) $$

Based on these boundary conditions, deflections u_1 and u_2 are derived as follows:



E	: Young's Modulus
I_c	: Geometric moment of inertia
K_H	: Horizontal spring stiffness
h	: Length of column
K_{rT}, K_{rB}	: Rotational spring stiffness
${}_1P_{cr}$, ${}_2P_{cr}$	: Buckling strength
M_T, M_B	: Reaction moment at ends
Q_T, Q_B	: Reaction force (shear) at ends
θ_T, θ_B	: Nodal rotation at ends
R	: Column out-of-plumbness
u, z	: Axes of coordinate

Figure 3. Column model

Figure 5. The two buckling modes

(a) Mode 1 (b) Mode 2

Figure 4. Simplified model and buckling modes

(a) *Member-buckling* (b) *Sway buckling*

Figure 6. Boundary conditions

$$u_1 = \left\{ -\frac{\xi}{3}\frac{z^3}{h^2} + \frac{\mu k_{rT}\eta}{2}\frac{z^2}{h} + \eta z \right\}\theta_T \quad (4)$$

$$u_2 = \left\{ \frac{\xi}{3}\frac{(z-h)^3}{h^2} + \frac{k_{rT}}{2}\frac{(z-h)^2}{h} - (z-h)z \right\}\theta_T \quad (5)$$

Here,

$$\xi = \frac{2\{(\mu k_{rT}+3)(k_{rT}+3)-1\}}{\mu k_{rT}+4}, \quad \eta = \frac{\theta_B}{\theta_T} = \frac{k_{rT}+4}{\mu k_{rT}+4}$$

$$\mu = \frac{K_{rB}}{K_{rT}}, \quad k_{rT} = \frac{K_{rT}}{EI_c/h}, \quad k_{rB} = \frac{K_{rB}}{EI_c/h} \quad (6a \sim e)$$

Then, virtual displacement Δw is assumed at the top of the column and Δw can be approximated by following equation:

$$\Delta w = \int_0^h \theta \Delta\theta dz = \int_0^h \frac{du}{dz}\frac{d\Delta u}{dz} dz \quad (7)$$

Hence, external virtual work ΔW_{ex} can be expressed as follows:

$$\Delta W_{ex} = {}_1P_{cr}\Delta w = {}_1P_{cr}\left(\int_0^{h/2} \frac{du_1}{dz}\frac{d\Delta u_1}{dz} dz + \int_{h/2}^h \frac{du_2}{dz}\frac{d\Delta u_2}{dz} dz \right) \quad (8)$$

In the above equation, Δu_1 and Δu_2 are obtained by replacing θ_T with $\Delta\theta_T$ in Equations 4 and 5, where $\Delta\theta_T$ is the virtual increment of the nodal rotation angle at the top of the column. On the other hand, internal virtual work ΔW_{in} can be expressed as follows:

$$\Delta W_{in} = \int_0^h M\Delta\phi dz + (K_{rT}\theta_T)\Delta\theta_T + (K_{rB}\theta_B)\Delta\theta_B = EI_c\int_0^{h/2} \frac{d^2u_1}{dz^2}\frac{d^2\Delta u_1}{dz^2} dz + EI_c\int_{h/2}^h \frac{d^2u_2}{dz^2}\frac{d^2\Delta u_2}{dz^2} dz + K_{rT}\theta_T\Delta\theta_T + K_{rB}\theta_B\Delta\theta_B \quad (9)$$

where, M is the sectional moment, ϕ is the curvature, and $\Delta\theta_B$ is a virtual increment of the nodal rotation angle at the bottom of the column. By equating external and internal virtual work, the buckling strength for the *member-buckling* mode can be derived as follows:

$${}_1P_{cr} = \frac{\Delta W_{in}}{\Delta w} \quad (10)$$

By combining Equations 4 trough 10, the general formula for the *member-buckling* strength under an arbitrary boundary condition can be derived as Equation 22 in Table 1. Moreover, the formulas under specific conditions are shown in Equations 18, 20, and 24.

2.2 Sway buckling

Here, the induction process of the *sway buckling* strength formula for a column of arbitrary boundary conditions is shown. As shown in Figure 5(b), the *sway buckling* mode is a phenomenon whereby the topside horizontal spring expands and becomes unstable before *member-buckling* occurs. The boundary condition is shown in Figure 6(b). The deflection curve is approximated as a cubic curve u. The boundary conditions are expressed by the following five equations:

$$u(0) = 0, \quad \left.\frac{du}{dz}\right|_{z=0} = \theta_B, \quad \left.\frac{du}{dz}\right|_{z=h} = \theta_T$$

$$\left.\frac{d^2u}{dz^2}\right|_{z=0} = \frac{K_{rB}\theta_B}{EI_c} = k_{rB}\theta_B\frac{1}{h}$$

$$\left.\frac{d^2u}{dz^2}\right|_{z=h} = \frac{-K_{rT}\theta_T}{EI_c} = -k_{rT}\theta_T\frac{1}{h} \quad (11a \sim e)$$

Based on these boundary conditions, u is given as follows:

$$u = \left\{ -\frac{\xi}{3}\frac{z^3}{h^2} + \frac{\mu k_{rT}\eta}{2}\frac{z^2}{h} + \eta z \right\}\theta_T \quad (12)$$

where,

$$\xi = \frac{k_{rT} + \mu k_{rT} + \mu k_{rT}^2}{\mu k_{rT}+2}, \quad \eta = \frac{\theta_B}{\theta_T} = \frac{k_{rT}+2}{\mu k_{rT}+2} \quad (13a, b)$$

Then, in Figure 6(b), virtual displacement Δw is assumed at the top of the column. The virtual increment of external work ΔW_{ex} by Δw is given as follows:

$$\Delta W_{ex} = {}_2P_{cr}\Delta w = {}_2P_{cr}\int_0^h \frac{du}{dz}\frac{d\Delta u}{dz} dz \quad (14)$$

where, Δu is obtained by replacing θ_T with $\Delta\theta_T$ in Equation 12. On the other hand, the virtual increment of internal work ΔW_{in} becomes.

$$\Delta W_{in} = \int_0^h M\Delta\phi dz + (K_{rT}\theta_T)\Delta\theta_T + (K_{rB}\theta_B)\Delta\theta_B + (K_H u(h))\Delta u(h) = EI_c\int_0^h \frac{d^2u}{dz^2}\frac{d^2\Delta u}{dz^2} dz + K_{rT}\theta_T\Delta\theta_T + K_{rB}\theta_B\Delta\theta_B + K_H u(h)\Delta u(h) \quad (15)$$

Since the virtual increments of external work and internal work are equal, the *sway buckling* strength can be calculated as follows:

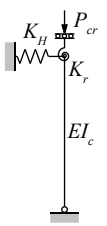
$$ {}_2P_{cr} = \frac{\Delta W_{in}}{\Delta w} \tag{16} $$

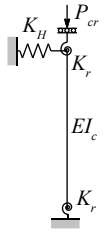
Based on Equations 12 through 16, the *sway buckling* strength formula for an arbitrary boundary conditions is given by Equation 23 in Table 1. Moreover, the formulas for specific conditions are given as Equation 19, 21, and 25. Here, k_H is defined as follows:

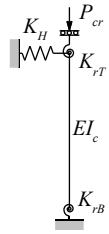
$$ k_H = \frac{K_H}{12EI_c/h^3} \tag{17} $$

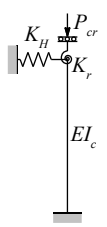
Table 2 shows the elastic buckling strength formula for an arbitrary boundary condition obtained using the buckling-slope-deflection method. The induction process of the equations are shown at the end of the present paper.

3. Application of the proposed formula to portal frames









This section compares the computer analysis and the proposed formula, shown in Table 1 obtained using portal frames having fixed column bases and verifies the validity the proposed formula. The proposed formula assumes that the frames receive an anti-symmetric load. However, the computer analysis and the proposed formula are also compared for other load conditions.

3.1 Calculation of spring stiffness

(1) Rotational springs

In order to calculate the buckling strength using the proposed formula, it is necessary to calculate the stiffness of each spring shown in Figure 5. Here, the calculation of the stiffness for portal frames is shown. First, the calculation method of the rotational spring stiffness is

Table 1. Proposed formulas

Support condition	Buckling mode	Proposed formula
Spr.-Pin 	*Member -buckling*	${}_1P_{cr} = \frac{3k_r^2 + 18k_r + 32}{11k_r^2 + 92k_r + 256} \cdot \frac{80EI_c}{h^2}$ (18)
	Sway buckling	${}_2P_{cr} = \frac{k_r(k_r+3) + 4k_H(k_r+3)^2}{2k_r^2 + 10k_r + 15} \cdot \frac{5EI_c}{h^2}$ (19)
SameSpr. 	*Member -buckling*	${}_1P_{cr} = \frac{k_r^2 + 10k_r + 16}{k_r^2 + 14k_r + 64} \cdot \frac{40EI_c}{h^2}$ (20)
	Sway buckling	${}_2P_{cr} = \frac{k_r(k_r+6) + k_H(k_r+6)^2}{k_r^2 + 10k_r + 30} \cdot \frac{10EI_c}{h^2}$ (21)
Arbitrary 	*Member -buckling*	${}_1P_{cr} = \frac{\xi^2 - 3\xi\mu k_{rT}\eta + 3\mu^2 k_{rT}^2\eta^2 + \xi^2 - 3\xi k_{rT} + 3k_{rT}^2 + 6k_{rT}(1+\mu\eta^2)}{3\xi^2 - 5\xi(3\mu k_{rT}+8)\eta + 20(\mu^2 k_{rT}^2 + 6\mu k_{rT} + 12)\eta^2 + 3\xi^2 - 5\xi(3k_{rT}+8) + 20(k_{rT}^2 + 6k_{rT} + 12)} \cdot \frac{80EI_c}{h^2}$ (22) $\xi = \frac{2\{(\mu k_{rT}+3)(k_{rT}+3) - 1\}}{\mu k_{rT} + 4} \qquad \eta = \frac{k_{rT}+4}{\mu k_{rT}+4}$
	Sway buckling	${}_2P_{cr} = \frac{4\xi^2 - 6\xi\mu k_{rT}\eta + 3\mu^2 k_{rT}^2\eta^2 + k_H\{-2\xi + 3(\mu k_{rT}+2)\eta\}^2 + 3k_{rT}(1+\mu\eta^2)}{6\xi^2 - 5\xi(3\mu k_{rT}+4)\eta + 10(\mu^2 k_{rT}^2 + 3\mu k_{rT} + 3)\eta^2} \cdot \frac{10EI_c}{h^2}$ (23) $\xi = \frac{k_{rT} + \mu k_{rT} + \mu k_{rT}^2}{\mu k_T + 2} \qquad \eta = \frac{k_{rT}+2}{\mu k_{rT}+2}$
Spr.-Fix. 	*Member -buckling*	${}_1P_{cr} = \frac{k_r^2 + 9k_r + 24}{k_r^2 + 11k_r + 44} \cdot \frac{40EI_c}{h^2}$ (24)
	Sway buckling	${}_2P_{cr} = \frac{(k_r+1)(k_r+4) + k_H(k_r+4)^2}{k_r^2 + 7k_r + 16} \cdot \frac{10EI_c}{h^2}$ (25)

$k_r = \frac{K_r}{EI_c/h}$ $\quad k_{rB} = \frac{K_{rB}}{EI_c/h}$ $\quad k_{rT} = \frac{K_{rT}}{EI_c/h}$ $\quad \mu = \frac{K_{rB}}{K_{rT}}$ $\quad k_H = \frac{K_H}{12EI_c/h^3}$

Table 2. *Member-buckling* strength formulas obtained by buckling-slope-deflection method

Support condition	*Member-buckling* strength formula	
Spring - Pin	$-k_r = s(1-c^2)$	(26)
Same spring on each end	$-k_r^2 = s\{s(1-c^2)+2k_r\}$	(27)
Arbitrary boundary condition	$-\mu k_{rT}^2 = s\{s(1-c^2)+k_{rT}(1+\mu)\}$	(28)
Spring - Fix	$-k_r = s$	(29)

$$s = \frac{\{\sin(\gamma)-\gamma\cos(\gamma)\}\gamma}{2\{1-\cos(\gamma)\}-\gamma\sin(\gamma)} \qquad c = \frac{\gamma-\sin(\gamma)}{\sin(\gamma)-\gamma\cos(\gamma)}$$

$$\gamma = \pi\sqrt{\frac{{}_{SD}P_{cr}}{N_E}} \qquad N_E = \frac{\pi^2 EI_c}{h^2} \qquad (30a \sim d)$$

${}_{SD}P_{cr}$: *Member-buckling* strength obtained by buckling-slope-dflection method

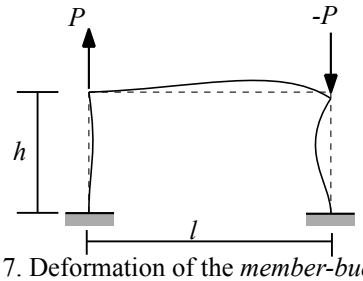


Figure 7. Deformation of the *member-buckling* mode

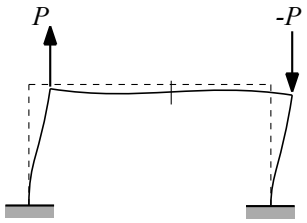

Figure 8. Deformation of the *sway buckling* mode

shown. The portal frame exhibits the deformation shown in Figure 7 when *member-buckling* occurs. In Figure 7, the point of contrary flexure of the beam is between the top of left-hand column and the center of the beam. Hence, the topside rotational spring stiffness is approximated by Equation 31. This is equivalent to the flexure rigidity of a simply supported beam, where the bending moment is received at one end of the beam.

$$K_r = \frac{3EI_b}{l} \qquad (31)$$

Moreover, the portal frame is assumed to exhibit the deformation shown in Figure 8 when *sway buckling* occurs. The topside rotational spring stiffness can be approximated by Equation 32, if it is assumed that the point of contrary flexure is at the center of the beam. This is equivalent to the flexure rigidity of a simply supported beam, where the anti-symmetric bending moment is received.

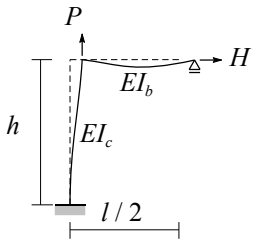
$$K_r = \frac{6EI_b}{l} \qquad (32)$$

In any case, the column base is fixed.

(2) Horizontal spring

It is necessary to calculate the horizontal spring stiffness of the top of the column only when the *sway buckling* strength is calculated. If a point of contrary flexure is assumed to exist in the center of the beam when *sway buckling* occurs (shown in Figure 8), then it is assumed that the L-shaped frame, which is to the left of the point of contrary flexure, restrains the right-hand column from moving laterally due to the buckling. Therefore, horizontal spring stiffness K_H is defined by the following equation:

$$K_H = K_{H0} + P / h \qquad (33)$$



The first term is the horizontal rigidity K_{H0} of the L-shaped frame that does not consider axial force, and the second term is the geometric stiffness provided by *P*-Δ *effect* through the tensile force. In order to verify the validity of Equation 33, computer analysis using tensile force P as the parameter is performed. This computer analysis is an elastic increment analysis that considers geometric non-linear using CLAP.f (Ogawa and Tada, 1994). The analysis frame is shown in Figure 9, in which each member is divided into 10 segments, and the cross sections are solid boxes.

Figure 10 shows the results of the computer analysis and the value of Equation 33. The vertical axis is the non-dimensional lateral rigidity against lateral force H, and the horizontal axis is tensile force P divided by N_E. The solid line is obtained by dividing Equation 33 by N_E, and the solid squares show the results of the computer analysis. The error margin is small although the value of Equation 33 becomes smaller than in the computer analysis.

3.2 Calculation of buckling strength and comparison

(1) Analysis frame and analytical conditions

The portal frame to which column bases are fixed is shown in Figure 11. In Figure 11, the load condition is an anti-symmetric load if $\lambda = 1$ and is a symmetric vertical load if $\lambda = -1$. In the proposed formula, since the right-hand column is modeled as shown in Figure 3, the rotational and horizontal spring stiffnesses are calculated by the method described in the previous section. In the computer analysis, an elastic increment analysis that considers geometrical non-linear using CLAP.f and eigenvalue analysis are performed. The analysis using CLAP.f is run until the vertical displacement of the top of

Young's Modulus	: E = 205,000 (N / mm^2)
Column Area	: A_c = 90,000 (mm^2)
Column Geometric Moment of Inertia	: I_c = 675,000,000 (mm^4)
Beam Area	: A_b = 102,600 (mm^2)
Beam Geometric Moment of Inertia	: I_b = 877,500,000 (mm^4)
Column Length	: h = 4 (m)
Beam Length	: l = 6 (m)
Flexure Rigidity Ratio	: (I_b / l) / (I_c / h) = 0.867
L-shape Frame Story Stiffness	: K_{H0} = 17,490,000 (N / m)

Figure 9. L-shaped frame (for verification of Equation 33)

h = 4 (m)
l = 8 (m)
E = 205,000 (N/mm^2)
$\alpha = l/h$ = 2.0
$\beta = I_b/I_c$ = 0.4,1.3
β/α = 0.2, 0.65

Figure 11. Analysis portal frame

the right-hand column becomes δ_z = - 400 (mm).

The cross section is designed such that the relative story displacement becomes 1/200 (rad) for lateral load (seismic load) Q (story shear force coefficient C_0 = 0.2), as established in the *Order for Enforcement of the Building Standard Act* (In Japanese), in elastic increment analysis that does not consider geometric non-linear. The long-term load (dead load and live load) is assumed to be a uniformly distributed load q = 50,000 (N/m) on the beam. Therefore, the seismic load for the section design is Q = 0.2 x 50,000 x 8 = 80,000 (N). The cross sections are solid boxes, and each member is divided into 10 segments.

When buckling analysis is performed, columns are inclined to 1/20,000 (rad) as an initial imperfection and are then modeled. The proportional load shown in Figure 11 is made to act after long-term load P_L is made to act. The long-term load P_L uses the symmetric load on the beam-to-column nodes calculated from uniformly distributed load q on the beam. Therefore, P_L = 50,000 x 8/2 = 200,000 (N).

(2) Parameters

The analysis parameters are β and λ, where β is the ratio of the geometric moments of inertia between the beam and the column, and values of 0.4 and 1.3 are used in the present study. Hence, a frame having a flexure rigidity ratio between the beam and the column of β/α = 0.4/2.0 = 0.2 (α is the aspect ratio $\alpha = l/h$ = 8/4 = 2) is denoted as A20B04 and a frame with β/α = 1.3/2.0 = 0.65 is denoted as A20B13. On the other hand, λ is a coefficient shown in Figure 11, for A20B04, λ = -1, 0, 0.5, 0.7, 0.8, 1.0, 1.2, 1.5, 2, and 5, and for A20B13, λ = - 1, 0, 0.5, 0.7, 1, 1.1, 1.5, and 2. Table 3 lists various characteristics of these frames.

(3) Calculation of buckling load by the proposed formula

The process of calculating the buckling strength using the proposed formula, shown in Table 1, is described in the following. First, Equation 31 is used to calculate rotational spring stiffness K_r when the *member-buckling* strength ${}_1P_{cr}$ is calculated, and Equation 32 is used when the *sway buckling* strength is calculated. The following equation is obtained from these two equations and Equation 6d:

$$\textit{member}: \quad k_r = K_r/(EI_c/h)$$
$$= 3\,(I_b/I_c)/(l/h) = 3\beta/\alpha = 0.6,\ 1.95 \qquad (34)$$
$$\textit{sway}: \quad k_r = 6\beta/\alpha = 1.2,\ 3.9 \qquad (35)$$

Table 3. Cross section specifications

name	I_b / I_c	I_c (mm^4)	A_c (mm^2)	I_b (mm^4)	A_b (mm^2)	N_E (N)
A20B04	0.4	123,000,000	38,420	49,200,000	24,300	15,550,000
A20B13	1.3	83,890,000	31,730	109,100,000	36,180	10,610,000

A_c: Column area A_b: Beam area
I_c: Column geometric moment of inertia I_b: Beam geometric moment of inertia $N_E = \pi^2 EI_c/h^2$

Moreover, the following equation is obtained when P is replaced with ($\lambda_2 P_{cr}$ - P_L) in Equation 33 and the resulting equation is substituted into Equation 17:

$$k_H = \frac{h^3}{12EI_c}\left(K_{H0} + \frac{\lambda_2 P_{cr} - P_L}{h}\right) \qquad (36)$$

However, it is assumed that $k_H = 0$ for $\lambda = -1$. Here, since the cross section is designed such that the relative story displacement becomes 1/200 (rad) for a lateral load of Q = 80,000 (N), K_{H0} is given as:

$$K_{H0} = \{80{,}000/(4/200)\}/2 = 2{,}000{,}000 \text{ (N/m)} \qquad (37)$$

Therefore, ${}_1P_{cr}$ is obtained when Equation 34 is substituted for Equation 24, and ${}_2P_{cr}$ is obtained when Equations 35 and 36 are substituted for Equation 25. Then, the smaller of both ${}_1P_{cr}$ and ${}_2P_{cr}$ is the buckling load of the right-hand column of the portal frame shown in Figure 11.

(4) Results

Figures 12 through 20 show the results of the computer analysis and the proposed formula. Figures 12 through 15 and 20(a) show the results for A20B04 ($\alpha = l/h = 2.0$, $\beta = I_b/I_c = 0.4$), and Figures 16 through 19 and 20(b) show the results for A20B13 ($\alpha = l/h = 2.0$, $\beta = I_b/I_c = 1.3$). Figures 12(a) through 19(a) are graphs of the non-dimensional load-displacement curves obtained by CLAP. f. The vertical axes show the perpendicular reaction force N_1 in the base of the right-hand column divided by N_E. The horizontal axes show the vertical and horizontal displacements, δ_z and δ_x, of the top of the right-hand column divided by the frame height h. The positive δ_z direction is upward, and the positive δ_x direction is to the right. The dashed-dotted lines indicate the buckling load of the right-hand column obtained by the proposed formula P_{cr}, and the chain double-dashed lines shows the buckling load of the right-hand column obtained by eigenvalue analysis V_{cr}. Figures 12(a) through 19(a) are the deformation diagrams when the computer analysis by CLAP.f finalizes, and Figures 12(c) througth 19(c) show the buckling modes obtained by eigenvalue analysis. In Figure 20, the vertical axes show the buckling loads divided by N_E, and the horizontal axes shows λ. The two solid lines (or curves) are given by the proposed formulas, and the dashed lines are given by Equation 29, which was obtained by the buckling-slope-deflection method. The cross symbols indicate the results of the eigenvalue analysis.

(5) Comparison

Based on Figures 12(a) and 16(a), when the frame receives a symmetric perpendicular load ($\lambda = -1$), the buckling load becomes less than N_E which means that the buckling length is longer than the floor height h. On the other hand, when the frame receives an anti-symmetric load ($\lambda = 1$, Figures 14(a) and 19(a)), the buckling load exceeds N_E. This means that the buckling length is shorter than the floor height h.

For the frame A20B04, as shown in Figure 20(a), the error between the value of the proposed formula and the results of the eigenvalue analysis is largest at the intersection of the two solid (proposed formula) lines. (The largest is +26% at $\lambda = 0.7$) It is thought that the reason for this error margin is that the proposed formula does not consider the intermediate buckling mode between *member-buckling* and *sway buckling*. The buckling mode changes continuously in the computer analysis, as indicated by Figures 12(b) through 15(b). For frame A20B13, as shown in Figure 20(b), the error between the value of the proposed formula and the results of the eigenvalue analysis is not so large. The largest error is +5.2% at $\lambda = 0.5$. The comparison of frames A20B04 and A20B13 indicates that the error between the proposed formula and the computer analysis decreases as the flexure rigidity ratio increases.

4. Conclusion

In the present paper, we proposed an elastic buckling strength formula for a column under an arbitrary boundary condition. The proposed formula targets the loads shown in Figure 2, which correspond to the column axis forces generated by the overturning moment of the lateral loads, and two buckling modes of *member-buckling* and *sway buckling* were assumed.

Moreover, using portal frames, the value obtained by the proposed formula was compared with the results of computer analysis, and the following conclusions were drawn.

(1) When the frame receives a symmetric perpendicular load, the buckling load becomes less than N_E. On the other hand, when the frame receives an anti-symmetric load, the buckling load exceeds N_E which means that the buckling length is shorter than the column length.

(2) For frame A20B04, the flexure rigidity ratio of which is 0.2, the error between value obtained by the proposed formula and the results of an eigenvalue analysis was greatest at the intersection of the two proposed formula lines. (The largest error is +26%). It is thought that the reason for this error is that the proposed formula does not consider the intermediate buckling mode between *member-buckling* and *sway buckling*.

(3) For frame A20B13, the flexure rigidity ratio of which is 0.65, the error between the value obtained by the proposed formula and the results of the eigenvalue analysis was not so large. The largest error was +5.2%.

(4) The error of the proposed formula and the computer analysis becomes smaller as the flexure rigidity ratio increases.

Appendix:

This appendix derives the *member-buckling* strength formula listed in Table 2 with the buckling-slope-deflection method.

Here, the induction process of Equation 28 is shown. The other equations (Equations 26, 27, and 29) are specific cases of Equation 28. Figure 6(a) indicated that there is no horizontal displacement at the top of the column, in the *member buckling* mode. The essential formulas of the buckling-slope-deflection method are as follows:

$$M_{TB} = \frac{EI_c}{h}(s\theta_T + sc\theta_B) = -K_{rT}\theta_T \tag{38}$$

$$M_{BT} = \frac{EI_c}{h}(s\theta_B + sc\theta_T) = -K_{rB}\theta_B \tag{39}$$

where M_{TB} and M_{BT} are the end node bending moments. The above two equations can be rewitten in matrix form as follows:

$$\begin{bmatrix} s + k_{rT} & sc \\ sc & s + k_{rB} \end{bmatrix} \begin{pmatrix} \theta_T \\ \theta_B \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \tag{40}$$

If $(\theta_T \ \theta_B)^{\mathrm{T}} \neq 0$, then buckling occurs. Therefore, the buckling conditional equation is given by the following equation:

$$(s + k_{rT})(s + k_{rB}) - s^2c^2 = 0 \tag{41}$$

Equation 28 is obtained by deforming Equation 41.

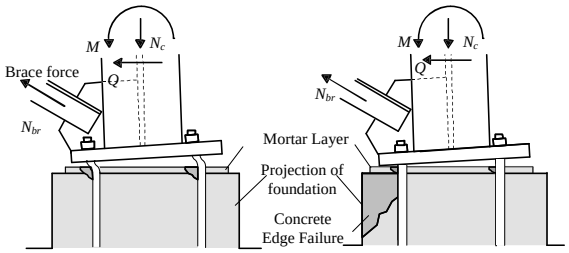
Abstract: Cyclic loading tests of column base in braced frames were conducted. Based on the test results, shear resistances governed by concrete edge failure of column base with various anchor spacing and reinforcement patterns were evaluated. Post-concrete edge failure behavior was also discussed to evaluate ultimate shear resistant mechanism considering the contribution of reinforcements around anchor bolts.

1. INTRODUCTION

Exposed-type column bases are widely employed in not only low or middle-rise steel moment-resisting frame but also braced frame to fasten the base plate of steel column to reinforced concrete foundation in Japan. For steel braced frame, these type column base connections requires sufficient lateral stiffness and strength to transmit large shear due to the brace force to concrete foundation as smoothly as possible thorough anchor bolts and/or with friction resistance between base plate and concrete foundation.



significant damages due to the brace force which are not only anchor steel failure (Fig. 1(a)) but also concrete edge failure of anchor bolts embedded near the free edges (Fig. 1(b)) were observed in steel braced building during recent earthquakes (BRI, 2003). These facts indicate that it is necessary to investigate the seismic performance of column base in braced frame subjected to large shear force. In addition, brittle failure such as concrete edge failure as well as early anchor bolt failure must be eliminated to ensure sufficient ductility. Although Concrete failure of a single or multiple anchor bolts under pure shear or combined tension and shear have been examined extensively, (Klingner, R. et al. 1982, Fuchs, W. et al. 1995, Kawano, H., et al. 2003) Shear resistance behavior of column base connection considering the shear transfer mechanism has not been discussed.

This paper presents the experimental investigation of shear resistance of exposed-type column base in braced frame governed by concrete failure.

2. TEST PROGRAM

2.1 Test Specimens

The test specimens were designed to simulate the exposed column base connections in the braced frames of low- to medium-rise buildings. The objective of this test is to investigate the shear resistance governed by the edge failure of the concrete foundation beam. The effect of the arrangement of anchor bolts and the reinforcement around the anchor bolts on the shear resistance were investigated. Moreover, the different failure modes of column base caused by the anchor bolts were investigated. There are six specimens, which were designed according to the survey of the column base connections in existing braced steel gymnasium (Asada et al. 2011), as shown in Table 1. The material properties of steel and concrete are shown in Table 2 and 3, respectively.

(a) Anchor steel yielding (b) Concrete edge failure

Figure 1 Failure Modes of Exposed Type Column Base on Projection of Foundation

Figure 2 shows the configuration of specimen and the arrangement of reinforcement. The specimen consists of the column, base plate (B.PL in the follows), gusset plate (G.PL), and the reinforced concrete foundation beam, in which the projection of foundation was designed. The column section was RH-200x200x8x12. The gusset plate was connected with the web of the column on the weak axis and a stiffener was welded on the other side of the web to resist the out-of-plane deformation. The base plate size is 350 mm in width, 420 mm in depth, and 40 mm in thickness. Four bolts were arranged at each corner of the base plate.

To investigate the edge failure of the RC foundation beam,

the failure of mortar layer was excluded by removing the mortar layer under the base plate for the specimens.

Generally, the shear resistance of the exposed column base is provided by a combination the friction along the contact area between the base plate and RC foundation beam and the bending and shear of anchor bolts. To investigate the contribution of the shear resistance of the anchor bolt, a Teflon sheet was inserted between the base plate and RC foundation beam to reduce the friction resistance in this study.

Figure 3 shows the embedment of the anchor bolt. In this study, the embedded length of anchor bolt (l_e) was 400 mm, two types diameters of anchor bolt (d), 20 mm and 23 mm, were used. The ratios of embedded length to diameter of anchor bolt were 20 and 17, respectively. The bottom end of the anchor bolt was fixed with the φ60×22 nut by welding. The Steel PC bar with the diameter of 23 mm was used for the anchor bolts of the specimens failed in RC foundation beam to promise the concrete edge failure before the significant yield of the anchor bolts. To avoid the slip of the base plate at the initial loading, the clearance between anchor bolts and bolt holes of base plate was filled by grout.

The dimensions of the RC foundation beam were the same for all the specimens, as shown in Fig. 2 (b). The distance from the anchor bolt to the free edge of the projection of foundation beam along the loading direction, c_1, which is the most critical parameter to the shear resistance governed by concrete edge failure of the RC foundation beam, was 160mm. The distance from the anchor bolt to the free edge perpendicular to the loading direction, c_2, was 1.5 times c_1 (240 mm) to exclude the effect of the free edge to the shear resistance of the concrete edge failure (Asada et al., 2010). The spacing of anchor bolts perpendicular to the loading direction, s_2, was twice of c_1 (320 mm). The spacing of anchor bolts along the loading direction, s_1, was chosen as the parameters. According to the survey of the existing steel gymnasium (Asada et al. 2011), three values were chosen as follows:s_1/c_1=0.75(s_1=120mm),1.0(s_1=160mm),1.5(s_1=240mm).

The reinforcement configurations of the foundation beam are shown in Fig. 2. Three types of reinforcement of the projection of foundation beam were adopted in this study. The main reinforcing bars of 10-D19 and hoops of D10@100 were used as the basic reinforcement for the projection of foundation beam, as shown in Fig. 2 (a). The mechanical anchors were used to avoid the overlap of the reinforcements. To investigate the contribution of the reinforcement along the loading direction of the projection of foundation beam, the hoops were removed and the main reinforcing bars were changed to 5-D19 for one specimen (unreinforced specimen). To investigate the effect of the reinforcement around the anchor bolts, the hairpin reinforcement was designed for one specimen (strengthen specimen), as shown in Figure 4.

The projection of foundation beam is 800 mm width perpendicular to the loading direction and 300 mm in height.

Table 1 List of Test Specimens

Specimens	Edge Distance and Anchor spacings				Reinforcment pattern
	c_1 [mm]	c_2 [mm]	s_1 [mm]	s_2 [mm]

2.2 Test Setup and loading program

The test specimen was placed in the loading frame shown in Figure 5. The foundation beam was connected with the loading frame by PC bars and screw jacks. The column top was clamped to two hydraulic jacks, one in the horizontal direction and the other in the vertical direction. The gusset plate was clamped to one jack to simulate the brace load N_{br}. The specimen was subjected to a constant vertical force with the axial force ratio of 0.05. A displacement-controlled load was applied in the horizontal direction. The displacement was expressed in terms of the drift angle R. The brace load N_{br} was controlled by the applied horizontal displacement of the top of column. The brace force behavior is described as shown in Fig. 7, the brace yielded at the drift angle R of 1/400 with the yield brace load of 200 kN in tension and the brace does not resist compressive load. For the specimens failed in RC foundation beam, one cycle of the drift angles of 1/400 and 1/100 rad and the monotonic loading to the horizontal displacement of the column base ${}_{cb}\delta_h$ of 20 mm after unloading were adopted.

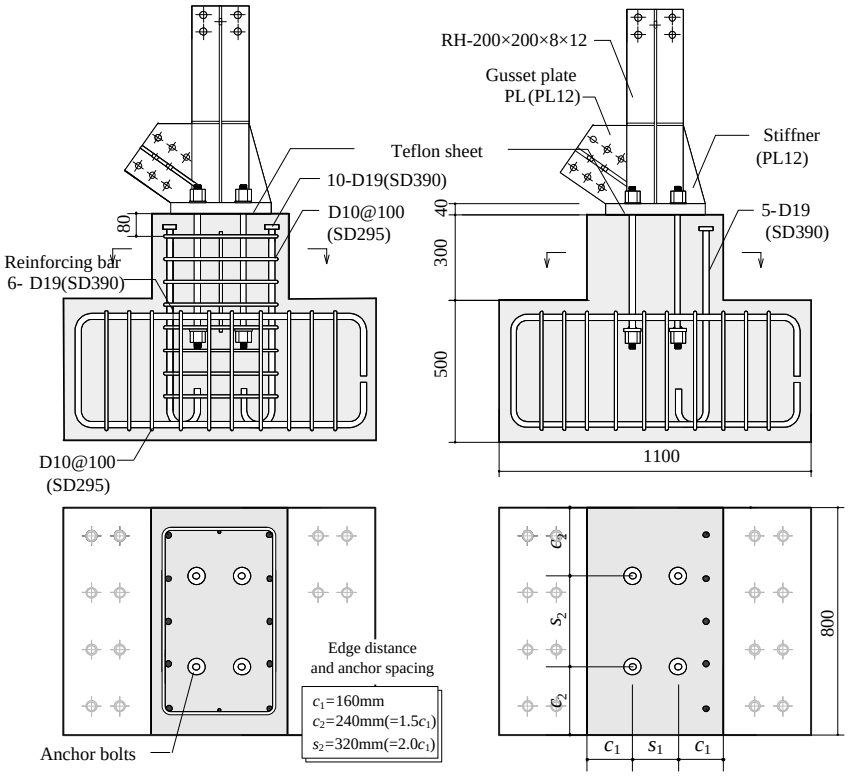

Table 2 Material Properties (a) Steel, and (b) Concrete

(a)

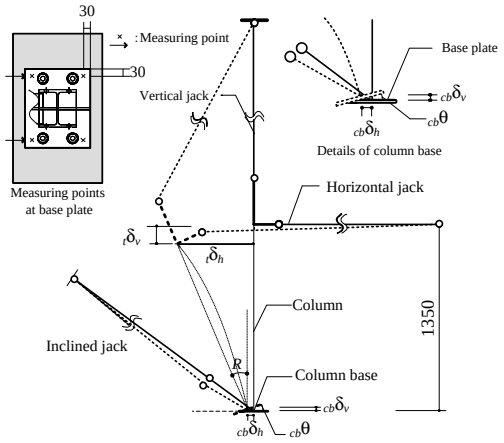
2.3 Measurement system

The deformation of the specimen was described in Figure 8. All the measured displacements were the relative displacement from the foundation beam. The story drift angle R is calculated as follows:

$$R = \frac{{}_t\delta_h - {}_{cb}\delta_h}{l_h - {}_t\delta_v - {}_{cb}\delta_v} \quad (1)$$

As shown in Figure 8, the rotation of the column base ${}_{cb}\theta$ is calculated as the vertical displacements measured from the base plate and the horizontal displacement of column base is measured from the front surface of the base plate. The incline of the jack was considered to calculate the resistance of the specimen.



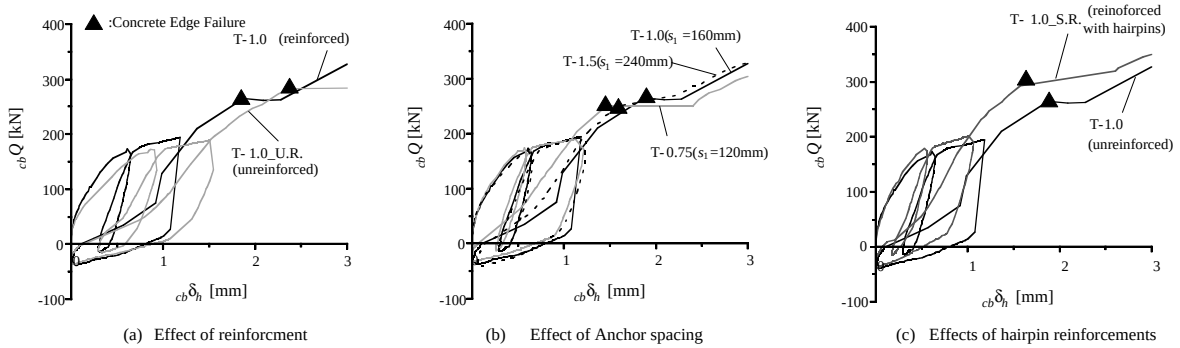


Figure 7 Measurement System

(a) Effect of reinforcment (b) Effect of Anchor spacing (c) Effects of hairpin reinforcements

Figure 8 Shear Resistance of Column Base till Concrete Edge Failure occurred

3. Test Results

3.1 Shear resistance behavior till concrete edge failure occurred

As observed from the test, the edge failure occurred at the column base horizontal displacement $_{cb}\delta_h$ of 3 mm. The relationships of shear resistance of column base $_{cb}Q$ and column base horizontal displacement $_{cb}\delta_h$ up to the concrete edge failure are shown in Figure 8. The shear resistance of column base $_{cb}Q$ is calculated as the combination of the shear force of column and the horizontal component of brace force. The cracking patterns of specimens at the column base horizontal displacement of 3mm and after testing are shown in Fig. 9.

As indicated in Figure 9, the concrete edge failure occurred at the column base horizontal displacement around 2 mm. When the concrete edge failure occurred, the diagonal cracks propagated from the anchor bolts at the upstream of the loading direction were observed for all the specimens. And the cracks caused by bending at the bottom of the projection of foundation beam were observed, too. For the specimens with the anchor bolts spacing s_1 not larger than the edge distance c_1, specimens "T-1.0", "T-1.0_U.R.", and "T-0.75", the diagonal cracks developed from the anchor bolts at the downstream (back A.B.) of the loading direction directly after the propagation of the diagonal cracks at the upstream anchor bolts (front A.B.). For the specimen with the anchor bolts spacing s_1 is 1.5 times the edge distance c_1, specimen "T-1.5", the diagonal cracks from the back anchor bolts developed when the shear resistance was 290 kN, after the propagation of the cracks from the front anchor bolts. The strength deterioration caused by the edge failure was not observed for all the specimens even for the unreinforced specimen, specimen "T-1.0_U.R". The reason will be discussed in the following section. In comparison with the unreinforced specimen, the initial stiffness of the reinforced specimens was larger. The initial stiffness was further increased because of the presence of the hairpin reinforcement around the anchor bolts.

As shown in Figure 9, the edge failure resistance of the reinforced specimen ("T-1.0") is slightly smaller than that of the unreinforced specimen ("T-1.0_U.R."). It is the same as observed in the previous study (Asada et al. 2010). The reduction of the strength is caused by the reduction of the effective concrete surface in the failure region, since the

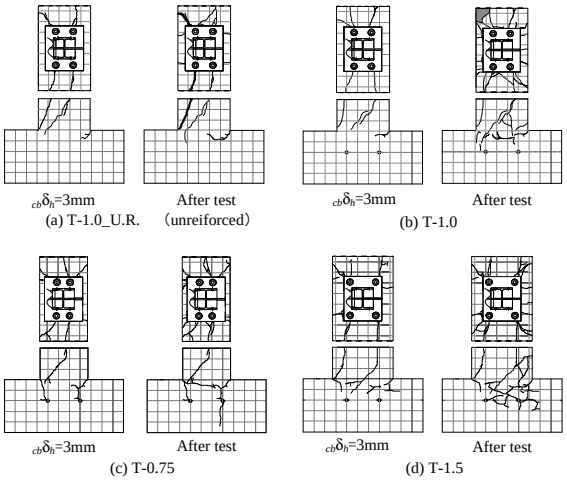

Figure 9 Cracking Patterns of Concrete Foundations

reinforcing bars occupied the part where the concrete was. Therefore, the increment of the edge failure resistance of the strength specimen ("T-1.0_S.R.") is slight compared with the unreinforced specimen ("T-1.0_U.R.").

3.2 Evaluation of the edge failure resistance

Two methods, the AIJ design guideline (AIJ, 2006) based on the 45 degree concrete cone method and CCD method (Hofmann, 2004), are adopted in this study to evaluate the edge failure resistance of the anchor bolts in shear. For the calculation, it is assumed that the four anchor bolts transferred the shear force evenly and the shear force when the edge failure caused by the front two anchor bolts occurred is the sum of the shear force transferred by the four anchor bolts. The evaluations based on AIJ design Recommendation (AIJ, 2010) and CCD method (Hofmann, 2004) are as follows.

$$_{AIJ_c}Q_{ce} = 2\times 0.31\sqrt{\sigma_B}\cdot A_c \qquad (2)$$

where, A_c is the projected areas for a group of anchor bolts, as shown in Figure 11(a).

$$_{CCD_c}Q_{ce} = 2\times\frac{A_{cc}}{A_{cc0}}\cdot\Psi_s\cdot\Psi_h\cdot Q_0 \qquad (3)$$

where,

$$Q_0 = 3.0\cdot d^{\alpha}\cdot l_e^{\beta}\sqrt{\sigma_B}\cdot c_1^{1.5} \qquad (4)$$

$$\alpha = 0.1\cdot\left(\frac{l_e}{c_1}\right)^{0.5} \qquad (5) \qquad\qquad \beta = 0.1\cdot\left(\frac{d}{c_1}\right)^{0.2} \qquad (6)$$

$$\Psi_s = 0.7 + 0.3 \cdot c_2 / (1.5 \cdot c_1) \le 1 \quad (7)$$

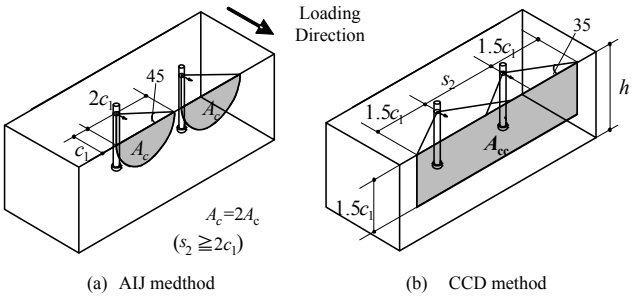
$$\Psi_h = (1.5 \cdot c_1 / h)^{1.5} \ge 1 \quad (8)$$

where, l_e is the embedded length of anchor bolt, d is the diameter of anchor bolt, A_{cc0} is the projected area for a single anchor bolt without the effect of the edge distance and group effect ($=4.5c_1^2$), h is the height of the projection of foundation, and A_{cc} is the projected area for anchor bolts considering the effect of edge distance and group effect, as shown in Figure 10-(b).

The calculated strengths are compared with the experimental results in Table 3. The calculated edge failure resistances using AIJ method and CCD method agree with the experimental results well. The calculated strengths of unreinforced specimen "T-1.0_U.R." and strengthen specimen "T-1.0_S.R" are smaller than the experimental results within 10% difference, which is conservative for design, while, the calculated strengths of reinforced specimens are slightly larger than the experimental results around 12% difference.

In this study, the edge distance along the loading direction c_1 is relatively small, the edge distance perpendicular to the loading direction c_2 and the anchor bolt spacing perpendicular to the loading direction s_2 are sufficient. Therefore, both the AIJ and CCD method are able to evaluate the resistance reasonably within an acceptable accuracy. However, the AIJ method is not able to trace the size effect of the edge distance along the loading direction c_1 and the reduction of resistance caused by the reduction of the edge distance perpendicular to the loading direction c_2.

3.3 Shear resistance after the edge failure



The relationships of shear resistance of column base ${}_{cb}Q$ and column base horizontal displacement ${}_{cb}\delta_h$ till the end of loading, when the horizontal displacement ${}_{cb}\delta_h$ was 20mm, are shown in Figure 11. As show in Figure 11, The shear resistances of the column base connections including unreiforced specimen "T-1.0_UR were increased steadily even after concrete edge failure occur. It is primarily because the shear resistance of the back anchor bolts (in tension side), is much larger than that of front anchor bolts (in compression side) governed by concrete edge failure. In addition, based on the crack patterns shown in Fig. 10, it is speculated that back anchor bolts resist to the shear force by forming of strut between the back anchor bolts and the main reinforcement of the foundation beam described in Figure 12.

Therefore, if the shear resistance of the back anchor bolts is larger than the concrete edge failure resistance, the shear resistance of the column base connections is governed by that of the back anchor bolts

Using the evaluation of shear resistance of studs with large enough edge distance in loading direction recommended by AIJ (AIJ 2010) the maximum shear resistance of the unreinforced specimen "T-1.0_UR" governed by back anchor resistance is calculated as follows;

$${}_cQ_{cu} = 0.5 \cdot {}_t n \cdot {}_b A \sqrt{\sigma_B \cdot E_c} \quad (9)$$

in which, ${}_tn$ is the number of the anchor bolts in tension side, ${}_bA$ is the section area of on anchor bolt, ${}_cE_c$ is the young Modulus of concrete, and σ_B is the compressive stress of concrete. As shown in Figure 11, the calculated shear resistance governed by the back anchor bolts using Eq. (9) agreed with the measured maximum shear resistance of the unreinforced specimen "T-1.0_U.R." well. After the loading, it is observed that the concrete bearing the back anchor bolts was crushed as shown in Photo 1. Such failure indicated that

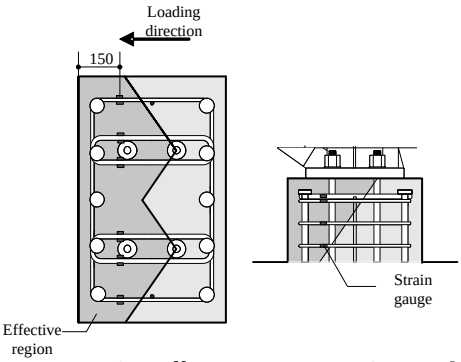

Figure 13 Effective Resistance Area and Arrangement of Strain Gauges

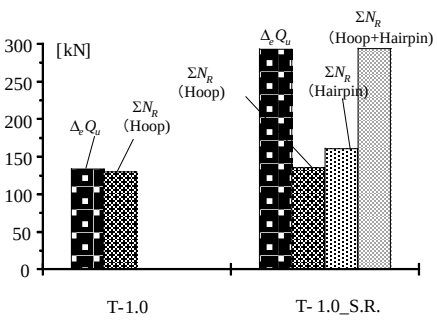

Figure 14 Contributions of Reinforcements around Anchor Bolts

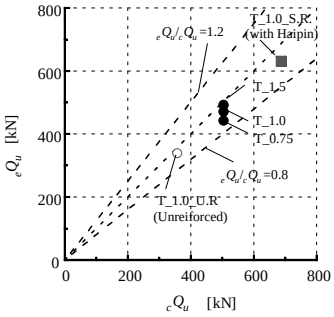

Figure 15 Comparison of Calculated and Experimental Maximum Shear resistance

the shear strength was mainly transferred by the strut mechanism between the back anchor bolts and the foundation beam after the concrete edge failure.

Note that, to form the strut for the shear resistance, the shear failure strength of the back anchor bolts is required to be larger than the concrete edge failure resistance. And the anchor bolts are needed to be embedded in the foundation beam with enough anchorage. Moreover, according to the crack patterns observed in this study, the edge distance of the back anchor bolts along the loading direction c_1+s_1 should not be smaller than the height of the projection of the foundation beam to ensure the strut develop sufficient width. However, there is few available test data on the strut mechanism. Further study is needed to quantify the conditions for the strut mechanism.

As shown in Figure 12, the maximum shear resistances of the reinforced specimens are larger than that of the unreinforced specimen. And the increments were nearly the constant regardless of the variation of the anchor bolts spacing s_1. The maximum shear resistance of the strengthen specimen "T-1.0_S.R" was further increased compared with the reinforced specimens, because of the presence of the hairpin reinforcement.

The contribution of the reinforcement to the shear resistance is discussed using the measured axial strain of the reinforcement. The arrangement of the strain gauges is shown in Figure 13 The strain gauges were attached on the reinforcements along the loading direction within the effective region (Asada et al. 2010), which is the same as the failure area of the CCD method.

The increment of the maximum shear resistance of the reinforced specimen "T-1.0" and the specimen reinforced with hairpin "T-1.0_S.R." from that of the unreinforced specimen "T-1.0_U.R." $\Delta_e Q_u$ is compared with the total axial force of reinforcement in the effective region at the maximum shear resistance ΣN_R in Figure 14. It is noted that the contribution of the reinforcement in the effective region is nearly the same as the increments of the maximum shear resistance for both specimens.

Based on the observations, the maximum shear resistance of the reinforced specimen is the combination of the tension resistance of the horizontal reinforcement in the effective region and the shear resistance of the back anchor bolts, Eq. 10.

$$_cQ_u = {}_cQ_{cu} + {}_cQ_{ru} = \min\left\{{}_cQ_{cu1}, {}_cQ_{cu2}\right\} + \sum {}_r a \cdot {}_r\sigma_y \quad (10)$$

in which, $\Sigma\, {}_r a \cdot {}_r\sigma_y$ is the yield strength of the reinforcement s in the effective region.

The comparison between the calculated and experimental maximum shear strength of the specimens, $_cQ_u$ and $_eQ_u$, after the concrete edge failure occurred is shown in Figure 15. The calculated strength agreed with the measured strength well. According to the test results, it is clarified that the shear resistance of the column base is improved by the presence of the horizontal reinforcement within the effective region.

4. CONCLUSIONS

Cyclic loading tests were conducted to investigate the shear resistance governed by concrete failure of exposed-type column base in steel braced frame. Form the experimental results, It is conformed that applicability of existing evaluation methods of concrete edge failure and maximum shear resistance of anchor bolts with high strength after concrete edge failure.

Abstract: Braced frames are commonly used lateral-load resisting systems in seismic design. In braced frames the braces are connected to the beams and columns by gusset plate connection. And fillet welds are commonly used to connect the gusset plate to frame. The ultimate strength of the weld between gusset plate and frame components is determined by the weld effective length, size and stress. However, there is not a standard design method for the interface weld in Japan. Experimental study was conducted and showed that the Whitmore effective region concept works well. To improve the understanding and design of the ultimate strength of welded gusset plate connections, a series of analytical study was undertaken. The verified numerical model was used to evaluate the ultimate strength of the welded gusset plate connection and interface forces at the gusset-to-beam/column. A parametric study was conducted to examine the influence of he gusset plate size, brace angles, and eccentricity of brace on the connection interface forces. Based on the results, an evaluation of the effective length was suggested.

1. INTRODUCTION

Braced frames are widely used for steel constructions in seismic regions. In general, the axial load from the brace is transferred to the beam and column through the gusset plate, which is normally bolted or welded to the brace and connected to the column and beam by welds. Gusset plate should have sufficient strength and stiffness to transfer the applied forces. Fracture of a gusset plate connection will result in considerable loss of strength and stiffness of the brace. The seismic performance of the braced frame will be thereby reduced. Many experimental and analytical studies have conducted to investigate the behavior of gusset plate connections. And the design provisions were updated based on the studies (AISC, 2005).

Fillet welds are widely used to connect the gusset plate to beams and columns. The fracture of weld between gusset plate and beams and columns is the brittle failure and should be avoided during the design (Astaneh-Asl, 1998 and Roeder et al. 2005). However, few studies have done yet on the interface weld of gusset plate connection (Thornton, 1991, Richard, 1986, and Gross, 1990). Although the welds were sized to develop the expected tensile yield capacity of the brace following the design provisions, the fracture of interface welds of gusset plate was observed in previous studies (Yoo et al. 2008) and earthquakes (Elnashai and Samo, 2008).

There are various design practices to evaluate the resistance capacity of interface welds of the gusset plate connection in Japan. However the adequacy of the methods of design with respect to safety and economy of construction has not been confirmed. In this paper, the current design practices of the interface welds of gusset plate connections in Japan are discussed with previous experimental study (Asada et al. 2011) and a series numerical analytical parametric study.

2. CURRENT DESIGN PRACTICE IN JAPAN

In Japan, three design methods of the interface weld of gusset plate connections are commonly used. The differences of the three design methods are the effective length of the interface weld and the direction of the interface force. The details of the three design methods are introduced as follows.

1. Method I -- AIJ method (AIJ, 2006)

This method is recommended by Architectural Institute of Japan (AIJ, 2006). The effective weld length and interface force direction were considered. As shown in Fig. 1, the effective weld length ($_{AIJ}l$) is nominally the shortest length between entire interface weld length and the length controlled by the 30-degrees effective region. If the end returns is not used, the effective length should subtract two times the nominal fillet weld size (S) for the calculation. In the following discussion, the influence of the end of weld is

neglected by assuming the end returns were used. The resistance of interface weld is assumed parallel to the brace. The resistance capacity of the interface weld is calculated as Eq. 1.

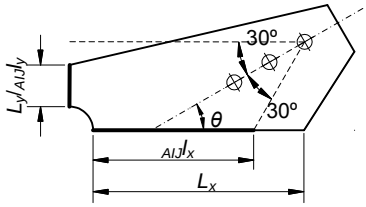

Fig. 1 Effective length of interface weld

$$N_{u,I} = 2_{AIJ}\, l_x (1+0.4\sin\theta) a \frac{{}_c F_u}{\sqrt{3}} + 2_{AIJ}\, l_y (1+0.4\cos\theta) a \frac{{}_c F_u}{\sqrt{3}} \quad (1)$$

where, θ is the brace angle; ${}_cF_u$ is the tensile stress of base material, and a is the throat size of weld.

2. Method II -- Practical method (BCJ, 2007)

Method II is the most commonly used in Japan for the interface weld design. The entire interface weld length is counted. And the direction of interface weld is not considered, by assuming the interface weld failed by pure shear. The resistance capacity of the interface force is calculated as Eq. 2.

$$N_{u,II} = 2(L_x + L_y) a \frac{{}_c F_u}{\sqrt{3}} \quad (2)$$

where, L_x and L_y are the entire interface weld lengths in beam and column side, respectively.

3. Method III -- Simple method (JSSC, 2009)

This is a simplest design method. It is simple with respect to calculations but it yields very conservative designs. As with Method II, the entire interface weld length is counted for the design. In this method, the entire horizontal and vertical brace component were assumed be transferred by the beam and column side, respectively. This method is similar to the Special Case 1 of the Uniform Force Method (UFM) (AISC, 2005).

$$N_{u,III} = \min(N_B, N_C) \quad (3)$$

$$N_B = 2 \cdot L_x \cdot a \cdot \frac{{}_c F_u}{\sqrt{3}} / \cos\theta \quad (3a)$$

$$N_C = 2 \cdot L_y \cdot a \cdot \frac{{}_c F_u}{\sqrt{3}} / \sin\theta \quad (3b)$$

The experimental research at Tokyo Institute of Technology (Asada et al. 2011) provided a basis of the analytical research and design methods. The test specimens were full-scale as illustrated in Fig.3. Each specimen consisted of two end plates (PL-26x200x269 and PL-26x200x258) and one gusset plate (t_p=12 mm). All specimens were fabricated by SM490 steel. The bracing angle of 30 degrees was used. Tapered gusset plates were used for all specimens. The parameter of the specimens was the geometry size of the gusset plate. Fillet welds were used to connect the gusset plates to the endplates. The designation of the specimen indicated the studied parameter and its value, e.g., Specimen B135-C45 is the specimen with the gusset plate having 135 mm and 45 mm interface weld along beam and column side, respectively.

All specimens were loaded monotonically till the failure of either gusset plate or interface weld. Linear variable displacement transducers (LVDTs) were used to monitor the displacements of the gusset plate specimens and the test frame assembly. In order to measure the strain distribution in the gusset plate, strain gages were placed on each specimen, on one side of the gusset plate.

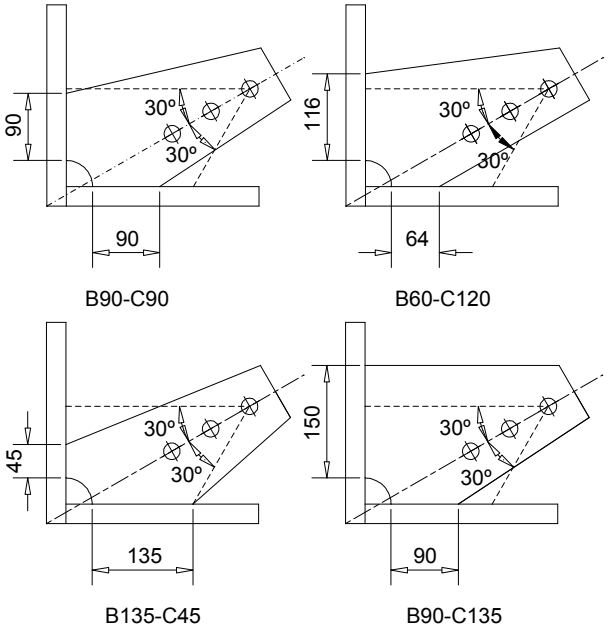

Fig.2 Gusset plate connection specimen

Four specimens failed in two different failure modes. Specimen B135-C45 failed by fracture of interface weld (Fig. 4 (b)). Specimens B90-C90, B60-B120, and B90-C150 failed by fracture of net area of gusset plate through the last bolt of brace-to-gusset connection (Fig. 4 (c)). The measured maximum axial forces transferred by the specimens are listed in Table 2.

The measured ultimate strength was used to assess the accuracy of weld size prediction of the three models introduced. As illustrated in Table 1, the Method III[8] provided the largest and most conservative weld size in comparison with the other two methods. The weld sized by Method I[6] is the closest to the measured from the experimental specimens.

It is noted that the interface weld could be designed reasonably if the contribution of the interface welds in both beam and column side are considered in the design. However, the consideration of the effective length and the interface angle is not clear. In the following sections, such

issues are explored using finite element method analysis. A numerical model is developed to simulate the gusset plate behavior till the fracture of interface weld. A series of parametric studies are conducted to investigate the effect of the gusset plate size and brace angle on the effective length and resistance capacity of interface weld.

Table 1 Experimental results

Specimen	$_{exp}P_{br,u}$ (kN)	Failure Mode	Weld size, S (mm)			
			Measured	Design		
				S_I	S_{II}	S_{III}
B90-C90	679	GP	5.5	7	9	15
B60- C120	608	GP	5.6	7	8	22
B135- C45	695	W	5.6	7	9	18
B90- C150	696	GP	5.7	7	7	18

* GP indicated the fracture of gusset plate; W indicates the fracture of weld

3. VERIFICATION OF NUMERICAL MODELING

A comprehensive series of nonlinear, inelastic FE analyses were performed to simulate the response of the test specimens using the ABAQUS 6.9 (ABAQSU, 2009). Figure 3 shows a typical FE model of a gusset plate connection specimen. The gusset plate at the intersection between beam and column was partitioned into 5 mm height slice to represent the weld. The FE model was constructed using 3D solid element for all of the members. 8-node linear brick, reduced integration element (C3D8R) was used for the gusset plate and two endplates. The equivalent region of weld on the gusset plate was modeled by 8-node linear brick element (C3D8). A mesh refinement study was conducted to determine the mesh size required to ensure convergence and accuracy of the FE solution and simultaneously minimizing the execution time. On the basis of this study, a fine mesh (5 mm) was used for the gusset plate, and finer mesh (2.5 mm) was used for the weld part. A coarser mesh was used for endplate due to the elastic behavior observed in the experiments.

Elastic-plastic and isotropic strain hardening material models were assigned to gusset plate based on measured stress-strain relationships obtained from the experimental research, as shown in Fig. 3 (b). Elastic material with the modulus of elasticity of 205000 MPa was assigned to the endplates. Elastic-plastic material with a maximum stress of 575 MPa and stress reduction to 100 MPa at strain of 0.1 was assigned to the weld region on the gusset plate, as shown in Fig. 3 (b).

The translational degrees of freedom at the nodes along the bolt holes of the two endplates were fully restrained. The load was applied through the nodes along the front half side bolt holes considering the bearing interaction between bolts and gusset plate. Monotonic in-plane displacement was loaded along the brace direction in tension, as shown in Fig. 3 (c).

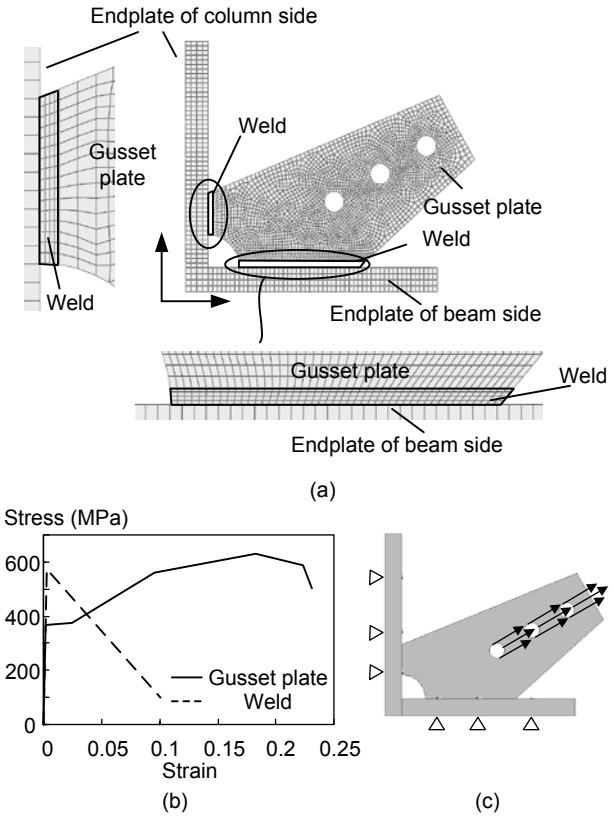

Fig. 3 Model of test specimen: (a) FE model; (b) material properties; (c) boundary condition

Specimens B135-C45 and B90-C90, which failed in different failure modes, were chosen to verify the FE model. The experimental and analytical relations between the axial load and the displacement for Specimens B135-C45 and B90-C90 are shown in Fig. 4. The FEM model closely approximated all aspects of the measured response. The difference between experimental and analytical maximum strength is 3% and 14% for specimens B135-C45 and B90-C90, respectively.

The analytical model also simulated the local behavior well. Figure 4 (b) and (c) show observed (experiment) and simulated (FE model) failure pattern. The failure portion of the analyzed specimen is indicated by the contours of the maximum principal plastic strain (PE) distribution. The failure regions are marked in white, where the tensile strain reached to the critical levels, i.e., the strain is larger than 10% and 20% for weld and gusset plate, respectively. As indicated in the strain contours, few portion of the gusset plate along the last bolt of the brace-to-gusset plate connection reached the critical strain level; however, the entire interface weld on column side reached the strain level far larger than the critical strain level for specimen B135-C45. For specimen B90-C90, the net section through the last bolt of the brace-to-gusset plate connection reached the critical strain level while the other portion was still in low strain level. The failure region shown by the critical strain level agreed with observed failure mode well.

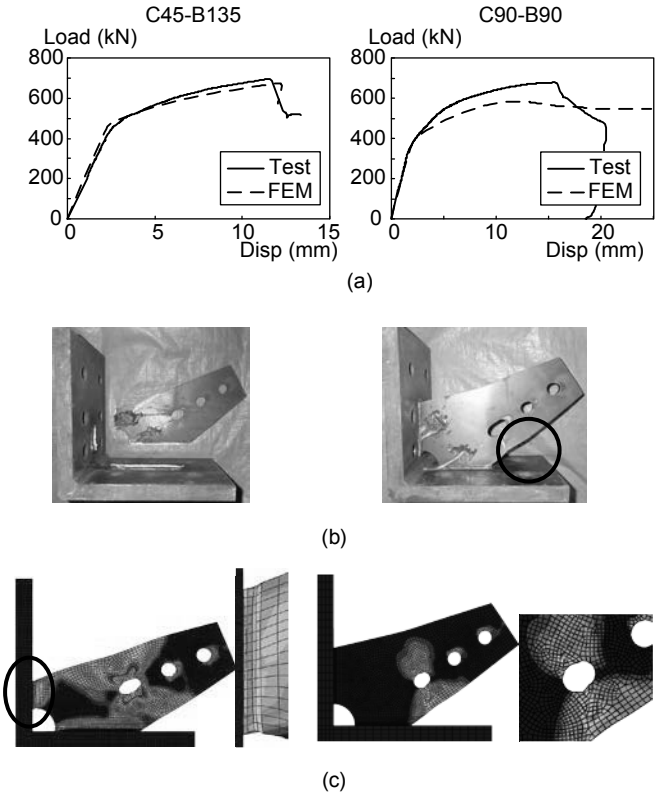

Fig. 4 Comparison between test and FE analysis: (a) load-displacement, (b) failure mode of experimental specimens, and (c) failure mode of analytical specimens

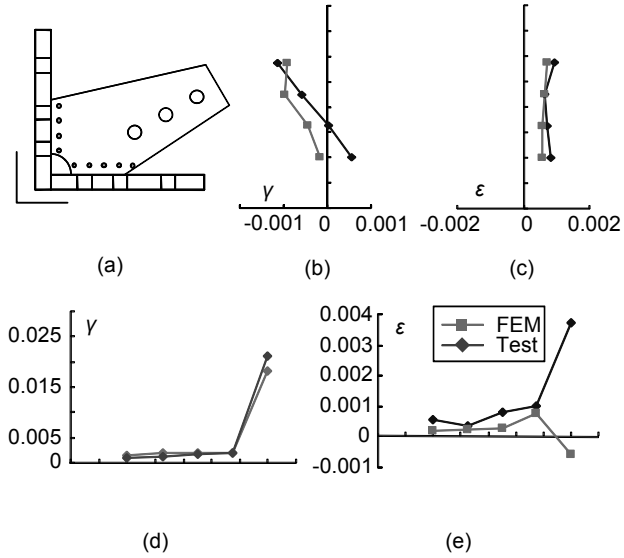

Fig. 5 Comparison of strain distribution of specimen B90-C90 between test and FE analysis: (a) strain gauge location; (b) shear stress on column side; (c) normal stress on column side; (d) shear stress on beam side; (d) normal stress on beam side

The strain distributions along the region close to the interface weld (Fig. 5 (a)) were measured in the experiments. The simulated strains distributions were compared with the experimental strains distribution at the maximum axial brace force in Fig. 5 (b-e). It is noted that the analytical normal and shear strain distribution agreed with the experimental results well. On the basis of these investigations, it can be concluded that the FE model simulated the local behaviors quite well.

It is noted in Fig. 4(b) of Part I that the gusset plate of Specimen B135-C45 yield around the blot holes when the maximum brace force was reached because of the interface weld fracture. Such damage in the gusset plate lowered the resistance of the gusset plate connection and the resistance demand of the interface weld was reduced. Therefore, to investigate the maximum resistance capacity of the interface weld, the elastic material property was assigned to the gusset plate. The load-displacements of Specimen B135-C45 with elastic and elastic-plastic material property were compared in Fig. 6 (a). The maximum strength transferred by gusset plate was significant increased with the elastic gusset plate. The Von-Mises stress distributions along weld of beam and column side are compared in Fig. 6 (b). The mises stress reached the maximum stress of weld and distributed uniformly along the interface weld for the model with elastic gusset plate in comparison with the one with plastic gusset plate. The capacity of the interface weld was fully developed with elastic gusset plate. The elastic gusset plate was used for the following parametric study.

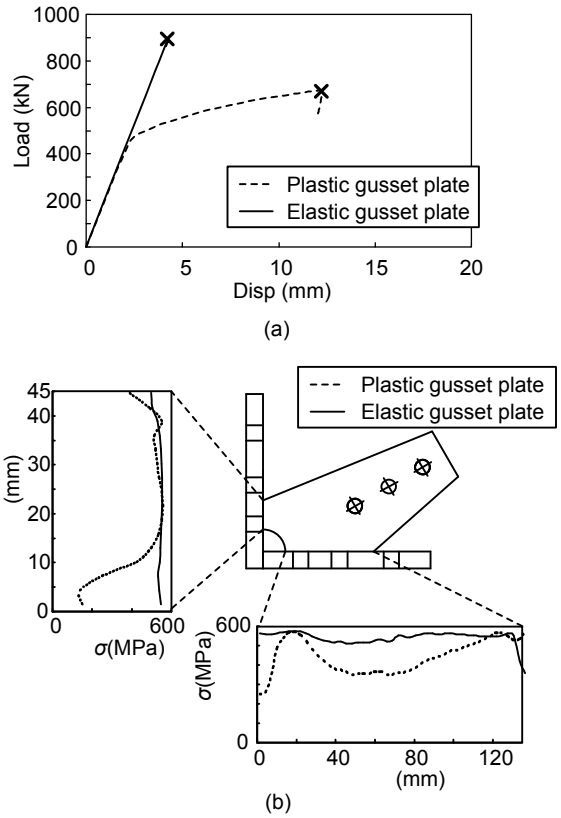

Fig.6 Comparison of results between plastic gusset plate and elastic gusset plate: (a) load-displacement response; (b) von Mises stress distribution along weld

4. PARAMETRIC ANALYSIS

4.1 Overview of analytical parameter study

The parameters include the geometry of the gusset plate (L_x, L_y), brace angle (θ), and eccentricity of the brace along beam side (e_x), as shown in Fig. 7. The brace angle (θ) is defined as the angle that the bracing member makes with the beam. Gusset plate size was varied based on the Whitmore effective region and the rectangular shape. Four types interface weld length were chosen for beam and column side, respectively. They are half the Whitmore effective length (0.5 $_{30}l$), the Whitmore effective length ($_{30}l$), the length between Whitmore effective length and rectangular length (0.5 ($_{30}l$+ $_{rect}l$)), and the rectangular length ($_{rect}l$). Brace angle was 30 and 45 degrees. Eccentricity along beam side is controlled by the offset ratio β (see Eq. (4)). In this study, the offset ratio of 0.25 and 0.33 were used.

$$\beta = \frac{e_x}{r_x + L_x} \tag{4}$$

where, r_x is the size of the weld access hole on beam side , e_x is the offset distance of the brace along the beam side.

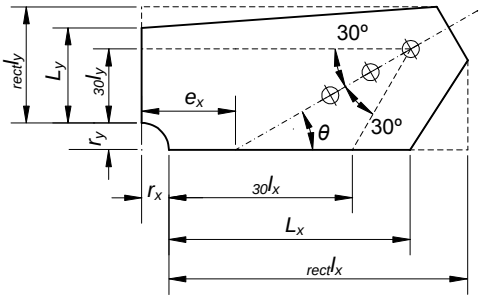

Fig.7 Gusset plate geometry details

The parameters groupings and specific values for individual specimens that were analyzed within each group are identified in Table 2 (shaded cells indicate the prototype models for the models with brace eccentricity). Analytical specimen B135-C45 indicates the gusset plate with the length of 135 mm and 45 mm in beam and column side, respectively. For the specimens with brace eccentricity, specimen B135-C90-033E indicates the gusset plate B135-C90 with the brace offset ratio of 0.33, the name in brackets indicates the size of the specimen.

Table 2 Model List

a) θ=30º, No eccentricity

4.2 Results

4.2.1 Interface stress distribution

Typical von-Mises stress distributions along interface weld at the ultimate strength were shown in Fig. 8, in which the dash line showed the AIJ effective length ($_{AIJ}l$). The analytical specimens B135-C45 and B108-C108 (Fig. 8 (a and b)), whose gusset plate size are within the Whitmore effective region, showed the uniform stress distribution of interface weld along both beam and column side. And the stress of interface weld reached the ultimate weld stress. For the analytical specimen B217-C217, whose gusset plate size is larger than the Whitmore effective region, the stress of the interface weld reached the ultimate weld stress and uniformly distributed within the Whitmore effective region. And the weld stress gradually reduced along the interface weld in the part out of the Whitmore effective region.

Figure8 (d) showed the stress distribution of the analytical specimen B135-C90, in which the column side interface weld length increased from 45 mm to 90 mm compared with the specimen B135-C45 (Fig. 8 (a)). In this specimen, the weld stress reached the ultimate stress and uniformly distributed along beam side, while the stress of interface weld on column side did not reach the ultimate weld stress. The same behavior was observed for the analytical specimen B108-C60 (Fig. 8 (e)), in which the column side interface weld length reduced from 108 mm to 60 mm compared with the specimen B108-C108 (Fig. 8 (b)).

The stress distribution of the analytical specimen B217-C217-033E (B300-C217), in which the brace axis is offset by 121 mm from the gusset plate corner, is shown in Fig. 8 (f). It is noted the weld stress uniformly reached the ultimate weld stress along beam side within the Whitmore effective region. However, the weld stress of column side did not reach the ultimate weld stress and uniformly stress distribution was not observed, even the interface weld along

column side is longer than the AIJ effective length.

As observed from the analytical results, the entire interface weld did not contribute to the resistance for all the size of gusset plate. The stress distribution of the interface weld is affected by the gusset plate size and brace angle.

4.2.2 Effective length

To quantify the resistance region of the interface weld, the effective length ($_{FEM}l$) is calculated using Eq.5. As illustrated in Fig. 9 (a), the weld stress is assumed to reach the ultimate stress and uniformly distributed along the interface weld within the effective length ($_{FEM}l$).

$$_{FEM}l = \frac{\sum L_i \cdot \sigma_i}{\sigma_{u,weld}} \quad (5)$$

Where, $_{FEM}l$ is the effective length calculated from the analytical results, L_i is the distance between each measured node, σ_i is the von-Mises stress at the measured node, $\sigma_{u,weld}$ (=575MPa) is the ultimate stress of the weld.

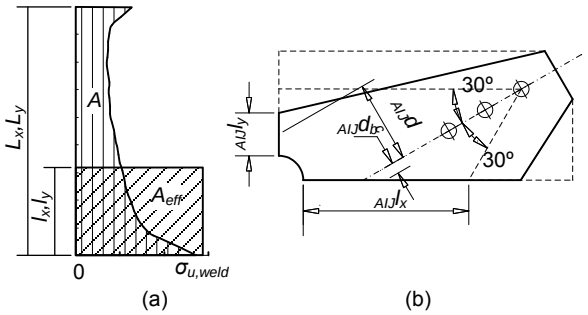

Figure 9 (a) Effective length from numerical results; (b) effective length of AIJ evaluation

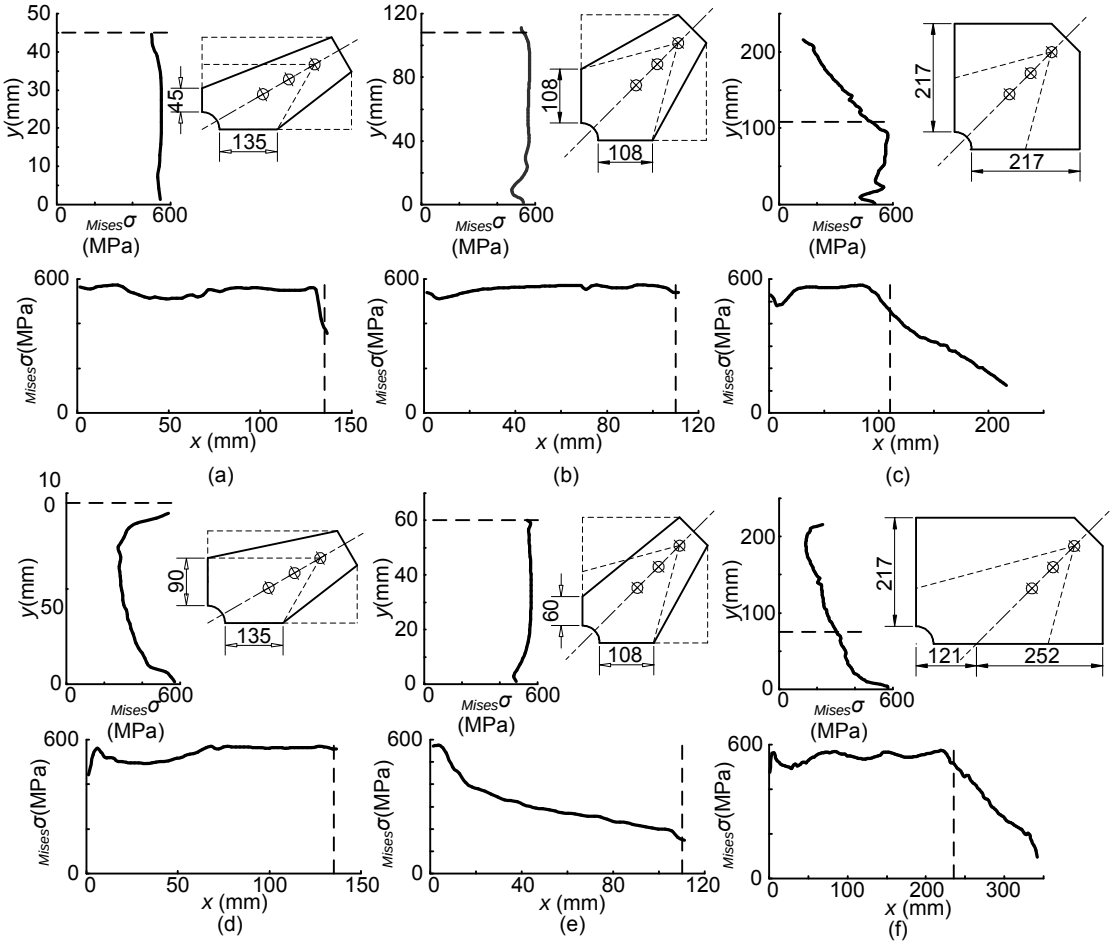
The effective length evaluated based on the numerical results ($_{FEM}l$) are compared with the AIJ effective length ($_{AIJ}l$) in Fig. 10. It is noted that the effective length of interface weld is evaluated well by AIJ method ($_{FEM}l_y/_{AIJ}l_y \approx 1.0$) when the gusset plate size is within the Whitmore effective region and the distance from each interface weld to brace axis is nearly the same ($_{AIJ}d_b/_{AIJ}d_c \approx 1.0$). The effective length of interface weld on column side is underestimated by AIJ method ($_{FEM}l_y/_{AIJ}l_y < 1.0$) when the beam side distance is smaller than the column side ($_{AIJ}d_b/_{AIJ}d_c < 1.0$). And the effective length of interface weld on beam side is



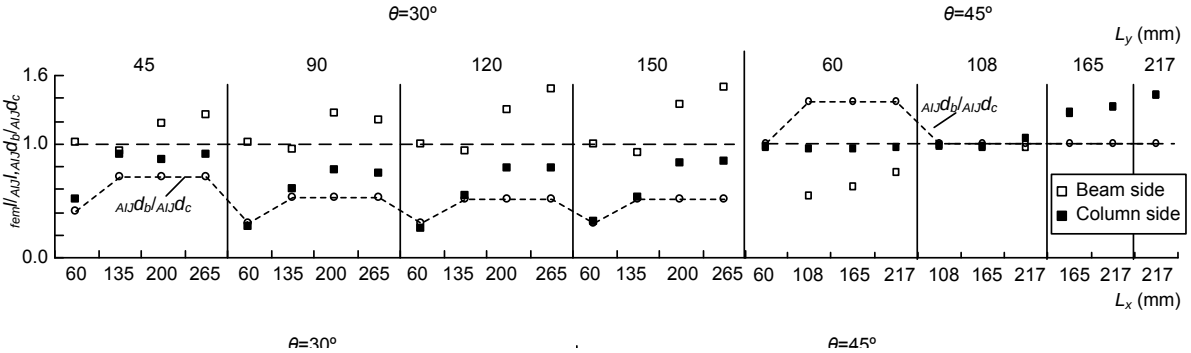


Figure 8 VonMises stress distribution along interface weld: (a) B135-C45; (b) B108-C108; (c) B217-C217; (d) B135-C90; (e) B108-C60; (f) B217-C217-033E (B340-C217)

underestimated by AIJ method ($_{FEM}l_x/_{AIJ}l_x$<1.0) when the beam side distance is larger than the column side ($_{AIJ}d_b/_{AIJ}d_c$>1.0).

When the gusset plate size is larger than the Whitmore effective region, the AIJ effective length ($_{AIJ}l$) tended to underestimate the effective length. It is primarily because the contribution of the stress distributed beyond the Whitmore effective region, as shown in Fig. 8 (c) and (f), is not counted by AIJ effective length. As the brace eccentricity along beam side increased, the effective length on column side was overestimated and the effective length on beam side was underestimated by AIJ effective length. And the beam side distance was reduced and the column side distance was increased as the brace eccentricity increased, the ratio of the beam and column side distance was thereby reduced.

5. CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK

As observed from experimental study, AIJ effective length provide more accurate evaluation of interface weld effective length among the current design methods. A series of parametric study was conducted to investigate the effect of gusset plate size, brace angle, and brace eccentricity on the stress distribution of interface weld and resultant force distribution of gusset plate. It is observed that AIJ effective length method is not able to consider the interaction between beam and column side interface length and the effect of brace angle. A revised evaluation based on AIJ effective length was proposed in this study based analytical results.

The evaluation of effective length and ultimate strength of weld is developed based on the numerical results. Experimental study is required to verify the proposed evaluation. In addition, more parameters should be considered, such as the connection between brace and gusset plate and the effect of gusset plate plastic behavior.

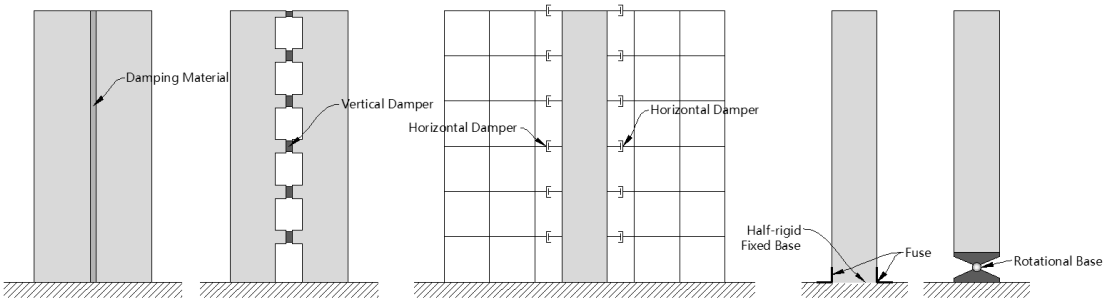
Abstract: The design philosophy of regarding shear walls as seismic damping controlled elements (by meliorating the constructional details of the wall or installing damping devices in it) has been proved to be an efficient approach to enhance the seismic performance of structures with shear walls. This paper summarized and illustrated the conception of structural system with seismic damping controlled shear walls (DSW) based on the existing relevant research findings. The walls are controlled using various deformation types of the walls to activate the damping devices, such as vertical dislocation between adjacent walls, base rotation or shear deformation of walls, etc. The performance-based design methodology of structural system with DSW, including design principles, structural performance indices and design method, was proposed on account of vertical damping mechanism. An example of DSW structure was designed utilizing the proposed methodology of which the feasibility was verified by nonlinear dynamic analysis.



1. THE CONCEPT OF DAMPING CONTROLLED SHEAR WALL SYSTEM

The R/C shear wall is always regard as the first defence system of a high-rise building because of its great stiffness and strength, however, the lack of deform ductility make the shear wall less reliable during earthquakes. Lots of methods have been proposed based on the concept of structural control to enhanced the seismic performance of R/C shear walls, such as slit shear wall #, damped coupling beam (Chung et al. 2009), composite in-filled damping wall (Zhao 2004), rocking wall (Wada et al. 2009), etc. With better performance in seismic ductility and energy absorption capability, these damping controlled walls become more and more concerned in the field of earthquake engineering.

Damping controlled shear wall system, DSW for short, is an improved shear wall structure system (i.e., structure with R/C walls, e.g., shear wall structure, frame-shear wall structure, frame-tube structure, etc.) with detail-changed and damping-controlled walls, of which the controlling measures include setting slits in the wall, appending energy dissipative devices (EDD), and so on. Well-designed DSW can show better seismic performance than traditional R/C wall system. The damping mechanism and expected performance of the damping-controlled wall which is mainly composed of the wall and EDDs, are defined below based on different earthquake precaution levels: Under small earthquakes, the wall and EDDs keep elastic, providing enough lateral stiffness and well serviceability, meanwhile, the dynamic properties of the wall can be adjusted by changing the parameters of EDDs; as for moderate or strong earthquakes, the EDDs would yield, resulting in the reduction of the wall's stiffness and the earthquake action, simultaneously the yielding EDDs would also dissipate earthquake energy instead of the structure by means of reciprocating elastoplastic deformation or interfacial friction, therefore, the failure mode of the wall is changed with higher ductility and severe damage can be avoided. Essentially, the DSW is a compromise between stiffness and ductility, that is, the wall is weaken in stiffness in order to get a controllable failure mode with enhanced ductility and equipped with EDDs to absorb earthquake energy and attenuate the dynamic response.

2. CLASSIFICATION OF DAMPING CONTROLLED SHEAR WALL SYSTEM

Damping effect of the DSW is mainly depend on the following two ingredient: the type (viz mechanism) and location of EDDs. A favorable type of EDD should be provided with stable hysteresis character, excellent low-cycle fatigue performance, perfect adaptability to the environment and temperature, and satisfactory durability, while an agreeable location of EDDs should be able to supply the EDDs with deformation large enough to dissipate energy efficiently and the structure should not be excessively damaged when EDDs reach the predicted maximum deformation. According to the existing research findings related to DSW, types/mechanisms of EDDs used in DSW are interfacial friction, mild steel damper, rubber and so on,

(a) Vertical coupled (b) Horizontal coupled (c) Base-released rocking wall

Figure 1 Classification of Damping Controlled Shear Wall System

and locations of EDDs are preset horizontal or vertical slits, structural joints, wall base, etc. Location of EDDs decides the mechanical mechanism, and then determines the analytical model, therefore, from the view of analysis and design, the DSWs can be classified as follows (Figure 1): (i) vertical coupled DSW, (ii) horizontal coupled DSW, and (iii) rocking-base DSW. The aforesaid three types of DSW can be combined in various forms in order to gain a satisfactory damping effect. This paper focuses on the seismic design methodology of DSW (VDSW for short).

3. PARAMETER STUDY OF VDSW

3.1 Analysis of VDSW Using Continuous Medium Method

Continuous medium method is a common used simplified method to analyze coupled shear walls, and the method is adopted herein to evaluate the mechanical property of VDSW, of which the dampers (i.e., EDDs), together with the R/C coupling beams, are considered as the equivalent coupling beams. As shown in Figure 2, the deflection δ of the equivalent coupling beam due to shear force V_d is

$$\delta = \delta_f + \delta_s + \delta_d = \frac{V_d l_b^3}{3EI_{cb}} + \frac{\mu V_d l_b}{GA_{cb}} + \frac{V_d}{2k_d}$$

Where $k_d = \dfrac{\partial F_d}{\partial u_d}$ is the stiffness of dampers.

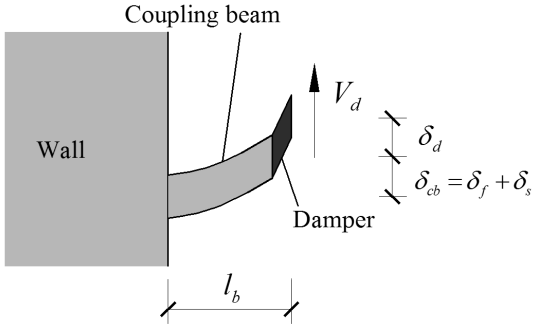


Figure 2 Deformation of coupling beams and damper (semi-structure)

Then we can get the stiffness of the equivalent coupling beam

$$K_{cb} = \frac{V_d}{\delta_{cb}} = \left(\frac{l_b^3}{3EI_{cb}} + \frac{\mu l_b}{GA_{cb}} + \frac{1}{2k_d} \right)^{-1} = \frac{3E\tilde{I}_{cb}}{l_b^3}$$

Where $\tilde{I}_{cb} = \dfrac{I_{cb}}{1 + \dfrac{3\mu EI_{cb}}{GA_{cb} l_b^2} + \dfrac{3EI_{cb}}{2k_d l_b^3}}$ is the converted moment of inertia of the equivalent coupling beam regarding the shear deformation of the beam and damper. Based on the derivation above, a factor is defined to reflect the magnitude of the Dampers' deformation with regard to the beams, that is

$$\lambda = \frac{K_{cb}}{2k_d} = \frac{3E\tilde{I}_{cb}}{2k_d l_b^3} \quad (1)$$

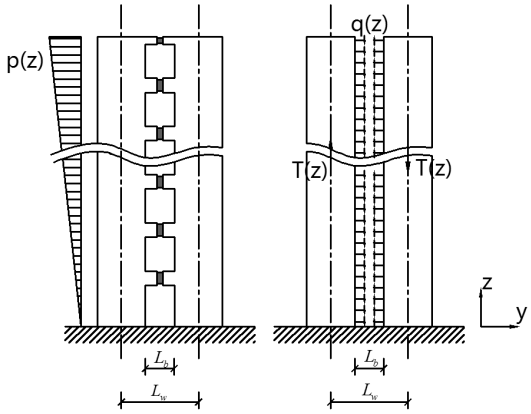

Figure 3 Continuous medium method for coupled wall

In the light of Figure 3, the differential equation of VDSW exerted by lateral load $p(z)$ based on the continuous medium method proposed by Rosman (Rosman 1964):

$$T''(z) - (\alpha k)^2 T(z) + \beta M(z) = 0 \quad (2)$$

If expressed with the variable of lateral deflection of the wall $y(z)$, the equation can rewrite as below:

$$\frac{d^4 y}{dz^4} - (k\alpha)^2 \frac{d^2 y}{dz^2} - \frac{1}{EI}\left[p(z) - \alpha^2 \left(k^2 - 1\right) M(z) \right] = 0 \quad (3)$$

Where $\alpha^2 = \frac{(GA)}{\sum EI_i} = \frac{12\tilde{I}_{cb}L_w^2}{L_b^3 h\sum I_i}$ (4)

($\alpha^2 = \frac{L_w k_d}{\sum I_i}$ When the coupling beam's stiffness can be regarded as infinite),

$\beta = \frac{\alpha^2}{L_w}$, $k^2 = 1 + \frac{\sum I_i}{\sum A_i c_i^2}$, $M(z) = \int_z^H p(\tilde{z})(\tilde{z} - z)d\tilde{z}$

is the overturning moment induced by lateral load $p(z)$.

Actually, equation (3) has a more generalized meaning, i.e., it can also describe the structural behavior of frame structures or frame-wall structures, but the expressions of α^2 and k^2 would be different (Smith et al. 1984). The analytical solutions of equation (3) were given by Bryan et al. under several typical loads (Bryan and Alex 1991). The solutions also can be achieved with the benefit of mathematical calculation software, such as MATLAB etc.

According to D'Alembert's principle, lateral $p(z)$ could be replaced by $-m\frac{\partial^2 y}{\partial t^2}$ when the wall is vibrated freely and the governing equation for undamped free vibration of the wall becomes:

$$\frac{\partial^4 y}{\partial z^4} - (k\alpha)^2 \frac{\partial^2 y}{\partial z^2} + \frac{m}{EI}\left[1 - \alpha^2\left(k^2 - 1\right)\frac{z^2}{2}\right]\frac{\partial^2 y}{\partial t^2} = 0 \quad (5)$$

An approximate solution of natural vibration period was given as follows (Heidebrecht and Smith 1973) :

$$T_n = \frac{2\pi}{\lambda_n^2}\sqrt{\frac{m}{E\sum I_i}} \approx \left(\frac{k^2 - 1}{\lambda_{fn}^4} + \frac{1}{\lambda_{sfn}^4}\right)\frac{2\pi}{k}\sqrt{\frac{m}{E\sum I_i}} \quad (6)$$

For the basic period

$$T_1 \approx \frac{H^4}{1.875^4}\left(k^2 - \frac{k\alpha H}{1.875 + k\alpha H}\right)\frac{2\pi}{k}\sqrt{\frac{m}{E\sum I_i}} \quad (7)$$

3.2 Evaluation of Dampers' deformation and VDSW's equivalent damping ratio

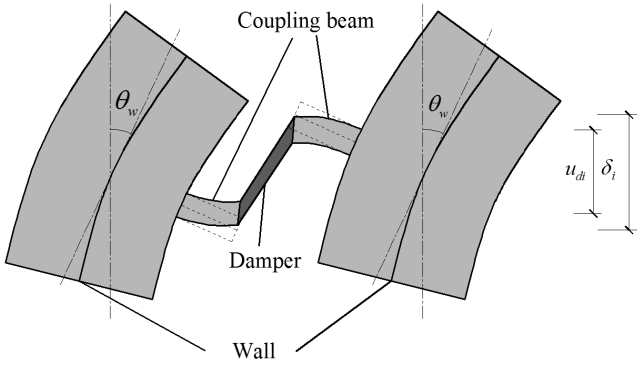

Figure 4 Geometrical Relationship Between δ_i and θ_w

The geometrical relationship between the dislocation of the coupling beam in the mid span δ_i and the rotational angel of the wall θ_w at the height of $z = h_i$ (i.e., the *i*-th floor) is shown in Figure 4, and it can be derived from the figure that

$$\delta_i \approx l_w\theta_w = l_w\frac{dy}{dz}\Big|_{z=h_i} \quad (8)$$

So the deformation of the damper is

$$u_{d,i} = \lambda\delta_i = \lambda l_w\frac{dy}{dz}\Big|_{z=h_i} \quad (9)$$

The equivalent damping ratio of VDSW can be expressed as $\xi_s = \xi_0 + \xi_d$, where ξ_0 stands for the damping ratio of original structure and ξ_d for the damping ratio provided by EDDs, which can be calculated as

$$\xi_d = \frac{W_d}{4\pi W_s} \quad (10)$$

Where, W_d, the energy consumed by EDDs, (together with the equivalent stiffness of damper in the *i*-th floor $k_{de,i}$) can be evaluated by:

$$W_d = 4\sum_i F_{dy,i}(1 - \eta_i)\left(u_{d,i} - \frac{F_{dy,i}}{k_{0,i}}\right) \quad (11)$$

$$k_{de,i} = \frac{F_{y,i} + \eta_i\left(k_{d0,i}u_{d,i} - F_{y,i}\right)}{u_{d,i}} \quad (12)$$

Where, $F_{dy,i}, u_{d,i}, \eta_i$ respectively stand for the damper's yielding force, maximum deformation, post-yielding, and stiffness ratio at the *i*-th floor.

W_s in equation (10) means the elastic potential energy of the structure, which is usually expressed as

$$W_s = \frac{1}{2}\sum F_i u_i \quad (13)$$

W_d, W_s can be evaluated using continuous medium method referred above in the initial stage of design, and the expressions turn out to be:

$$W_d = 4\sum_i F_{dy,i}(1 - \eta_i)\left(\lambda l_w\frac{dy}{dz}\Big|_{z=h_i} - \frac{F_{dy,i}}{k_{0,i}}\right) \quad (14)$$

$$W_s = \int_0^H \frac{1}{2}p(z)y(z)dz \quad (15)$$

Where, $y(z)$ is the solution of equation (3) using dampers' equivalent stiffness.

Besides, the distribution mode of dampers' mechanical parameters is one of the key issues in the design procedure of VDSW, for a proper distribution could bring EDDs' function into full play with relatively less dampers. There are two key parameters for displacement-type EDDs adopted herein: the initial stiffness k_{d0} and the yielding force F_{dy} (for ideal friction damper, only F_{dy} should be considered). When designing, the distribution of parameters can be assumed to be uniform, and after a pilot analysis the distribution mode should be adjusted in accordance with the deformation and shear force response of the coupling beams, while the adjustment should be carried out based on the principle of conservation of total dissipated energy.

3.2 Performance Indices

3.2.1 Coupling Ratio

Coupling ratio (*CR*), of which the definition is shown in equation (16), is chosen to be one of controlling indices for preliminary design. It has been proved that (Harries et al. 2004) *CR* is the key factor reflecting the mechanical performance of coupled shear walls, in detail, that is the coupling degree provided by coupling beams to the adjacent wall piers under lateral loads, that is to say, *CR* is essentially the synthesized representation of both the structural ingredient and load ingredient. Shear walls with an extremely large or small value of *CR* would resulting in poor structural performance, thus *CR* can be regarded as design index of coupled shear wall as well as performance evaluation index.

$$CR = \frac{L_w \sum V_{beam}}{L_w \sum V_{beam} + \sum m_i} = \frac{L_w \sum V_{beam}}{OTM} \tag{16}$$

Where OTM is the overturning moment induced by lateral loading.

As for the determination of a proper value of *CR*, M. J. N., Priestley (2005) pointed out that the value of *CR* that will induce tension force in the walls should be avoided; Harries (2001) gave the upper limit of CR, 66%, for a uniformly distributed coupling beams; El-Tawil (2010) indicated that 30%~45% may be an appropriate range of CR for design.

CR of VDSW referred in this paper subjected to triangularly distributed loading can be evaluated using the following equation (Chaallal and Nollet 1997):

$$CR = \frac{3}{k^2(k\alpha H)^2}\left\{\frac{(k\alpha H)^2}{3} - \cosh(k\alpha H) + \tanh(k\alpha H)\left[\sinh(k\alpha H) - \frac{k\alpha H}{2} + \frac{1}{k\alpha H}\right]\right\} \tag{17}$$

As for the elastoplastic stage of VDSW with yielding EDDs and wall bases, the expression of CR is given as follows:

$$CR = \frac{L_w \sum F_{dy}}{L_w \sum F_{dy} + \sum M_y} \tag{18}$$

Where $\sum F_{dy}$ is the sum of the dampers' yielding force and $\sum M_y$ is the sum of the walls' yielding moment at the base section.

3.2.2 Common Used Indices

The limit values of story drift angle, base rotation, and so forth, are commonly used indices to assess shear wall structures for performance based design of structures. The indices are divided into two types in the paper for different design purposes, i.e., absolute indices $[R]$ and relative indices γ, of which absolute indices is the limit values specified by design codes and relative indices referred herein means the variation (reduction for most cases) ratio of maximum structural response of unimproved/uncontrolled structures vs. absolute performance indices, that is:

$$\gamma = [R] / R_{\max} \tag{19}$$

For newly built traditional structures, it would be best to use absolute indices during design, but for structures to be retrofitted or damping controlled, relative indices may provide a more effective and purposive design procedure. The relative indices may need to be adjusted during iterative analyses after every pilot calculation.

4. DESIGN PROCEDURE OF VDSW

The basic framework of VDSWs' design methodology is proposed in the paper referring to the concept of seismic performance-based design and Chinese codes for design. The flowchart of the design procedure is drawn in Figure 5. According to the previous discussion on the expected performance of DSW under different earthquake precaution levels, the design procedure is divided into two stages, that is, the (I) elastic stage and (II) elastoplastic stage, which are described below in detail:

(I) Elastic stage: Firstly, perform the preliminary design of the uncontrolled structure in accord with traditional design method; then determine a proper period of the structure or a proper value of *CR* in order to obtain the initial stiffness of uniform dampers k_{d0}. Specific execution steps are as follows:

Step 1: Preliminary Design of uncontrolled structure. Referring to the specification of codes and design experiences, the profile of structural members is determined elementarily and then basic parameters of the structure referred before, such as $k\alpha H, T, CR$, etc., also should be calculated to get the knowledge of the initially designed structure.

Step 2: Determination of k_{d0}. The value of k_{d0} can be determined by equation (7) or (17) with a pre-selected basic period T_1 or coupling ratio CR. An alternative method to choose a proper value of T_1 is provided as follows referring to the displacement-based design method: With a preset value of α and deformation mode of the wall, such as the deformation shape under triangular loading or the first mode of free vibration, the structure is transformed into a SDOF system, and then the basic period of the equivalent SDOF system $T_{1,0}$ in line with the performance indices and displacement spectrum under frequently-occurred earthquakes, and with a updated α a new value of the period $T_{1,1}$ is got by the method above, then repeat the procedure until $T_{1,i} \approx T_{1,i-1}$, at that time, it can be regarded that $T_1 = T_{1,i}$. The determination of CR should be based on the design experiences, a rational range of CR would be 0.3~0.66 (El-Tawil et al. 2010).

Step 3: Performance Check. Check the structure response with the performance indices under frequently-occurred earthquakes by taking the value of k_{d0}

obtained in *Step 2*, and adjust k_{d0} if not satisfied.

The elastic stage can be carried out by design softwares for analysis and design to reduce the calculation and get a better accuracy. Dampers can be modeled as link elements in software or simply considered by reducing the stiffness of the coupling beams based on equation (1).

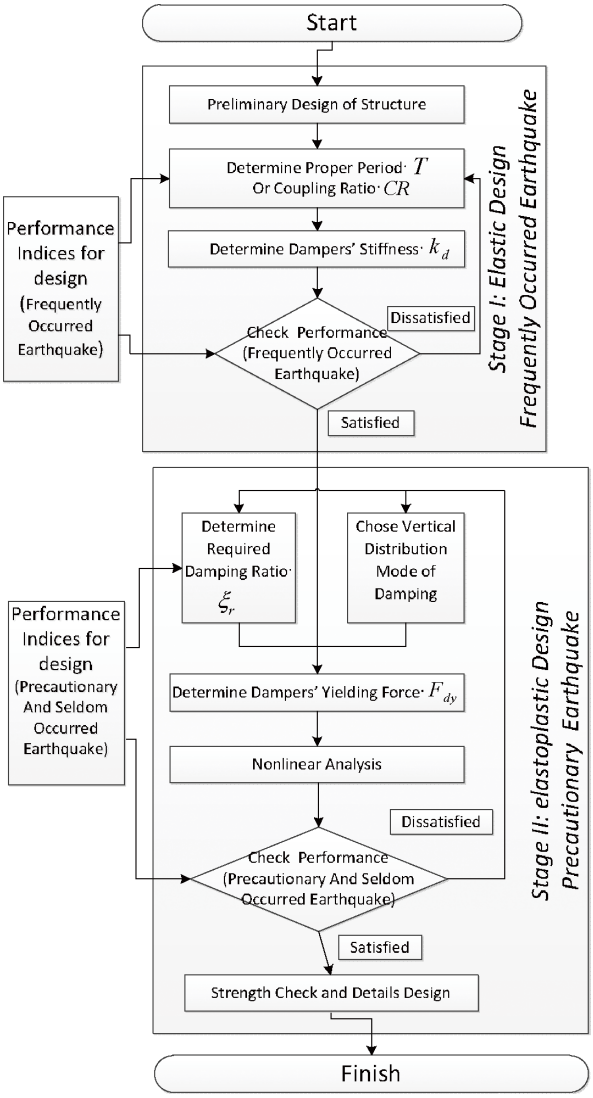

Figure 5 Design flowchart for vertical damping controlled shear wall

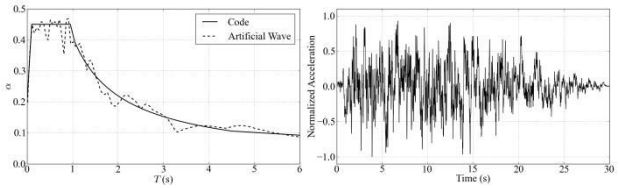
(II) Elastoplastic stage: Decide the required damping ratio ξ_r, and then the yielding force of the damper at every floor $F_{dy,i}$ can be obtained in combination with a proper distribution mode of the damping and the determined k_{d0}. Then exert the force capacity check and the adjustment of the reinforcement of the members' sections, and so does the detail design for the joints between the dampers and the coupling beams or wall piers.

Step 1: Determination of demand damping ratio ξ_r. ξ_r is decided in the step according to performance indices to the specification of codes and design experiences, and then the damping ratio provided by dampers $\xi_d = \xi_r - \xi_s$. Methods to find out ξ_r is discussed as follows: (i) Displacement based design method using absolute indices, i.e., the method involved equivalent SDOF system converting and displacement spectra, since the deformation mode would change due to the plastic condition of the dampers, so the equivalent stiffness of dampers k_{de} (approximately as $0.4k_{d0} \sim 0.6k_{d0}$ on experiences) should be adopted, and the calculation may needs some iterations. (ii) The method adopted in the paper based on relative performance indices. Analyze the structure with dampers' stiffness as k_{de} under precautionary earthquake and relative performance indices can be worked out according to equation (19) base on the analytical response. Thus ξ_r can be evaluated by comparison of multi spectra curves with various damping ratios.



Step 2: Determination of $F_{dy,i}$. The yielding force of the damper at every floor $F_{dy,i}$ can be worked out by equation (11) in combination with a proper distribution mode of the damping and the previously chosen k_{d0}. Then nonlinear dynamic analysis has better be executed in order to accommodate the distribution mode of the damping, to be exactly, the distribution of $F_{dy,i}$, a feasible redistribution of $F_{dy,i}$ is based on the response deformation of dampers with a constant $\sum F_{dy,i}$, i.e., $F'_{dy,i} = \dfrac{u_{di}}{\sum u_{di}} \sum F_{dy,i}$.

Step 3: Performance Check. With the selected parameters, performance check of the system under precautionary and seldom occurred earthquakes is carried out to find whether the system meets the predestinate performance demands. Several pilot calculation may be required to get a satisfactory damping effect, and after the iterative processes, the design procedure would be pulled back to the traditional routine, i.e., strength checking, reinforcement adjustment, and the like. So far, the design of VDSW would come to an end.

5. DESIGN EXAMPLE

A design example of a planer coupled shear wall reformed by vertical EDDs was carried out using the method mentioned above, and the design procedure is shown below, besides, the calculation is both conducted by the equations above and the FEM software named OpenSees in order to check the accuracy of the equations.

Earthquake Parameters and Performance Indices for design. Seismic precautionary intensity of the wall is 8 with the characteristic period of 0.90s, and then we could get the design spectrum in light of the code and an artificial earthquake wave in alignment with the spectrum, which are drawn in Figure 6. Story drift angle is chosen as the index for performance check, and limit values of story drift angle $[\theta]$ for shear wall structures are shown in Table 1.

(a) Spectrum (b) Artificial earthquake wave

Figure 6 Design Spectrum and earthquake wave

Table 1 Limit values of story drift angle for shear wall structures

Earthquake Precaution Level	Frequently Occurred	Precautionary	Seldom Occurred
$[\theta]$	1/1000	1/400	1/120

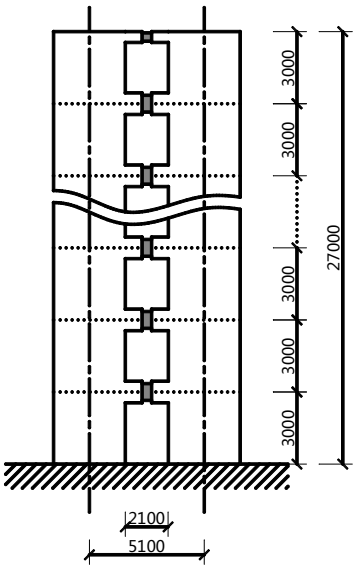


Figure 7 Profile of The Wall

(I) Elastic Stage

General Information of the original wall. The is demonstrated in , which is a ten-story planar coupling shear wall with the height of 27m. The thickness of wall piers is 250mm and the width is 3000mm, while the span of coupling beams is 2100mm and the section height is 1200mm. C40 concrete and HRB 335 steel bars are used for the construction of the wall. Seismic precautionary intensity of the wall is 7 with site IV. According to equation (7) and (17) we can work out that $k\alpha H = 13.502$, $T_1 = 0.545$ s, $CR = 0.798$, while the results calculated by the software are $T_1 = 0.575$ s, $CR = 0.792$.

Determination of k_{d0}. We use the *CR* method to determine the uniform stiffness of the damper k_{d0} for convenience. The initially assumed *CR* equals 0.66, and then it can be achieved that $k\alpha H = 5.300$, after that, based on equation (4), k_{d0} would be calculated out to be $k_{d0} = 102$ kN/mm , and the resulting basic period $T_1 = 0.694$ s by equation (17) and $T_1 = 0.704$ s by software.

Performance Check. The FEM model of the wall is set up to check the performance of the preliminarily designed VDSW under frequently occurred earthquake. After analysis, peak response of story drift angle is $1/1422 < 1/1000$, i.e., the performance is satisfied.

(II) Elastoplastic Stage.

Determination of ξ_r. The structure is analyzed with dampers' stiffness as $k_{de} = 0.7k_{d0}$ under precautionary earthquake and the resulting peak value of story drift angle is $\theta_{\max} = 1/303 > 1/400$, so relative performance indices is $\gamma = 303/400 = 0.758$, thus it can be evaluated by design spectra that $\xi_r = 11.34\%$, so $\xi_d = \xi_r - \xi_s = 6.34\%$.

Determination of $F_{dy,i}$. Assuming that $F_{dy,i}$ is uniformly distributed, we can work out the value of $F_{dy,i}$ with known k_{d0} and ξ_d, that is $F_{dy,i} = 85$ kN. Then the distribution mode of $F_{dy,i}$ is adjusted by the analytical response of dampers' deformation (Figure 8). Story drift angle response with different damping settings is shown in Figure 9. From the figure it can be found that the adjusted distribution of damping shows a better controlling effect. The analytical damping ratio provided by dampers is $\xi_d = 6.40\% \approx 6.34\%$.

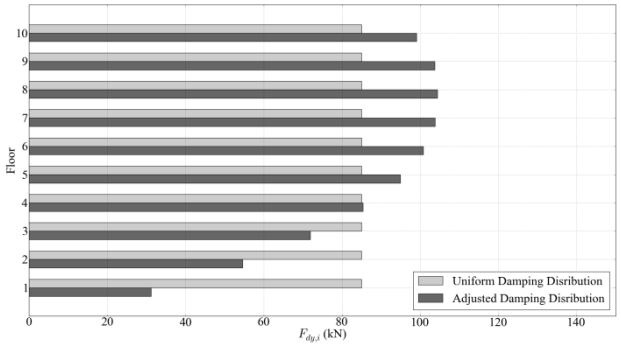

Figure 8 Distribution Modes of $F_{dy,i}$

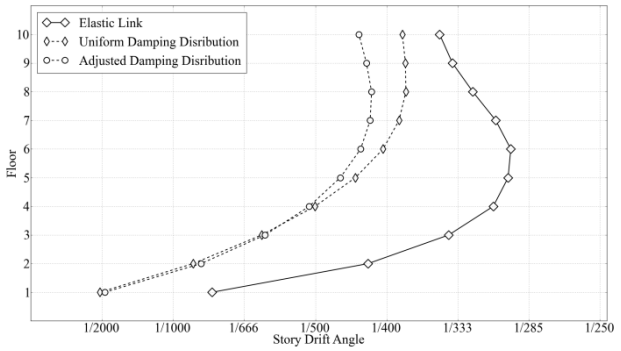

Figure 9 Story Drift Angle Response (Precautionary Earthquake)

Performance Check. Figure 9 exhibits that the peak response of story drift is $\theta_{\max} = 1/418 < 1/400$ under precautionary earthquake and the analysis of the designed

VDSW under seldom occurred earthquake was also performed, yielding the response of Story drift angle is $\theta_{\max} = 1/147 < 1/120$. The hysteretic curves of the damper with maximum deformation under different earthquake levels are shown in Figure 10 and the stable, plump curves prove that dampers are efficiency in energy dissipation. The analytical results mean that the performance demand is satisfied thus the selected parameters of dampers are agreeable. Since the paper is mainly focusing on the design of the dampers, the succeeding design steps are omitted.

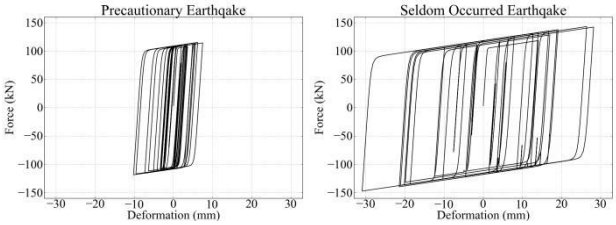

Figure 10 Hysteretic Curves of Dampers

6. CONCLUSIONS

The paper has summarized and represented the concept, brief profile, and classification of damping controlled shear wall system. The design methodology of vertical coupled DSW is proposed based on the simplified analysis of the structure system and a design example is performed to verify the feasibility of the method. Though it is of efficiency, the method should be improved in order to avoid interactive calculations.

Abstract: The self-centering steel plate shear wall (SC-SPSW) system has been developed to combine the lateral load resisting benefits of the SPSW with the self-centering capabilities of post-tensioned connections by replacing the typical moment resisting connections of a conventional SPSW with post-tensioned (PT) beam-to-column connections. This system resists the lateral load and dissipated energy through development of tension field action and yielding in the thin steel infill panel, known as the web plate, while the PT beam-to-column connections reduce the potential for damage in the beams, and provide system recentering and post-earthquake functionality. In the event that yielded or damaged web plates require repair or replacement following an earthquake, the building is designed to return to a recentered and functional state while the relatively quick and easy repair of the plates takes place, greatly reducing the downtime associated with costly beam and column repairs. A performance-based design procedure has been developed for the SC-SPSW, and analytical and experimental studies show that the system is capable of meeting proposed performance objectives.

1. INTRODUCTION

Steel plate shear walls (SPSWs) have been used as the primary lateral load resisting system of buildings in high seismic areas (Selie and Hooper 2005, Sabelli and Bruneau 2007). When SPSWs are subjected to severe earthquakes, the thin steel infill plates, referred to as the web plates, buckle in shear and resist lateral load through the development of tension field action. Energy dissipation is provided primarily through yielding in the diagonal tension field. The moment-resisting (MR) beam-to-column connections in conventional SPSWs can develop plastic axial-flexural hinges due to the forces imposed by the web plate during sever earthquakes, which can lead to significant residual deformations and costly repairs of the horizontal and vertical boundary elements (HBEs and VBEs).

In an attempt to reduce post-event repair and loss of functionality, the SPSW has been combined with the self-centering capabilities of post-tensioned (PT) beam-to-column connections to create a self-centering SPSW (SC-SPSW) system. In a SC-SPSW (Fig. 1a), the typical MR HBE-to-VBE connections are replaced with PT connections (Fig. 1b) that allow the connection to rock about the HBE flanges and form a gap, θ_r (Fig. 1c). The formation of this gap, referred to as decompression, causes the PT strands in the connection to elongate elastically, which provides the forces necessary to recenter the building, and prevents damage at the HBE ends. Unlike other self-centering frame systems (Garlock et al. 2007, Kim and Christopoulos 2008) where the lateral strength of the system is primarily provided by the strength of the PT connection and its components, the lateral strength of the SC-SPSW is primarily provided by the web plate, which also serves as the replaceable energy dissipating fuse of the system, while the PT connections primarily serve to recenter the building after an earthquake.

This paper presents an overview of the mechanics and behavior of the SC-SPSW system. An outline of a proposed performance-based design procedure for the SC-SPSW system and a description of current SC-SPSW subassembly experimental studies are also presented.

2. SC-SPSW BEHAVIOR

2.1 HBE Forces

The HBE is a key component in the SC-SPSW system. Understanding the mechanics of the HBE and the interaction of the web plate and PT connection forces acting on the HBE is important in understanding the behavior of the system and SC-SPSW design concepts.

Fig. 2 shows a free-body diagram of an intermediate HBE after connection decompression, where $\omega_{b(i)}$ and $\omega_{b(i+1)}$ are the distributed forces from the yielded web plate below and above the HBE acting in the direction of the diagonal tension field, T_{PT} is the total force of the PT strands acting on opposite flanges at the ends of the HBE, referred to as the connection rocking points, $P_{HBE(VBE)}$ is the compressive force acting at the HBE rocking points that is due to the distributed web plate forces pulling in the VBEs, $P_{HBE(web)}$ is the reaction force at the ends of the HBE due to the net axial distributed load acting on the HBE when the web plates above and below the HBE are of different strength or thickness, and V_L and V_R are the shear reactions at the left and right ends of the HBE, respectively. Expressions for $P_{HBE(VBE)}$ and $P_{HBE(web)}$ can be found in Sabelli and Bruneau (2007), and expressions for the shear forces and total PT force, including losses due to HBE shortening, can be found in Dowden et al. (2011). Although in construction, radial corner cutouts (as shown in Fig. 1a) would be necessary to prevent localized damage to the web plate during connection decompression, for the purpose of simplicity in this paper, the corner cutouts are ignored, and the web plate is assumed to extend over the entire length of the HBE, L.

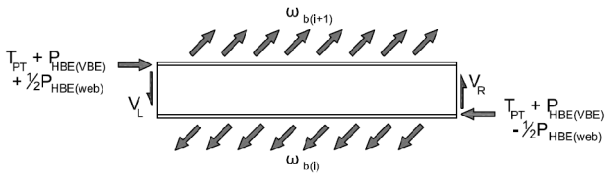

Figure 2: Free-body diagram of intermediate HBE

For design of the HBE, a moment diagram must be developed from the free-body diagram in Fig. 2 to better understand the interaction between the PT and web plate forces acting on the HBE. As shown in Fig. 3, the HBE moment diagram can be separated into components. Fig. 3a shows the linear moment diagram component due to the compressive forces from the total PT and VBE pull-in forces acting at the rocking points. The magnitude of the moment at the end of the HBE due to this component is the compressive reaction force from these components, T_{PT} + $P_{HBE(VBE)}$, times the lever arm of $d/2$, where d is the depth of the HBE. Fig. 3b shows the parabolic moment diagram component due to the vertical components of the net distributed web plate force acting on the HBE, $\Delta\omega_{yb}$. Fig. 3c

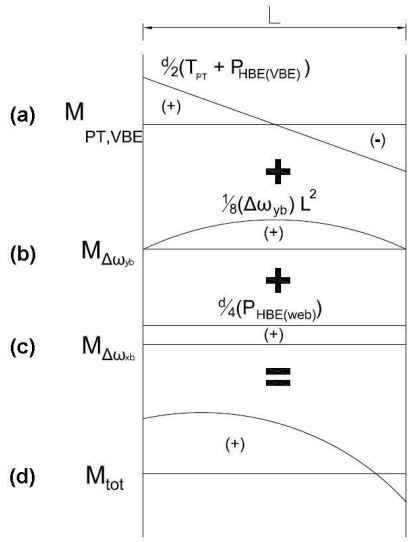

Figure 3: (a) Compression flange reaction component, (b) net vertical web plate component, (c) net horizontal web plate component, and (d) combined moment diagram of intermediate HBE

shows the constant moment diagram component due to the net horizontal distributed web plate forces acting on the HBE. The magnitude of this component is the end reaction due to the net horizontal web plate loading, $\frac{1}{2}P_{HBE(web)}$, times the lever arm of $d/2$. Each of these components can be superimposed onto one another to determine the total moment diagram shown in Fig. 3d. More details on the moment, shear, and axial force diagrams of an intermediate HBE in a SC-SPSW can be found in Dowden et al. (2011).

It is important to note in Fig. 3d that it is possible for the maximum moment to be along the length of the HBE. This condition makes the HBE susceptible to the occurrence of in-span flexural hinging, which can affect development of the tension field and can lead to a reduction of lateral load resistance in the SPSW (Purba and Bruneau 2010). In-span hinging can be avoided if the linear component of the moment diagram (i.e. the PT and VBE pull-in force contributions) is sufficiently large to force the maximum moment to occur at the end of the HBE. Since the PT force is dependent on the amount of gap opening, which is related to the column drift, the PT can be design in such a way to ensure that the maximum moment occurs at the end of the HBE at a specified drift level before the onset of HBE yielding (Dowden et al. 2011), which will prevent the detrimental occurrence of in-span hinging in the HBE.

2.2 SC-SPSW Cyclic Behavior

The cyclic behavior of the SC-SPSW can be determined by combing the behaviors of the individual system components: the SPSW and the PT frame responses, as shown in Fig. 4.

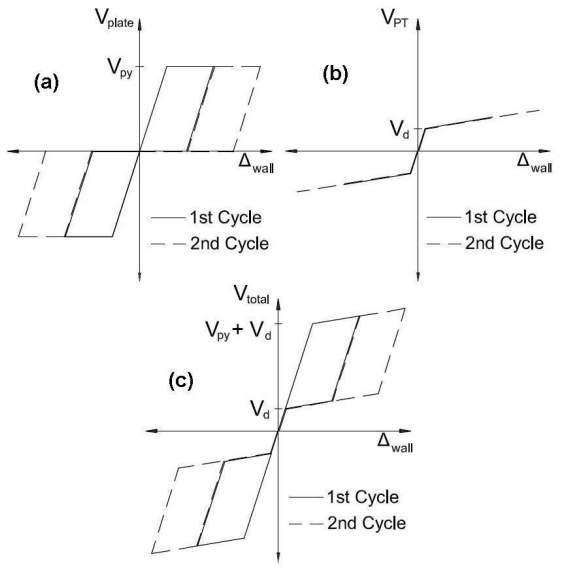

Figure 4: Idealized system-force-displacement response of (a) SPSW, (b) PT frame, and (c) SC-SPSW

The idealized SPSW behavior (Fig. 4a) is characterized by a large initial stiffness due to the lateral force resistance provided by the tension field, followed by yielding of the plate at a load V_{py} in the direction of the tension field. The pinched hysteresis is due to the thin web plate buckling in compression under reverse cyclic loading. As a result, the low SPSW stiffness after web plate unloading requires smaller restoring forces in order to recenter the system, a benefit of SPSWs that is leveraged when combined with the recentering capabilities of the PT connections. Note that in the idealized behavior shown in Fig 4a, the entire web plate is assumed to yield simultaneously and behave in an elastic-perfectly-plastic manner, and the buckling strength of the web plate in shear is ignored. Also, the idealized SPSW is assumed to not resist any loading until it reaches its previous peak plastic strain, after which point it resists additional load with its initial stiffness. As will be discussed later, SPSW behavior is more complex than this, but these idealizations are made to facilitate an understanding of general SPSW cyclic behavior.

The PT frame behavior is characterized by a bilinear elastic behavior. The initial stiffness is equivalent to that of a welded moment resisting frame. After decompression at a load V_d, the frame stiffness is reduced due to the formation of the gap in the connection. Assuming that the PT and frame elements remain elastic, the PT frame system follows the same force-displacement path upon uploading, resulting in no energy dissipation contribution from the PT frame alone.

Combination of the two systems to form the SC-SPSW results in a flag-shaped hysteresis that is typical of self-centering systems, where the primary strength of the system is provided by the SPSW and the recentering capability is provided PT frame after the web plate is fully unloaded, returning the building to zero displacement.

2.3 PT Connection Behavior

The PT connection behavior is best characterized by a plot of the moment at the connection, M_{conn}, versus gap rotation, θ_r. Fig. 5 shows a schematic of the idealized SC-SPSW connection response with the same simplifying assumptions of web plate behavior that were made in Fig. 4. Before connection decompression, the gap rotation is zero. The moment at the end of the HBE at the time of decompression, M_d, is determined by the HBE depth, d, and the initial force in the PT, T_o.

$$M_d = T_0 \, d/2 \tag{1}$$

For purposes of simplification, the connection shown in Fig. 5 is assumed to decompress before the web plate develops any significant forces.

After decompression, the connection strength increases due to the increase in axial load at the ends of the HBE caused by the increase in web plate forces. As shown previously, the connection moment is determined by the total compressive force at the end of the HBE acting with a lever arm of $d/2$. Also note that in Fig. 5, it is possible for the ultimate connection capacity under positive and negative loading to be different. This is due to the $\pm \frac{1}{2}P_{HBE(web)}$ term in the end reaction force in Fig. 2. For example, for a SC-SPSW being loading to the right in Fig. 2, if the plate thickness below the HBE is larger than the thickness above, then the left connection will have a higher capacity than the right due to the net leftward force from the distributed web plate forces.

Assuming elastic-perfectly-plastic yielding of the web plate, after web plate yielding, the connection strength increases at a rate of k_d^{θ} (Garlock 2002), which primarily depends on the HEB depth, d, and the total PT axial stiffness. Upon unloading, the connection initially looses strength due to the loss of effective post-tensioning provided by the web plates as they unload. Once the web plates are fully unloaded, the connection recompresses at a stiffness of k_d^{θ}.

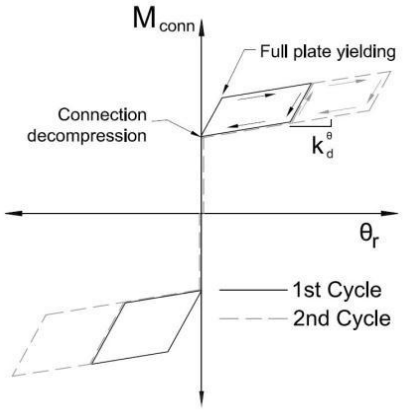

Figure 5: SC-SPSW PT connection response

3. PERFORMANCE-BASED DESIGN APPROACH

The behavior characteristics of the SC-SPSW allow for the system components to be designed to meet a specified performance level under a specified seismic input level. The seismic hazard levels considered in the proposed SC-SPSW performance-based design (PBD) approach are earthquakes with a 50%, 10%, and 2% probability of exceedence in 50 years (denoted as 50/50, 10/50, 2/50, respectively). These earthquake hazard levels are approximations of the frequent, design, and maximum credible earthquakes, respectively.

3.1 Performance Objectives

The PBD procedure for the SC-SPSW was developed to achieve the following performance objectives:

1. *No connection decompression under wind or gravity loading.*
2. *System recenters and no repair required under frequent* (50/50) *earthquake demands.* Recentering is assessed using a residual drift limit of 0.2%%, corresponding to out-of-plumb limits in construction. The no repair limit state requires that the web plate remain essentially elastic and is assessed using a peak story drift limit of 0.5%, the median drift at which web plate repair is required in conventional SPSW experimental studies (Baldvins et al. 2010).
3. *System recenters and only web plate repair required under design* (10/50) *earthquake demands.* The web plate may have significant yielding; however, the boundary frame and PT elements should remain elastic and the system should recenter. The damaged web plate can be replaced relatively quickly and simply, resulting in a more rapid return to occupancy following an earthquake (Qu et al. 2008). The story drift at this hazard level should be less than the 2% code-based drift limit for design level earthquakes.
4. *Collapse prevention for the maximum credible earthquake* (2/10). Residual drifts and minor frame yielding may occur; however, soft-story mechanisms and significant PT and frame yielding should be avoided. A target drift limit of this performance objective was assumed to be 4%, based on engineering judgment and the drift at which significant strength loss was observed in conventional SPSW experimental studies (Baldvins et al. 2010).

Since designing for elastic (no repair) behavior under frequent earthquake demands may not be feasible or economical in some locations with significantly large 50/50 earthquake accelerations. For this reason, Performance Objective 2 (the no repair performance objective) is considered an optional objective.

3.2 PBD Procedure

The following procedure was developed to meet the previously described performance objectives:

1. Make initial assumptions about SC-SPSW geometry and number of walls in the building.
2. Determine the seismic loads and lateral load distribution. Here a modified load distribution as developed by Chao et al. (2007) was used to account for higher-mode effects, as SC-SPSWs and other self-centering PT systems (Garlock 2002) designed using typical code-based load distributions have exhibited larger drift demands and damage in the upper stories due to these higher-mode effects.
3. Design the web plates to remain elastic under 50% in 50 year loads. If the optional "no repair" performance objective is not being considered, then design the web plates for code-based design forces (approximated here as the 10/50 shear forces reduced by a response modification factor, R).
4. Design the PT connection to have sufficient stiffness to ensure recentering under the influence of P-Delta effects (Clayton 2010).
5. Capacity design the PT and HBE to remain elastic and prevent in-span hinging at a target drift of 4%, corresponding to the 2/50 earthquake demands. (Dowden et al. 2011)
6. Capacity design the VBE to remain elastic up to 5% drift (Berman and Bruneau 2008).
7. Check that design meets code-based drift limits and that the required amount of PT can fit reasonably within the depth of the HBE.
8. Iterate as needed until a final design is converged upon.

3.3 Evaluation of Design Procedure

To assess the adequacy of the proposed design procedure, seven different 3- and 9-story SC-SPSW buildings were designed according to the previously described procedure. These buildings were based on the SAC building located in the Los Angeles, California area (Gupta and Krawinkler 1999). Variations in the prototype buildings were inclusion of the optional "no repair" performance objective and variation in the number of SC-SPSWs in the building. Details of these designs can be found in Clayton (2010).

To determine if the buildings designed according to the proposed procedure were able to meet the intended performance objectives, a numerical model of each SC-SPSW was subjected to a suite of 60 ground motions representing the three seismic hazards considered in the design (Clayton 2010). The performance of these models was evaluated by a series of response parameters, including the peak story drift, the residual story drift, the occurrence of PT yielding, and the occurrence of HBE and VBE yielding as evaluated by the interaction equation per Eqn. H1-1 (AISC 2005).

As an example, the median and 84th percentile peak

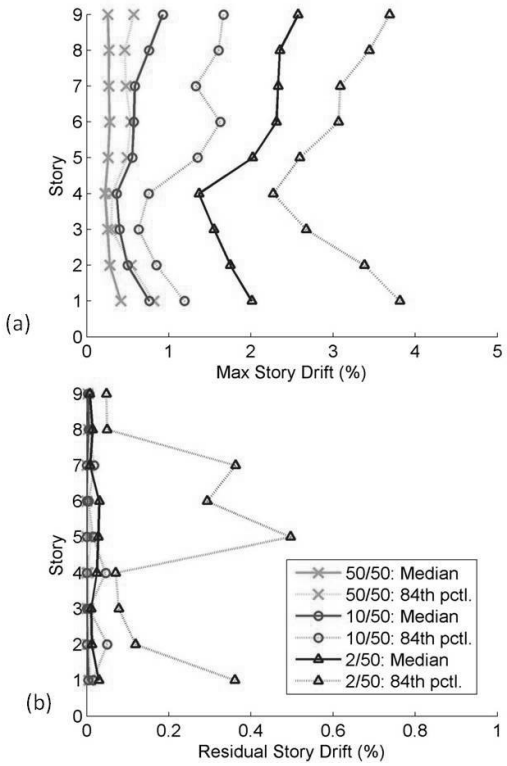

Figure 6: Example of median and 84th percentile (a) peak story drift sand (b) residual story drifts at each hazard level for a 9-story SC-SPSW.

story drift and residual story drift under each hazard level for a typical 9-story SC-SPSW for which the no repair performance objective was considered optional is shown in Fig. 6. Fig. 6b shows that the SC-SPW was able to recenter (residual story drift less than 0.2%, as described previously) at the 10/50 hazard level as was intended in Performance Objective 3. Fig. 6a shows that the peak story drifts were less than the 2% code-based drift limit at the 10/50 hazard level (Performance Objective 3). This figure also shows that peak story drifts were less than the 4% drift limit assumed for design at the 2/50 hazard level, meaning that there were little to no occurrences of PT or frame yielding at this hazard level, thus meeting Performance Objective 4. Additional results for the other buildings showed that the SC-SPSWs designed according to the proposed PBD procedure were capable of meeting the intended performance objectives with little or no modification to the design procedure (Clayton 2010).

4. EXPERIMENTAL STUDY

Experimental investigation of the SC-SPSW system is currently taking place at the University of Washington. The initial experimental testing of a SC-SPSW subassembly is aimed at capturing the effects of the interaction of the PT and web plate forces acting on an intermediate HBE and to validate numerical modeling methods.

4.1 Test Setup

A schematic of the test setup is shown in Fig. 7. The 2-story configuration of the setup was used to simulate the boundary conditions for an intermediate HBE (middle HBE in Fig. 7), where the web plates above and below the HBE induce an effective post-tensioning in the HBE due to pull-in of the VBEs ($P_{HBE(VBE)}$). The SC-SPSW subassembly measures 3235 mm wide (centerline VBE dimension), with story heights (HBE centerline dimensions) of 1724 mm.

Due to the HBE rocking about its flanges, as a gap forms in the connection, the VBEs spread apart (Garlock et al. 2007). This beam growth is accommodated in the physical model with a roller under the left VBE, allowing the frame to expand horizontally without imposing additional compressive forces on the middle HBE due to VBE restraint at its base. For similar purposes, the top and bottom anchor HBEs also have PT HBE-to-VBE connections, such that the gap opening, and thus the beam growth, at these levels are similar to the middle HBE.

Shear forces at the PT HBE-to-VBE connections are transferred through slotted shear tab connections. Long slotted bolt holes are used in the shear tab to allow for connection rotation. The HBE flanges at the connections are also reinforced to protect against local damage due to the large compressive forces acting on the flanges after decompression. Also, corner cutouts are provided in the web plates to prevent localized damage in the plate as a gap forms in the connection.

The boundary frame elements are of A992 steel and are designed to remain elastic during testing so that they can be reused for multiple tests. The PT strands are 13 mm diameter Grade 270 seven-wire strand with reusable 3-wedge barrel anchors at each end. The PT strands are all placed symmetrically about the centerline of the HBE within the depth of its flanges and are also designed to remain elastic during testing. The web plates are of ASTM A1008 steel with a yield strength of approximately 190 MPa and are connected to the boundary elements via a bolted fishplate connection. The bolted web plate-to-fishplate connection allows for the yielded web plates to be easily removed and

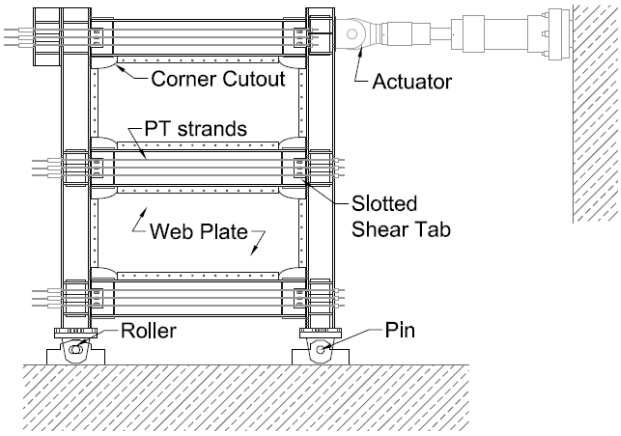

Figure 7: Schematic of test setup.

replaced following each test.

The test matrix includes variations in the web plate thicknesses, HBE depth, initial PT force, and number of PT strands in the connection to study the effects of web plate and PT connection strengths and stiffnesses.

4.2 Instrumentation and Displacement History

Instrumentation was installed on the specimen to measure applied loads, global displacements, gap rotations, PT forces, and HBE and VBE strains. The cyclic displacement history for the tests are a modification of ATC-24 (ATC 1992), similar to the history used in previous SPSW experiments by Vian et al. (2009), with 3 cycles at each increment of 0.25 of the estimated yield displacement, δ_y, up to δ_y. After this point, the peak displacements were incremented in multiples of δ_y up to approximately 2% drift, after which, the peak displacements were increased in increments of 0.5% drift up to 4%. Three cycles were done at each displacement increment up to approximately 1% drift, and only two cycles were done at each subsequent drift level.

4.3 Experimental Results and Observations

The results presented here are for a test with W18x106 HBEs with 6 PT strands at each HBE, where each strand was post-tensioned to an initial force of 55.6 kN. The web plates in this test were 20 Gage (0.9mm thick). Fig. 8 shows the force-displacement response of the test specimen up to 4% drift.

In comparing the hysteretic response of the system with that of a general idealized SC-SPSW system (Fig.4c), notice that the test specimen exhibits the expected flag-shape hysteresis with recentering (residual drift < 0.2%) at zero-loading. As noted previously, the web plate hysteretic behavior is more complex than the idealized assumptions made in Fig. 4. For example, the web plate in the specimen is capable of resisting a portion of lateral load with a reduced stiffness before it reaches its previous peak plastic strain, as seen by the reloading stiffness in repeated cycles in Fig. 8.

The reduction of strength at larger drift levels was due to tearing of the web plate that was first observed at 2.5% drift. The web plate tearing was typically observed along the edge of the fish plate, and was most likely due to out-of-plane deformation of the web plate being restricted by the edges of the fishplate that is welded to the HBE. At 4% drift, the tears in the web plate propagated through the entire panel, causing a large reduction in lateral load capacity of the SC-SPSW; however, at this drift level, no damage was observed in the boundary frame and PT elements. This web plate damage, and ultimate failure, is believed to be a result of the bolted fishplate connection that was used to facilitate rapid replacement of the web plates for multiple tests; therefore, future tests will be done with a welded web plate-to-fishplate connection detail that would typically be used in practice to determine how the progression of web plate damage depends on the type of web plate connection detail.

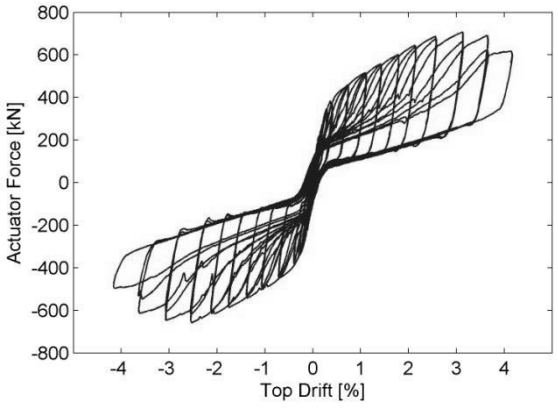

Figure 8: Force-displacement response of specimen.

5. CONCLUSIONS

The fundamental behavior of the SC-SPSW was presented through a description of the web plate and PT force interaction in the HBEs and by developing an understanding of the cyclic behavior of the SPSW and PT frame components of the SC-SPSW system. The fundamental SC-SPSW behavior was used to develop a set of performance objectives to be used in a performance-based design (PBD) procedure for the system. A summary of analytical results showed that the proposed PBD procedure was capable of producing 3- and 9-story SC-SPSWs that could meet the proposed performance objectives at three different seismic hazard levels.

The experimental investigation of a SC-SPSW subassembly was introduced. The force-displacement response for a single specimen was presented. The overall behavior of the specimen matched relatively well with the general idealized behavior assumed in the aforementioned description of cyclic SC-SPSW behavior, with the exception of the complex web plate behavior that was neglected in the idealization. The test specimen was able to recenter when loaded up to 4% drift with no damage to the frame and PT members. Strength loss in the system was due to tearing in the web plates along the bolted web plate-to-fishplate connection. This damage is believed to be due to the bolted connection detail that was used for repeatable testing of the specimen; however, future tests will be conducted to evaluate whether similar web plate damage is observed when a more conventional welded web plate-to-fishplate connection detail is employed. These experimental results, along with others, will later be used to validate numerical SC-SPSW models and determine the methods for SC-SPSW construction.

Abstract: In present paper Endurance Time (ET) method which is a new time-history based dynamic pushover procedure is introduced and application of this method in seismic analysis of steel concentrically braced frames is studied. In this method structure is subjected to a set of predesigned increasing acceleration functions and various responses of the structure are recorded during synthetic seismic excitation. The averages of maximum values for various responses in nonlinear time-history (NTH) analyses extracted from real ground motions are expected to be close to those obtained from ET method up to equivalent target time. For this purpose a set of 9, 11, 13 and 15 stories steel frames were designed and plastic hinge method was selected as source of nonlinearity in all cases. Results were compared based on maximum story displacement, interstory drift ratio and story shear obtained from two methods. Results show satisfactory consistency between two methods. Finally, it was concluded that the ET method can be used as alternative method for seismic analysis of concentrically braced steel frames.

1. INTRODUCTION

Because of the simplicity, reality and accuracy of performance-based earthquake engineering (PBEE), many of structural codes are moving towards using this concept in their design guidelines (Hamburger, 1998). In PBEE, structures should be capable of satisfying various performance levels, under a spectrum of design ground motions which are extending from minor to severe excitation levels. Recent developments in computational technology lead to the application of numerically intensive analysis methods in the field of earthquake engineering and reduce the amount of uncertainties in PBEE.

Quest to find new analysis methods which can estimate actual seismic performance of engineering structures under various excitation levels, always was one of important concerns of earthquake engineers. Endurance Time (ET) method which is introduced by Estekanchi et al. (2004) is basically a simple dynamic pushover test that tries to predict various responses of structures at different excitation levels by subjecting them to some predesigned intensifying dynamic excitations which are called Endurance Time Acceleration Functions (ETAFs) (Riahi et al., 2009). Because of the increasing demand of the ETAFs, structures gradually go through elastic to yielding and nonlinear inelastic phases, finally leading to global dynamic instability.

Application of ET method in linear seismic analysis of structures has been studied before (Estekanchi et al., 2007). In this study, a-series of ETAFs have been applied to various moment resisting and braced steel frames which were designed based on Iranian National Building Code (INBC) and the results of analysis were compared with conventional equivalent static and response spectrum seismic analysis procedures. It was found that story drifts and internal forces from ET method are consistent with response spectrum analysis and static analysis results within acceptable tolerances. In another case, Estekanchi et al. (2008) were used damage indexes in ET method as the endurance criteria. In this investigation, correlation between the values of various damage indexes obtained from Nonlinear Time-History (NTH) analysis of steel moment frames subjected to scaled earthquakes were compared with those from ET method at the same level of spectral acceleration. It was found that the average value of various damage indexes can be estimated from ET analysis results. Application of ET method in nonlinear analysis of SDOF system was investigated by Riahi et al. (2009) as well. In this study they compared the results of ET analyses with real ground motions analysis results in different strength ratio, ductility and damping ratios. Also they considered the effects of stiffness degeneration and strength deterioration in studies. They showed that the results of ET method are in good agreement with the exact response history results of the similar ground motions.

In another study, Riahi et al. (2009) were investigated the accuracy of the ET method in estimating average deformation demands of low and medium rise steel frames using f-series of ETAFs. In their study an

elastic-perfectly-plastic model and also a bilinear material model were considered. It was shown that, although the results of the ET analysis are not exactly consistent with the results of ground motions analysis, the ET method can clearly identify the structure with a better performance even in the case of structures with a relatively complicated nonlinear behavior.

In present paper, the concept of ET method is first described and brief review is done on characteristics of second generation of ETAFs which used in this study. Compliance and level of accuracy of this method in nonlinear seismic analysis of mid-rise and high-rise steel concentrically braced frames (SCBF) is investigated. The accuracy of ET method in prediction of the response in SCBFs is investigated by using a set of 9, 11, 13 and 15 stories frames with three bays. In addition, plastic hinge method is used as source of material nonlinearity behavior in present study. It is shown that ET analysis estimates the results of NTH analysis with reasonable accuracy.

2. CONCEPT OF ENDURANCE TIME METHOD

ET method is a time-history based dynamic pushover procedure used in seismic analysis and performance evaluation of structures by measuring their resilience when they are subjected to ETAFs (Riahi et al., 2009). In this method, numerical or experimental model of structures are subjected to intensifying ETAFs and structural responses, such as drifts and shears are recorded during the analysis up to the point where the structure collapses or the analysis is terminated. Then behavior of the structure can be observed at target time which is calculated using design response spectrum.

If this test is utilized for two frames with unknown properties, the longer endurance time, which is time duration from start of the test or analysis to collapse or target point, is interpreted as better performance of that frame (Estekanchi et al., 2008). In this method after design of frames based on appropriate codes, the system is excited using a set of ETAFs and equivalent target time is calculated by suitable method for each structure respectively. Various responses of the frames at equivalent target time describe behavior of the frame in a certain performance level. In the next step, the maximum results obtained from ET method up to equivalent target time are compared with those obtained from NTH analysis of real ground motions.

3. SPECIFICATION OF SCBFs, GROUND MOTIONs and ETAFs

A set of SCBFs with different number of stories were selected as case studies. This set consists of 2D regular frames with 9, 11, 13 and 15 stories and three bays which lead to categorize of them as mid-rise and high-rise frames. These frames are designed according to the UBC-97 design code (1997). All considered frames are classify in group 4 of occupancy category based on UBC-97 and therefore seismic importance coefficient is set to one in these frames. The main purpose in design of such structures is to minimize loss of life under earthquake ground motions with 475-year return period (10% probability of occurrence in 50 year). It means that based on FEMA356 (2000) life safety (LS) performance level should be satisfied in this condition.

It is not worthy that in order to considering the stiffness effects of infilled frames and also non-structural components of structure, stronger sections were considered in present analyses rather than designed sections so that the first mode period of the simulated model be close to analytical period in code. The section properties of all frames and also characteristics of them are described in table 1.

The tri-linear material model with a post-yield stiffness equal to 3% of the initial elastic stiffness and considering effects of strength degeneration were used to study the nonlinear behavior of the frames. This model has been used widely in previous investigations and therefore represents a benchmark to study the effect of hysteretic behavior. Furthermore, recent studies have shown that this is a reasonable hysteretic model for steel beams (Foutch and Shi, 1998). For more realistic nonlinear behavior, the chord rotation model is also used in this study. This model is the easiest to use and FEMA-356 gives specific guidelines for this model. To apply these material models in the analysis, the PERFORM software was used (PERFORM user manual, 2010). Only one (horizontal) component of the ground motion has been considered, while dynamic soil-structure interaction is neglected. P-Δ effects have been included in the analysis. A viscous damping of 5%, as customary for these types of frame, has been applied in the analyses. This value of damping is consistent with the value used for generating codified response spectra and ET acceleration functions.

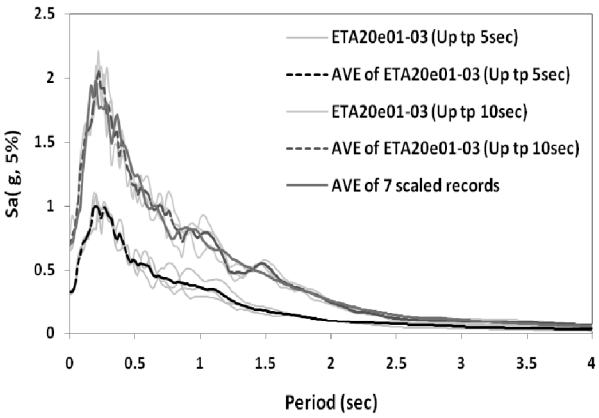

Figure 1 Acceleration response spectrum of ETA20e at various times for ξ=5%

For analysis of frames based on ET method e- and f-series of ETAFs which are shown as ETA20e01-03 and ETA20f01-03 are used in present study. These sets were generated using the average of scaled response spectrum of seven ground motions called as GM1 set which were selected be Valamanesh et al. (2010). These accelerograms which are recorded on site class C and used in FEMA 440 are presented in table 2. The smoothed spectrum of GM1 is target spectrum in generating e- and f-series. As it is clear in figure 1, the response spectrum of a window of ETAFs from t_0=0 to t_1=10 matches reasonably well with the average response spectrum of the seven ground motion records. It is important to note that the ET response spectra remain proportional to the target spectra from seven ground motions at all times. For example, response spectrum in t=10s is twice of spectrum in t=5s. Acceleration, velocity and displacement functions of ETA20e01, as a sample, are shown in figure 2.

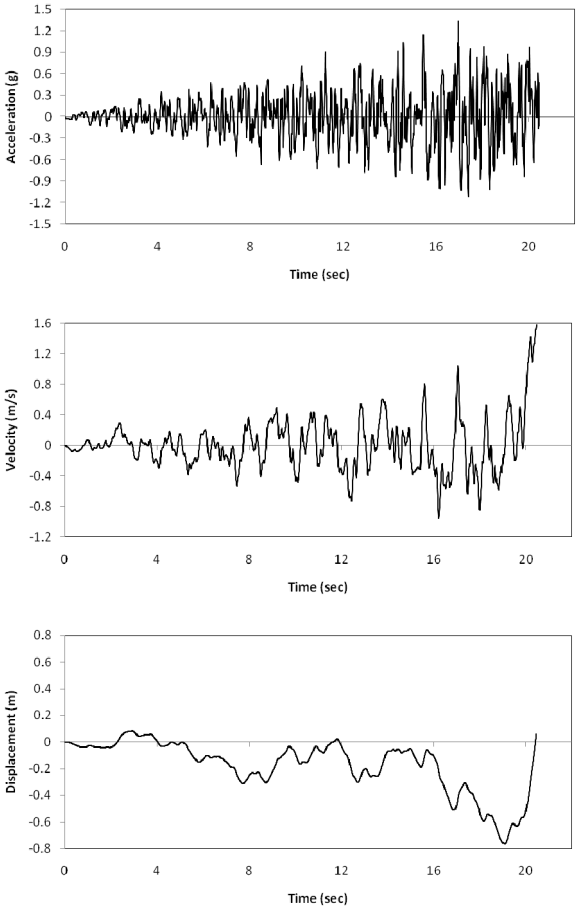

Figure 2 Acceleration, velocity and displacement functions of ETA20e01

In present paper, to compare the results of ET analysis with real earthquakes, GM1 set is used. To be consistent with the seismic codes, the GM1 set of ground motions should be scaled. Considering that in the present study only single horizontal component of ground motions are used to analysis of frames, records are scaled individually. For this purpose it is suppose that the average of 5% damped linear response spectra does not fall below the design spectrum for the period range $0.2T_i$ to $1.5T_i$ where T_i is the fundamental period of vibration of each frame modeled as a linear system. Here, scale factors are obtained in a way that the ground motion spectrum matches the UBC-97 (1997) spectrum in the mentioned range. Scale factors obtained by this method for the GM1 set are shown in table 3 for each frame.

Equivalent Target Time (sec)	13.31	10.68	11.55	11.00

Because of increasing nature of ETAFs, it is questionable that how the results of two methods can be compared with each other. As it is clear, in this method the time is correlated with intensity and different responses of structure are calculated for various values of dynamic load intensity in an ET analysis. To establish a relation between the results of the ET and NTH methods, the intensity value of the NTH analysis should be found in the ET analysis. Therefore, a procedure should be defined to find an equivalent target time in the ET analysis in which the intensity values of the two methods have equal values.

Various quantities can be used to characterize the intensity of a ground motion record, i.e. Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV) and Spectral Acceleration at the structure's first-mode period ($S_a(T_1)$). In present research, $S_a(T_1)$ is used as dynamic load intensity to obtain the equivalent target time.

The equivalent target time can be calculated for a single record or a set of records. In the proposed technique at the current study, 10^{th} second of ETAFs is selected as base target time and therefore, the average response spectrum resulted up to the 10^{th} second of ETAFs is interpreted as base response spectrum (which is corresponding with base target response spectrum for generation of ETAFs). Consequently, equivalent target time is calculated by multiplying ψ factor, called as spectrum ratio, in constant 10 as shown in Eq.1:

$$t_{eq}(T_R) = \psi(T_R, T_{eff}) \times 10 \tag{1}$$

in which $t_{eq}(T_R)$ is equivalent target time for the desired performance level with return period T_R and $\psi(T_R, T_{eff})$ is spectrum ratio with return period T_R and for effective period interval equal to T_{eff}. In the present study spectrum ratio is calculated as follow:

$$\psi(T_R, T_{eff}) = \frac{S_a^{T_R, T_n}}{S_a^{ET, T_n}} \tag{2}$$

where $S_a^{T_R, T_n}$ is average of the spectral acceleration of the seven ground motions at the first-mode period (fundamental period) and S_a^{ET, T_n} is the value of the smooth response spectrum used for the generation of ETAFs at the first-mode period. The calculated equivalent target times for each frame are tabulated in last row of table 3. Based on table 3, the equivalent target time for SCBF15@3 is 13.31s. It means that the results obtained from average of ET analyses up to 13.31s should have the same or close values to the average maximum values resulted from TH analyses from seven ground motions. This rule is indefeasible in other frames.

4. RESULTS AND DISCUSSION

In the following subsections, ability of ET method in estimating various parameters such as displacement, story shear and interstory drift ratio is considered.

4.1 Story Displacement

In this subsection, displacements obtained from ET method at equivalent target time and NTH analyses are compared with each other along stories of frames. Figure 3 shows non-concurrent envelopes of displacement for different frames extracted from NTH analyses and ET method. As shown in this figure dispersion of results between ETAFs are very less than seven ground motions. Although, using three or six ETAFs can reduce percentages of errors between average of ET and NTH analyses, its effect is negligible especially for mid-rise frames. It means that in SCBFs using only e- or f-series of ETAFs for estimation of NTH results is enough. Maximum of average displacements estimated by e- and f-series and also GM1 set for SCBF09@3 are 127mm, 128mm and 132mm. As it is clear both e- and f-series have very excellent estimation of exact displacement in this frame. The percentage of errors between ET and NTH analyses are only -3.8% for e-series and -3.0% for f-series. The sign (-) indicates that ET method estimates

lower results in comparison with NTH method. Roof displacements for SCBF11@3 based on e-, f-series and GM1 set are 190mm, 187mm and 184mm respectively which lead to about +3.2% errors in e-series and +1.6% errors in f-series for this frame. For SCBF13@3 maximum displacement for mentioned dynamic loads are obtained as 227mm, 237mm and 229mm. Errors based on e- or f-series of ETAFs are +0.4% and +3.4%. In SCBR15@3 the results of displacement based on e-, f-series and GM1 set are obtained as 285mm, 273mm and 285mm which lead to error about -4.2% in f-series while results obtained from e-series and NTH are exactly same. Except of roof displacement which has been estimated by ET method in high accuracy, total trend of maximum displacements in each story are very close in ET and NTH methods.

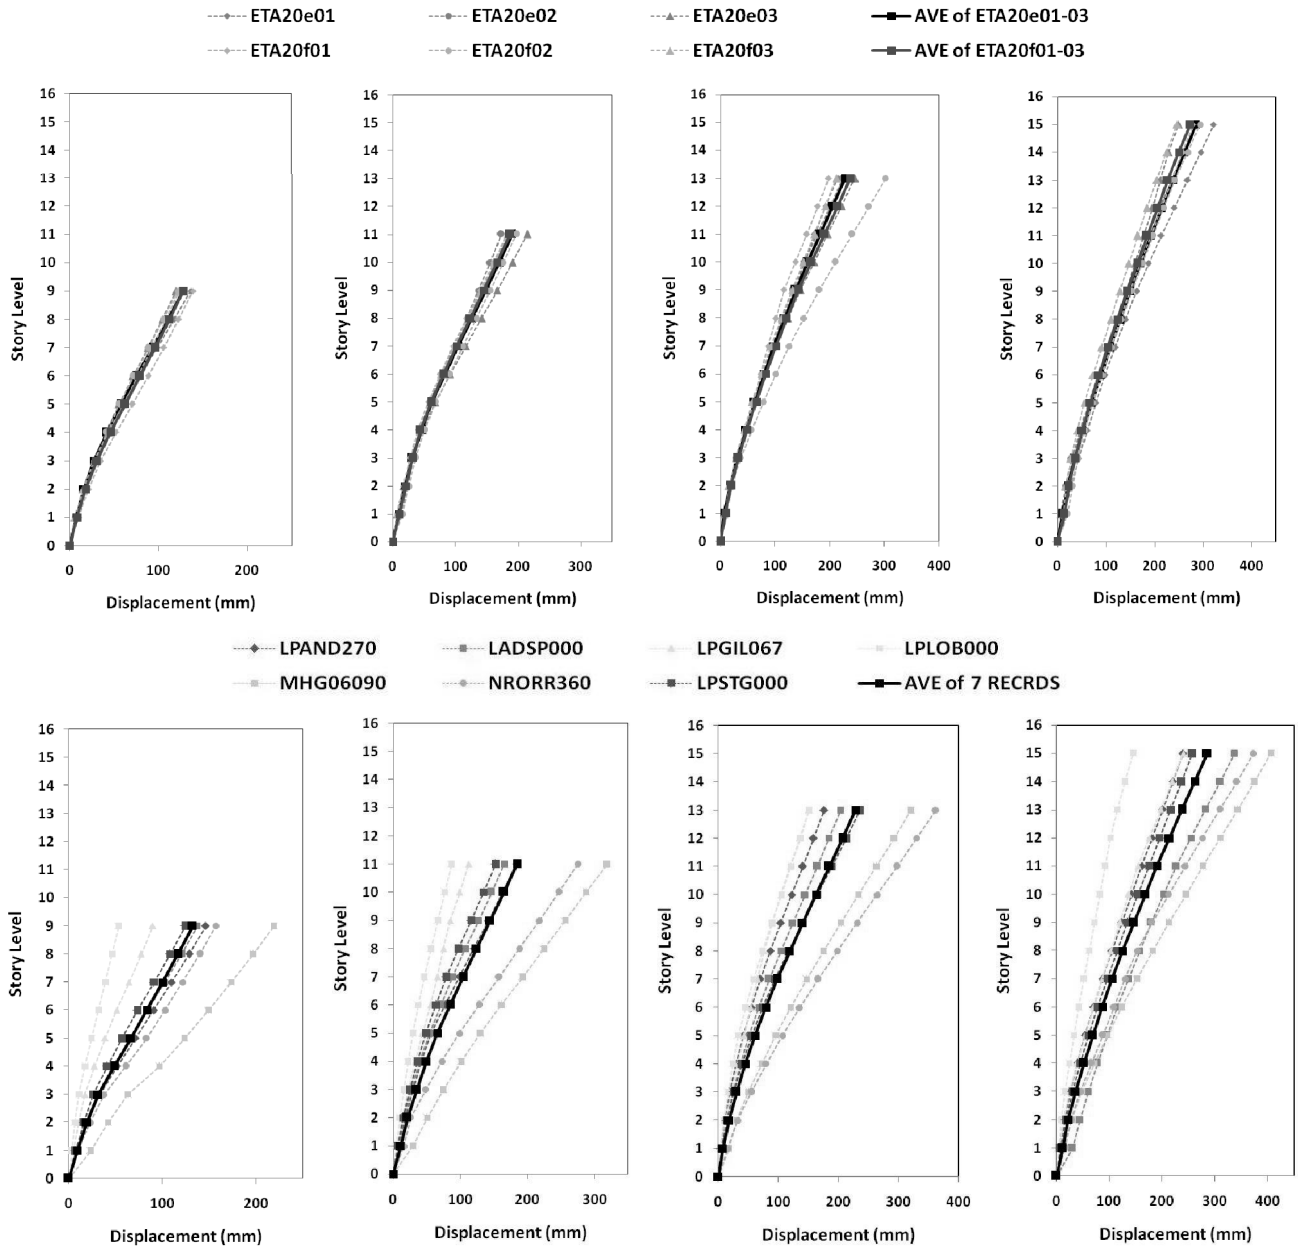

Figure 3 Non-concurrent envelope of story displacement resulted from ET and NTH analysis

4.2 Story Shear

Figure 4 shows non-concurrent envelopes of story shear for different frames extracted from NTH analyses and ET method. Generally there is good consistency between the results of two methods. Like displacement, in this response dispersion of results are very limit in ET rather than NTH method. It is not worthy that dispersion of results obtained from NTH method for shear is less than displacement. Moreover the average results of e- and f-series of ETAFs are very close together but their

consistency is less than displacement. The value of base shear for SCBF09@3, SCBF11@3, SCBF13@3 and SCBF15@3 resulted from average of GM1 set are 2509KN, 2351KN, 2546KN and 2485KN respectively. The corresponding values extracted from e-series are 2880KN, 2770KN, 2781KN and 2644KN. Values of base shear from f-series for mentioned frames are 2823KN, 2993KN, 2788KN and finally 2854KN. So the percentage of errors between ET and NTH methods based on using e- or f-series are about +14.7% and +12.5% for SCBF09@3, +17.8% and +27.3% for SCBF11@3, +9.2% and +9.5% for SCBF13@3 and finally +6.3% and +14.8% for SCBF15@3. As it is clear all errors have positive sign and it means that ET method overestimates results of NTH method.

On the other hand ET has better estimation of shear in last story in each frame. Average errors between e- and f-series of ETAFs with NTH method are +12.1% and +4.9% for SCBF09@3, +22.4% and +17% for SCBF11@3, +3.7% and -0.1% for SCBF13@3 and finally +10.5% and +4.9% for SCBF15@3.

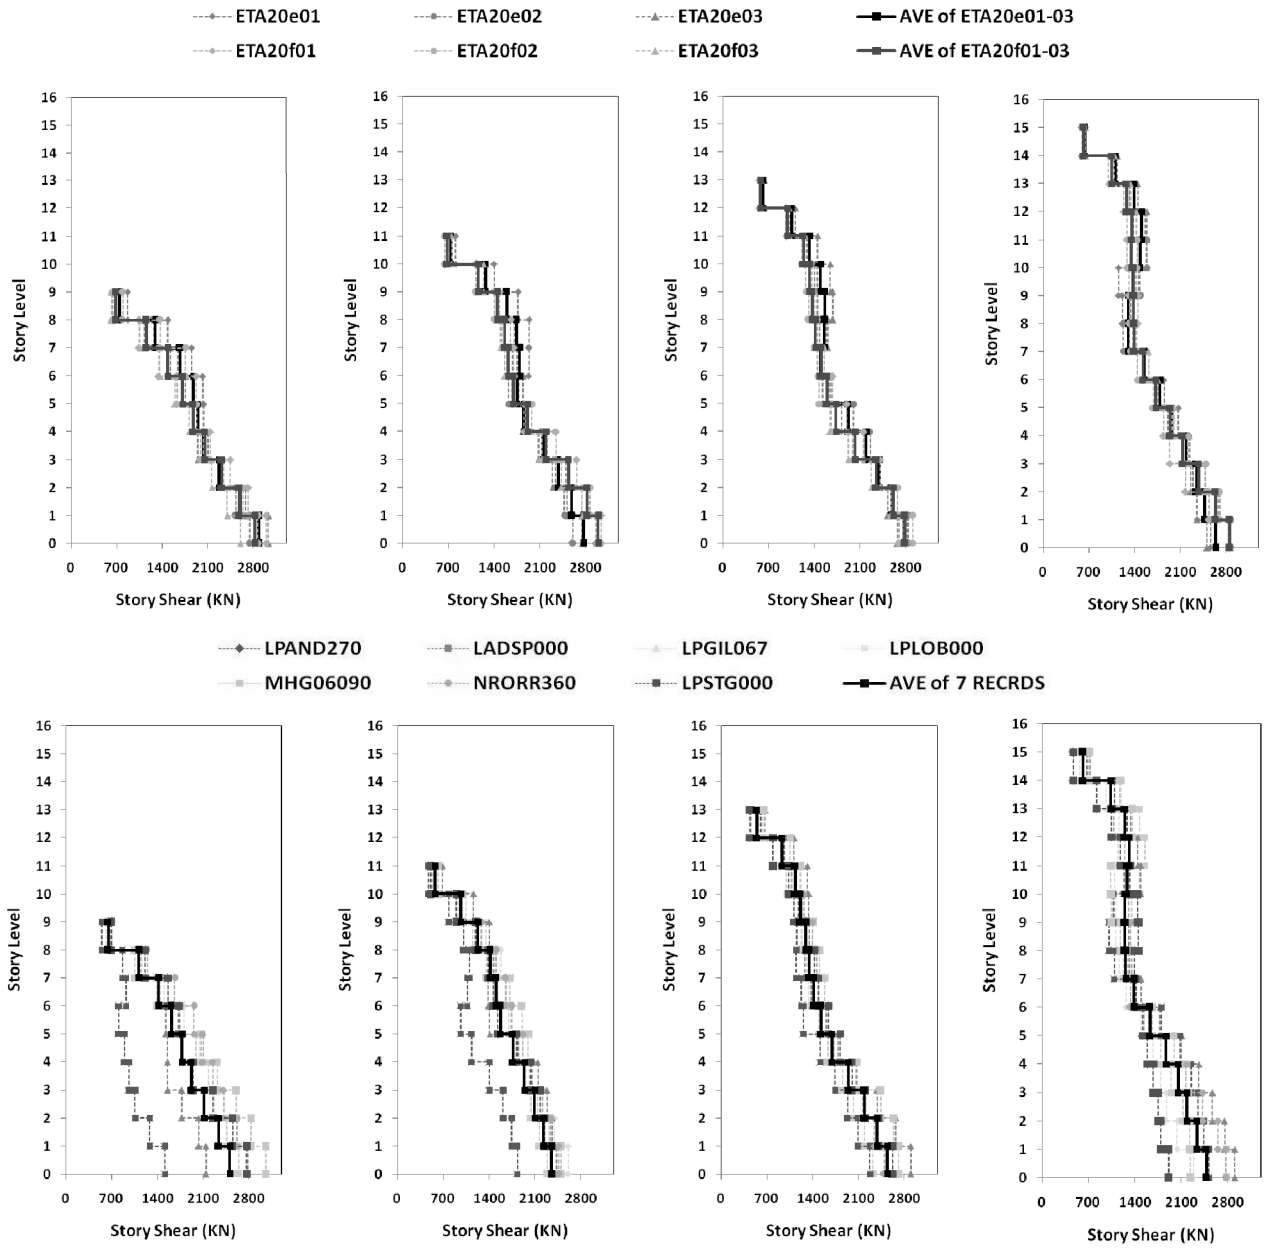

Figure 4 Non-concurrent envelope of story shear resulted from ET and NTH analysis

4.3 Interstory Drift Ratio

Figure 5 shows maximum interstory drift ratio for different frames extracted from NTH analyses and ET method. As can be seen in this figure, in all cases the average of interstory drift ratio extracted from e-, f-series and GM1 set satisfy LS performance level (in all cases θ_{max} are below the 1.2%). Maximum interstory drift ratio for all frames in upper stories is more than lower ones. This effect is significant especially for high-rise frames. Although dispersion of results in real ground motions are meaningful, they are close together in ET method. Results of θ_{max} by using e- or f-series of ETAFs are very close in SCBF09@3, while increasing height of frames lead to some differences between e- and f-series. θ_{max} for the SCBF09@3, SCBF11@3, SCBF13@3 and SCBF15@3 resulted from average of GM1 set are 0.62%, 0.72%, 0.77% and 0.83%. The corresponding values extracted from e-series are 0.63%, 0.75%, 0.81% and 0.93% and the values of θ_{max} from f-series for mentioned frames are 0.60%, 0.72%, 0.75% and finally 0.84%. Therefore the percentage of errors between ET and NTH methods based on using e- or f-series are about +1.6% and -3.2% for SCBF09@3, +4.1% and 0.0% for SCBF11@3, 1.3% and -2.6% for SCBF13@3 and +12% and +1.2% for SCBF15@3. As it is clear by using three ETAFs as ET analyses all percentage of errors except SCBF15@3 are very low. It is not worthy that using six ETAFs (combination of e- and f-series) lead to decrease percentage of errors to about +6.6% for SCBF15@3.

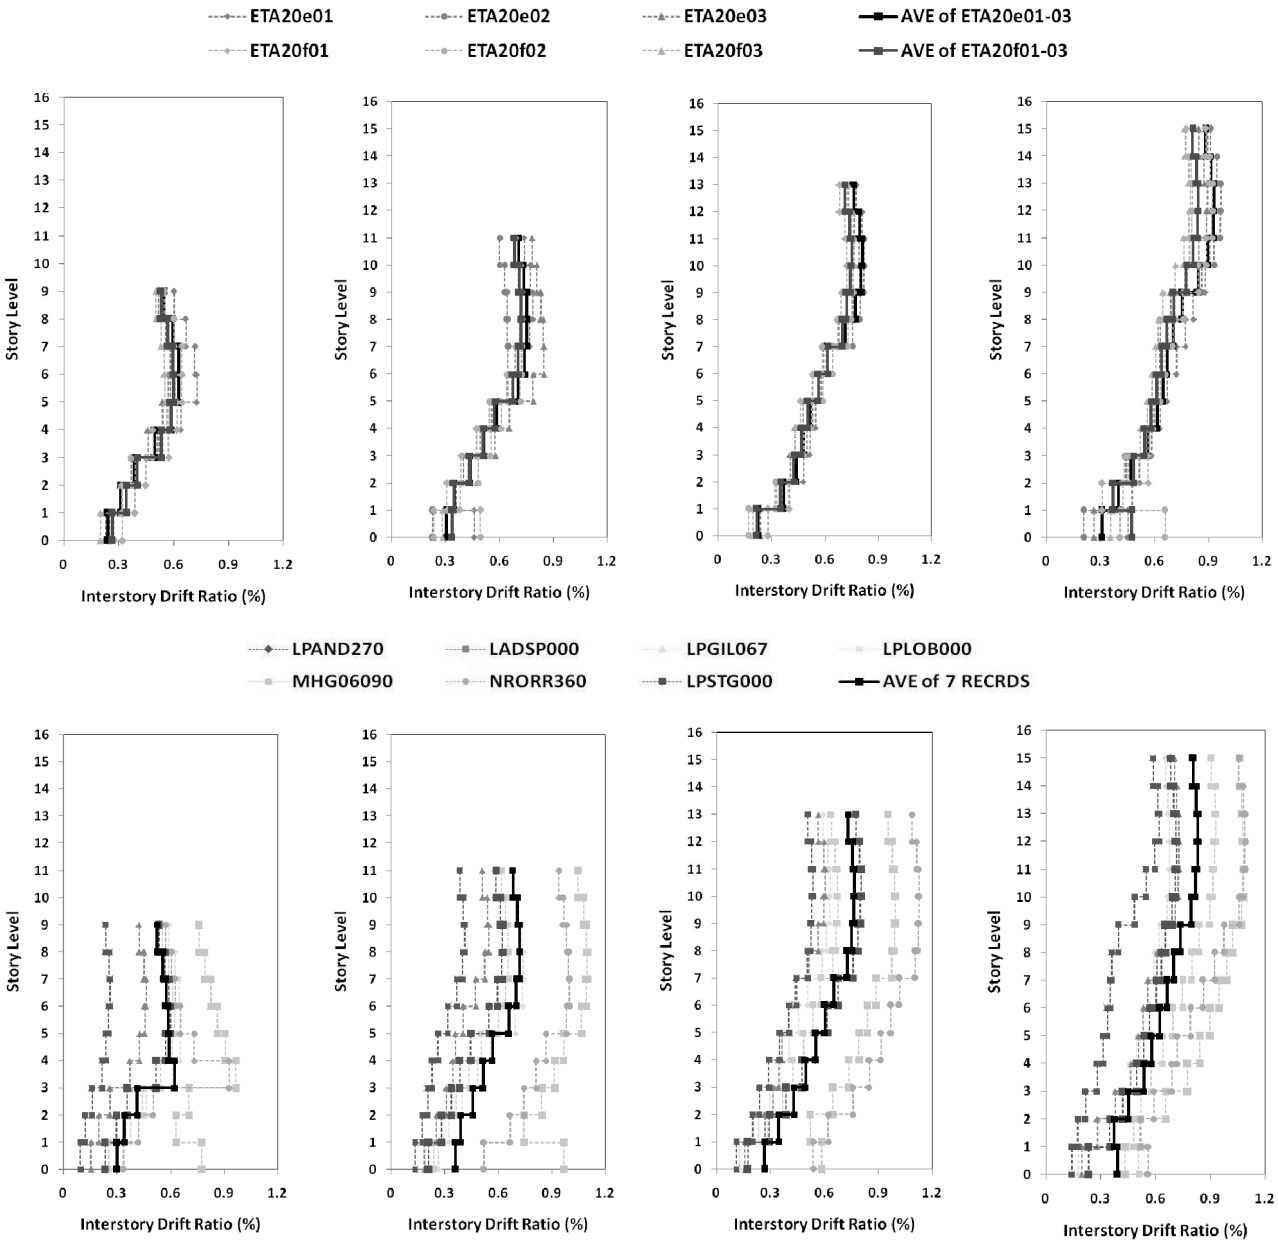

Figure 5 Maximum interstory drift ratio resulted from ET and NTH analyses

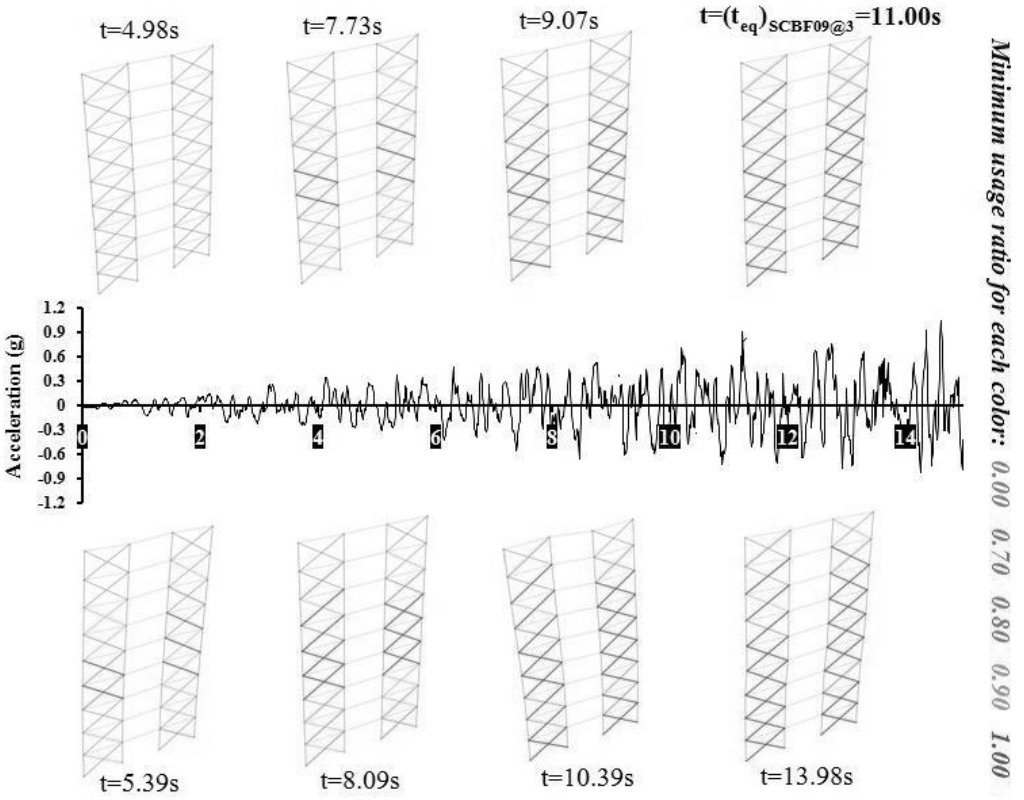

Figure 6 Strain ratio in braces of SCBF09@3 under ETA20e01 at various times

4.4 Maximum Strain Ratio in Braces

Figure 6 shows strain ratio in braces of SCBF09@3, as a sample, at various times under ETA20e01 acceleration function using appropriate colored contours. As can be seen with time passing, the structure experience higher PGA and energy and therefore number of braces which exceed certain criteria increase. For example, based on this figure, it is clear that none of braces exceed ratio=1 in t=4.98s and all of them in safe rang, but one of each concentrically braces in 3rd floor have potential for exceed ratio=1 with little increases in time (increases in input energy consequently). This happens when ETA20e01 apply to frame up to t=5.39s. In this time some of braces in 3rd, 4th and 5th floors exceed ratio=1. Monitoring behavior of frame at various times under an ETAF gives appropriate information about both location and extension of overstrain areas in frame and is effective way to find weakest elements in system and retrofit of them. Finally figure 6 presents status of frame at t=11.00s (which is equivalent target time for SCBF09@3). Based on previous results about estimation of responses by ET method at equivalent target time, it is not worthy that this figure (at t=11.00s) is an average of status of braces under real ground motions (GM1 set). It shows that almost all braces except braces in floor 9 and some braces in floor 8 exceed ratio=1. It is important to remember that because of random nature of ETAFs, it is better to use at least three of them and taking their average for reducing uncertainties in analyses.

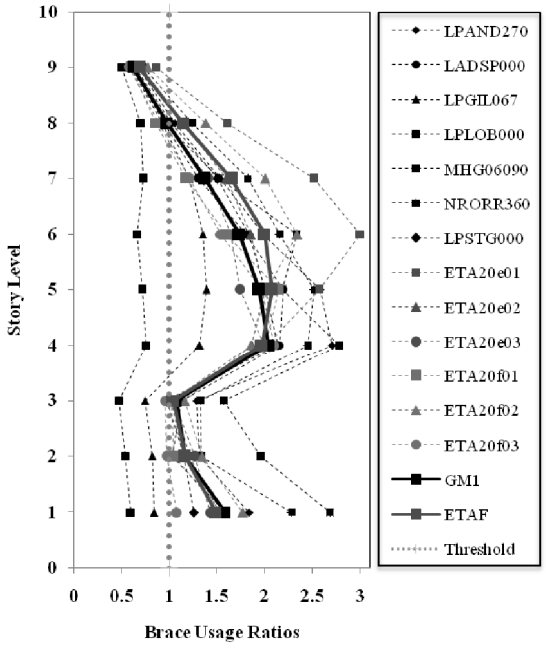

Figure 7 Maximum strain ratio in braces of SCBF09@3 extracted from NTH and ET methods

To investigate accuracy of figure 6 in estimation of maximum train ratio, total behavior of mentioned frame (SCBF09@3) under seven ground motions (GM1 set) and also six ETAFs (e- and f-series) are studied. Figure 7 represents maximum strain ratios for braces in each story of frame under total time of real ground motions and up to t=11.00s (equivalent target time) based on ETAFs. As can be seen except LPLOB000 which is not exceed ratio=1 and LPGIL067 which is not exceed ratio=1 in lower stories, all other five ground motions and also all six ETAFs exceed ratio=1 in almost all stories except 9th floor and in some cases 8th floor. So the results of figure 6 are satisfied by complete review of responses in figure 7.

5. CONCLUSIONS

In the present paper, Endurance Time method as a new time-history based dynamic pushover procedure was introduced and its application in estimation of various structural responses in concentrically braced steel frames was investigated. A set of mid-rise and high-rise frames were designed as 2D frames for this purpose. In addition, the results of Endurance Time analysis were compared with average results of real ground motions. Results show that Endurance time method estimate total displacements of stories with high accuracy. Maximum percentage of error between nonlinear time-history method and Endurance Time analysis for this response is only 4.2%. For interstory drift ratio, Endurance time method has very good estimation of nonlinear time-history method for all frames except 15-story frames. In all cases maximum percentage of errors are limit to 4.1%, but in 15-story frame percentage of error rise to 12% by using e-series of acceleration function. In this frame combination of e- and f-series of acceleration functions, decrease errors to about 6.6%. Although Endurance Time method gives very good estimation of displacements and interstory drifts, the percentage of errors are increases for shear. Total percentage of errors between average of GM1 set and six ETAFs for base shear are 13.6% for SCBF09@3, 22.5% for SCBF11@3, 9.3% for SCBF13@3 and 10.5% for SCBF15@3. As can be seen errors decrease for high-rise frames in comparison with mid-rise ones. Finally the most interesting ability of Endurance Time method is analysis of structural system and estimation of various responses with less number of analyses. This characteristic is important when it is required to analyze of system in different intensities, where Endurance Time method can gives useful information about responses in various intensities just be single analysis. Also this method is capable to detect weakest elements and parts in system when they are subjected to seismic inputs and can be used for retrofit of weak and under-designed systems.

Abstract: A numerical study is performed to gain insight into applying a novel method to detect high-frequency dynamic failure in buildings. The method relies on prerecorded catalog of Green's functions for instrumented buildings. Structural failure during a seismic event is detected by screening continuous data for the presence of waveform similarities to each of the cataloged building responses. In the first part of this numerical study, an impulse-like force is applied to a beam column connection in a linear elastic steel frame. A time-reversed reciprocal method is used to demonstrate that the resulting simulated displacements can be used to determine the absolute time and location of the applied force. In the second part of the study, a steel frame's response to two loading cases, an impulse-like force and an opening crack tensile stress, is computed on a temporal scale of microseconds. Results indicate that the velocity waveform generated by a tensile crack can be approximated by the velocity waveform generated by an impulse-like force load applied at the proper location. These results support the idea of using a nondestructive impulse-like force (e.g. hammer blow) to characterize the building response to high-frequency dynamic failure (e.g. weld fracture).

1. INTRODUCTION

There has been recent interest in using acoustic techniques to detect damage in instrumented civil structures. An automated damage detection method that analyzes recorded data has application to building types that are susceptible to a signature type of failure, where locations of potential structural damage are known a priori. Such a method would be valuable if it could be used to detect types of damage that are otherwise difficult and costly to detect. In particular, this method has application to the detection of brittle failure of welded beam-column connections in steel moment resisting frames (MRFs). The 1994 Northridge earthquake exposed this type of damage, which can occur without accompanying damage to architectural finishes and cladding; in some cases, detection requires intrusive inspections that can be costly and time-consuming (Rodgers et al. 2007). An automated damage detection method could be used to located areas of probable damage to guide post-earthquake building inspection.

Acoustic damage detection methods rely on the comparison of a recent signal to an archived baseline response function, known as a template. The template is recorded at a time when the structure is undamaged. The sensor network must have a high sampling rate to capture the propagation of waves throughout the structure. Acoustic techniques have been explored experimentally and numerically for thin plates and beams (Park et al. 2007, Wang and Rose 2003, Wang et al. 2004), which serve as waveguides that effectively carry information from the location of structural damage to a receiver. This information, namely differences in waveform and amplitude between the current signal and the template, are used to diagnose damage.

Acoustic methods can be passive or active, and sensor networks can be permanently installed or temporary. Giurgiutiu (2005) reviews current techniques, including embedded ultrasonic non-destructive evaluation (NDE), which uses a transmitter to interrogate the structure while a receiver records the structural response.

1) *Pitch-catch*: A pulse is emitted by a transmitter and travels through the material to a receiver. Differences in guided wave shape, phase, and amplitude are used to detect damage in the medium between the transmitter and receiver.
2) *Pulse-echo*: A pulse is emitted by a transmitter, which also acts as a receiver to detect damage in the form of additional echoes.
3) *Time-reversal*: A signal sent by a transmitter arrives at a receiver, where the signal is time-reversed and reemitted. Structural damage that causes linear reciprocity to break down leads to discrepancy between the original signal and the final signal received by the transmitter.
4) *Migration*: Recorded waves are back-propagated through the material by systematically solving the wave equation to image reflectors in the medium.

In this paper, a complementary acoustic method is

presented, that makes use of a prerecorded catalog of Green's functions and a matched filter method to passively detect the original failure event. This technique is different from existing acoustic methods as it is designed to recognize seismic waves radiated by the original brittle failure event. The matched filter method has been successfully used in other fields (Gibbons and Ringdal 2006, Anstey 1964), but the method has yet to be explored in the context of acoustic damage detection of civil structures.

The proposed method is described in greater detail in the following section. Two numerical studies are performed; the first compares our method to a similar time-reversed reciprocal method, and the second provides a waveform comparison between a non-destructive event and a failure event.

2. MATCHED FILTER METHOD

The proposed method would make use of a prerecorded catalog of Green's functions for an instrumented building to detect structural damage during a later seismic event. Continuous data collected on a passive network is screened for the presence of waveform similarity to one of the Green's function templates. The method is outlined below.

1) Identify probable points of failure in an instrumented building before structural damage has occurred. As pre-Northridge steel MRFs are susceptible to the brittle failure of welded beam-column connections, these would be the locations of probable failure for this type of building.

2) At each labeled location, apply a short-duration high-frequency pulse (e.g. using a force transducer hammer). The response of the building at each instrument site is the Green's function specific to that source location-receiver pair. The Green's functions are archived in the catalog of templates to be used later to screen the high-frequency seismogram for a damage signal.

3) For each possible source location k, perform a running cross-correlation between the Green's function templates for that source location and a moving window of the seismogram that recorded the shaking event, stacking over the receivers. Cross-correlation between the k^{th} Green's function template x_i^k recorded by the i^{th} receiver and the seismogram x_i recorded by the i^{th} receiver is given by

$$C_i^k(t) = \frac{\int_0^T x_i^k(\tau) x_i(t+\tau) d\tau}{\left(\int_0^T \left(x_i^k(\tau)\right)^2 d\tau \int_0^T \left(x_i(t+\tau)\right)^2 d\tau \right)^{1/2}}. \quad (1)$$

Time T is the duration of the template, and the cross-correlation is normalized by the autocorrelation values for the given time window.

Compute the stacked cross-correlation function by summing over the R receiver locations to obtain

$$C^k(t) = \frac{1}{R} \sum_{i=1}^{R} C_i^k(t). \quad (2)$$

4) If damage occurred at or near the k^{th} source location, the stacked cross-correlation function given by Eq. (2) should peak at a value close to one at the correct time of the structural damage event. In the case of multiple locations of damage, then the stacked cross-correlation functions should each peak at a value close to one at the corresponding times, provided the correct Green's function templates are used. This procedure could be extended to the three-dimensional case.

The proposed method makes some assumptions. The first is that the signal due to the failure event will be observable over the predominant building response to seismic loading. Rodgers et al. (2007) carried out experimentation on a one-third scale model steel moment frame and found that "high-frequency high-amplitude transient accelerations" were observable over the structural response to shaking and could be attributed to connection fracture. They further analyzed building records from the 1994 Northridge earthquake by identifying transient signals and classifying the possible causes, and they were able to determine with a 67% success rate whether each building had undergone connection fracture.

A second assumption is that the template will not change significantly over time. However, it has been shown that changes in environmental conditions as well as moderately large local earthquakes can lead to observed changes in a building's natural frequency (Clinton et al. 2006). This has not been extended to observed changes in wave propagation through the structural components of the building. A similar matched filter method has been successfully employed by Gibbons and Ringdal (2006) to detect similar low-magnitude seismic events by cross-correlating a waveform template with successive time segments of incoming data and stacking over the seismic array.

A third assumption is that the sensor network will be able to capture waves propagating away from the damage location throughout the structure. Kohler et al. (2009) have carried out preliminary experimentation on the UCLA Factor building using hammer blows to generate Green's function templates. The structural response to the hammer blow was observable well above ambient noise, and the signal could be seen to propagate away from the source location at a downsampled rate of 200 sps, achieved by filtering the 500 sps accelerometer array data for frequencies between 10 and 95 Hz.

A fourth assumption is that the Green's function template will be similar to the damage signal. This assumption is addressed in Section 4.

3. A TIME-REVERSED RECIPROCAL NUMERICAL EXPERIMENT

A time-reversed reciprocal method is applied to demonstrate that the location of a nondestructive

impulse-like force can be determined by using the numerically computed displacement records to time-reverse and retransmit the signal. First, the response of a two-story one-bay steel frame to an impulse-like force applied to a beam-column connection is computed. A cross section of the three-dimensional steel model is shown in Figure 1 below. Each beam and column has a square cross section of length 0.5 m. The model parameters are governed by linear elastic material properties of A36 structural steel (E = 200 GPa, μ = 80 GPa, ρ = 7850 kg/m^3), which correspond to seismic velocities of c_s = 3.2 km/s and c_p = 5.6 km/s. The hex 8 mesh elements have a discretization length of 2.5 cm; the total time is 4 ms with a time step of 2 μs. CUBIT is used for mesh generation, PyLith for physics code, and ParaView for visualization (Aagaard 2008).

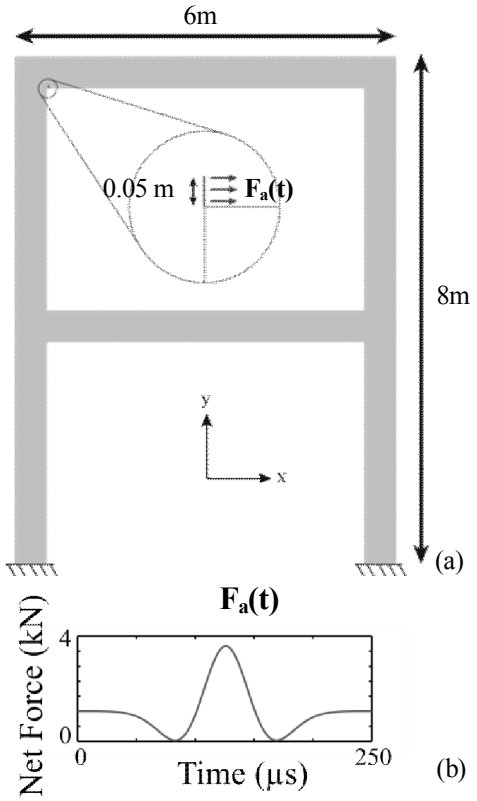

Figure 1 Numerical Setup for Steel Frame: (a) Impulse-like force is applied at beam-column connection in a direction parallel to the x-axis (b) Ricker wavelet is used for time-force history.

3.1 Forward Simulation

The response of the steel frame to an impulse-like force applied to a beam-column connection is computed. As shown in Figure 1 above, the force is applied along the positive x-axis to the close-up section of the connection. The total force is distributed proportionally over nodes according to the amount of surface area contained by each node. The force-time history is a Ricker wavelet.

Waves propagate away from the location of the source, reflecting off the edges of the frame, as shown in Figure 2 below. Resulting displacements are recorded at the twelve receiver locations approximately evenly spaced along the central cross section of the frame. A representative sample of displacements is provided in Figure 3(a) below.

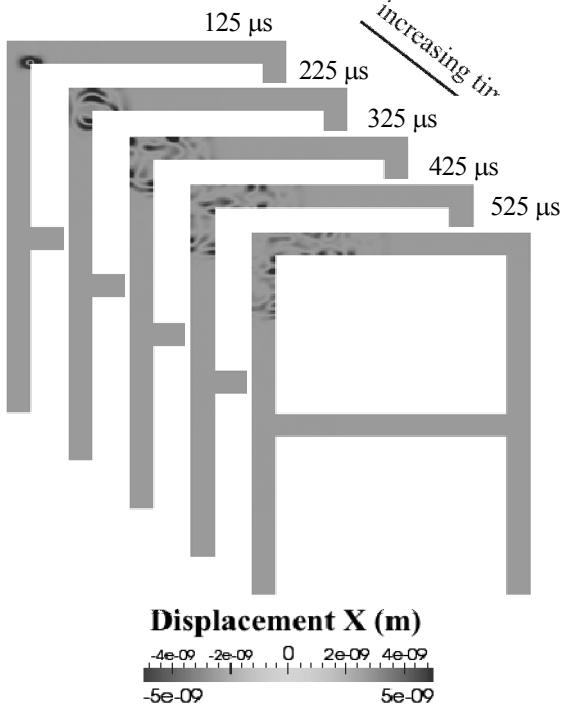

Figure 2 Response of Steel Frame to Nondestructive Impulse-like Force Applied to Beam-Column Connection.

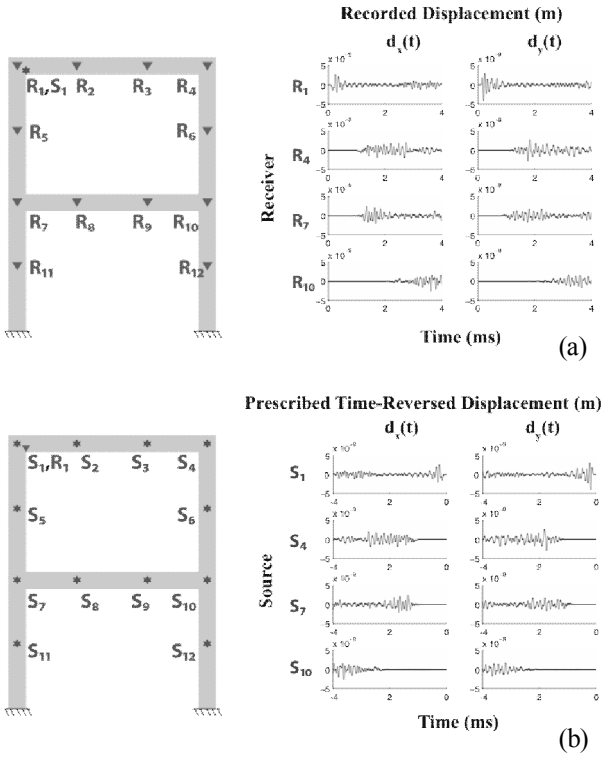

Figure 3 Receivers, Sources, and Displacements: (a) Receiver locations and examples of recorded displacements for forward simulation. (b) Source locations and corresponding prescribed time-reverse displacements for reverse simulation. Due to symmetry, $d_z(t) = 0$.

3.2 Reverse Simulation

Following the time-reversed reciprocal method, the receiver and source locations are interchanged, and each of the displacement records is time-reversed and applied at the respective new source location as prescribed Dirichlet conditions, as shown in Figure 3(b) above. The retransmitted signal propagates through the frame, and the waves generated by the twelve new source locations interfere constructively to focus at the original source location $\mathbf{S_1}$, where the nondestructive load was applied, and at the correct time. To simplify timing, the reverse simulation begins at -4 ms and ends at 0 ms, with waves focusing on the beam-column connection at the correct time of -125 μs, demonstrated in Figure 4 below. Thus, by using a time-reversed reciprocal method, the recorded displacements are used to determine the absolute time and location of the original applied force.

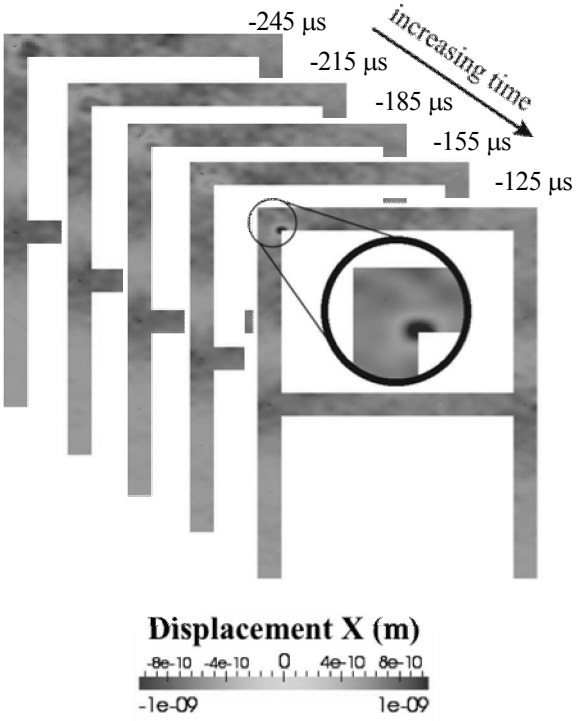

Figure 4 Response of Steel Frame to Prescribed Time-Reversed Displacements. Waves generated at each of the twelve source locations converge at the correct location at the correct time.

4. NUMERICAL APPLICATION OF MATCHED FILTER METHOD

A time-reversed reciprocal method as presented in the previous section is not application-realistic, as the location of the receiver may not coincide with the location of damage, and thus, the focusing of the transmitted time-reversed signal could go undetected. The purpose of this section is to investigate numerically an alternative yet similar approach that makes use of Green's functions, waveform similarity, and wave propagation reciprocity. The matched filter method is used to screen data recorded by a passive seismic network for waveform similarities to an archived template, ultimately relying on experimental, not simulated, building response. To validate the feasibility of the proposed method, it is first necessary to provide justification for using the structural response to an impulse-like force to approximate the structural response to an opening crack tensile stress.

4.1 Comparison of Structural Response to Two Different Source Conditions

The response of a steel frame to two different loading cases, an impulse-like force and an opening crack tensile stress, both shown in Figure 5, is compared to determine whether the waveform generated by a nondestructive source can be used to approximate the waveform generated by a structurally damaging source. The same material properties and dimensions as in Section 3 are used. A square notch is introduced in the opening crack tensile stress case, to simulate crack initiation at the beam-column connection. The square notch has a length of 0.05 m, consistent with the dimensions used for the unnotched frame.

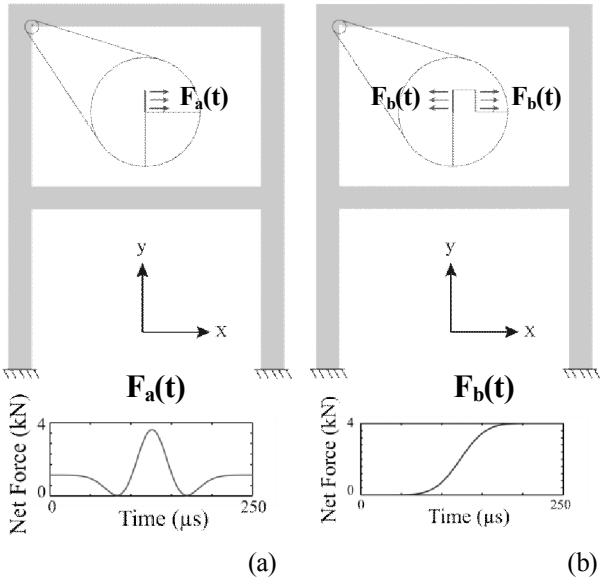

Figure 5 Numerical Setup: (a) Impulse-like force using Ricker wavelet force-time history applied to top left beam-column connection in an unnotched frame, and (b) Opening crack tensile stress using error function force-time history applied to the same connection in a notched frame.

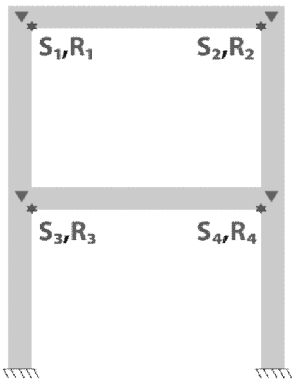
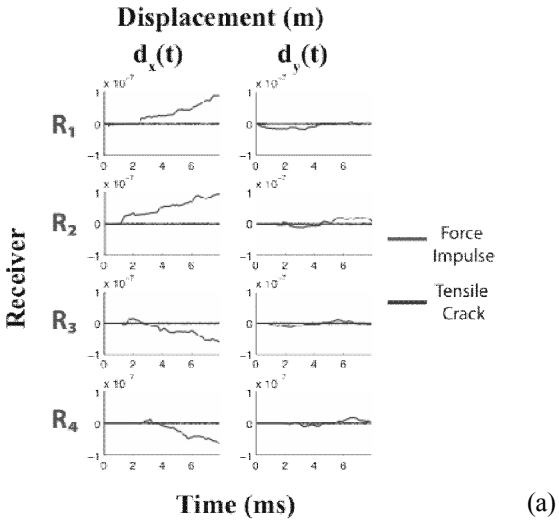
Resulting displacements and velocities are recorded at four receivers located along the central cross section of the frame, shown in Figure 6 below. The simulation is repeated at each of the four source locations for both a force impulse and a tensile crack.

The displacement records, provided in Figure 7 below, generated by using the nondestructive source differ significantly between the displacement records generated by using the structurally damaging sources, primarily due to the static offset across the notch. The two sets of velocity





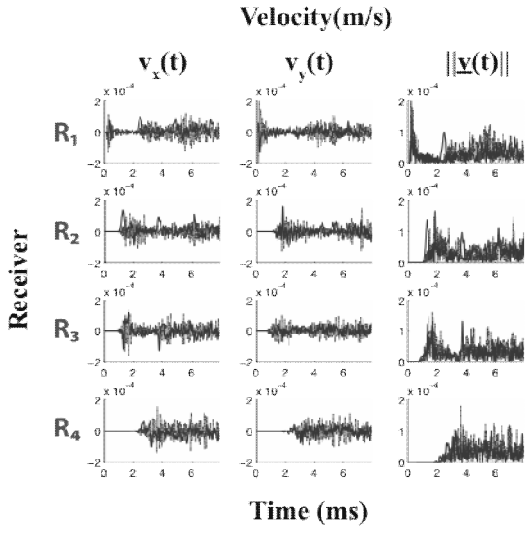


Figure 6 Source and Receiver Locations.

(a)

(b)

Figure 7 High-Frequency Seismograms Using Source Location S_1: (a) Displacements differ significantly between the impulse-like force (red) and opening crack tensile stress (blue) case. (b) Velocities provide a better agreement, and polarity differences are improved by taking the absolute value or magnitude of the record. Due to symmetry, $d_z=v_z=0$.

records are more similar to each other than are the two sets of displacement records. The similarities between force impulse and tensile crack velocity waveforms underscore the fact that, for traveling elastic waves, the strains are proportional to their associated particle velocities, regardless of the source mechanism. Thus, the template is created using the velocity record.

4.2 Stacked Cross-Correlation Values

A stacked cross-correlation method is used to determine the similarity of velocity waveforms generated by a force impulse at source location S_k and a tensile crack at source location S_l. The summarized method follows:

1) A set of velocities $\{\underline{v}_1^k(t), \underline{v}_2^k(t), \underline{v}_3^k(t), \underline{v}_4^k(t)\}$ are recorded for a force impulse applied at source location S_k, where $\underline{v}_i^k(t)$ is the three-component velocity vector recorded at the i^{th} receiver. Due to symmetry and the fact that the receivers are located along the central cross section of the frame, the z-component of the velocity vector is zero.

2) The set of envelopes $\{\underline{e}_1^k(t), \underline{e}_2^k(t), \underline{e}_3^k(t), \underline{e}_4^k(t)\}$ is computed using the velocities. The magnitude of each 3-component envelope is passed through a low-pass filter to produce a set of scalar functions of time $\{e_1^k(t), e_2^k(t), e_3^k(t), e_4^k(t)\}$. These records are archived as our template signals for damage caused at the k^{th} source location. The duration of our template is time T.

3) Similarly, a set of scalar filtered envelopes for a tensile crack at the l^{th} source location S_l are computed:
$\{\tilde{e}_1^l(t),\tilde{e}_2^l(t),\tilde{e}_3^l(t),\tilde{e}_4^l(t)\}$

4) For simplicity, pad each record $\{\tilde{e}_1^l(t),\tilde{e}_2^l(t),\tilde{e}_3^l(t),\tilde{e}_4^l(t)\}$ with a duration of T zeros at both the beginning and end, and compute the cross-correlation value for each receiver location as given by

$$C_i^{kl} = \frac{\max\limits_{t\in(-T,2T)}\left(\int_0^T e_i^k(\tau)\tilde{e}_i^l(t+\tau)d\tau\right)}{\left(\int_0^T \left(e_i^k(\tau)\right)^2 d\tau \int_0^T \left(\tilde{e}_i^l(\tau)\right)^2 d\tau\right)^{1/2}}. \quad (3)$$

5) Compute the stacked cross-correlation value by summing over all four receiver locations to obtain

$$C^{kl} = \frac{1}{4}\sum_{i=1}^{4} C_i^{kl}. \quad (4)$$

The maximum value of C^{kl} occurs near time $t = 0$, and is recorded in the k^{th} row and l^{th} column in Table 1 below. Correlation values are highest when the location of the tensile crack and the location of the force impulse are the same.

Table 1 Stacked Cross-Correlation Values.

Force Impulse Source Location \ Tensile Crack Source Location	S_1	S_2	S_3	S_4
S_1	**0.92**	0.78	0.79	0.84
S_2	0.78	**0.92**	0.84	0.79
S_3	0.77	0.92	**0.91**	0.81
S_4	0.88	0.77	0.81	**0.91**

5. CONCLUSIONS

By applying a time-reversed reciprocal method to a two-story one-bay steel frame, the location and application time of an impulse-like force can be determined.

The velocity waveform of a tensile crack can be approximated by the velocity waveform of an impulse-like force applied at the same beam-column connection of a steel frame.

The results support the use of waveform cross-correlation using a pre-event catalog of Green's function templates to determine the location and time of occurrence of a subsequent fracture recorded on a network of vibration sensors.

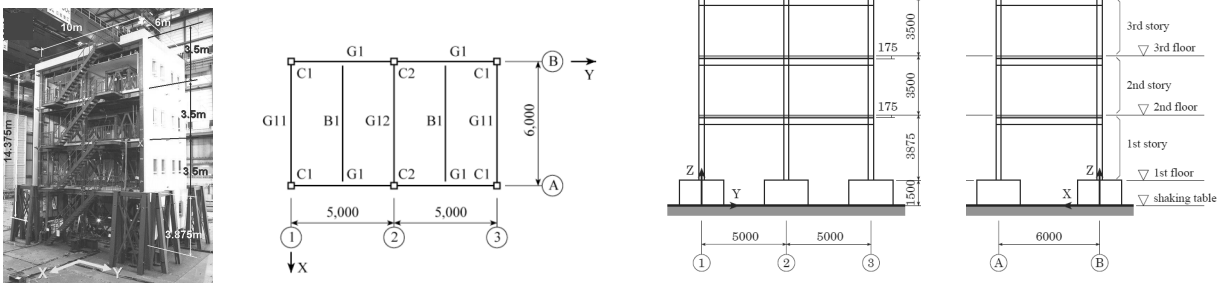
Abstract: This paper presents the dynamic collapse analysis of a full-scale four-story steel building which was experimented to collapse at the E-Defense, in Miki, Japan, in 2007, using the ground acceleration histories recorded at the JR Takatori station during the 1995 Hyogo-ken Nanbu earthquake. Deterioration of columns on the first story level due to local buckling is thought to be one of major reasons for the building collapse. Fiber method approach is adopted in the analysis to simulate local buckling at the column ends. Hypothetical analyses estimate the collapse capacity of the building specimen at approximately 0.9 times Takatori ground motion level. The collapse capacity of the building specimen under various propagating directions of the 1.0 times Takatori ground motion is also investigated, showing that the building likely collapses under any propagating direction of the ground motion.

1. INTRODUCTION



In September 2007, a full-scale four-story steel building was experimented to collapse on the E-Defense which is the world's largest three-dimensional shake-table located in Miki City, Hyogo Prefecture, Japan. The ground acceleration histories recorded at the JR Takatori station during the 1995 Hyogo-ken Nanbu earthquake were used as the input for the shake-table experiments under various scales. Experimental result shows that collapse occurred under the 100% Takatori motion, due to local buckling leading to deterioration of columns in the first story level.

Collapse behavior of the building in this experiment has attracted a lot of researchers to study and establish an effective model for simulating the collapse manner. However, behavior of the specimen involving yielding and local buckling of columns is still very difficult to simulate. The study deals with establishing a simple analytical model of the building specimen addressing that key point.

Fiber method approach was adopted to simulate local buckling behavior of column members. The analytical model consists of both structural and non-structural components. Dynamic responses of the frame model subjected to the same input ground motions as those adopted in the test are analyzed and compared to experimental data. Collapse mechanism is analytically interpreted, and hypothetical analyses for evaluating collapse capacity of the building specimen are also carried out.

2. BUILDING SPECIMEN

The building specimen is a full-scale 4-story steel moment frame with concrete slabs and autoclaved aerated concrete panels for exterior walls. The plan dimension is 6 m × 10 m, and the total height from the upper surface of stiff foundation is about 14 m (Fig. 1).

PLAN ELEVATION

Figure 1 Building Specimen

Table 1 Sections and Materials of the Steel Frame

	Beam (SN400B)			Column (BCR295)
Story	G1	G11	G12	C1,C2
4	H-346×174×6×9	H-346×174×6×9	H-346×174×6×9	RHS-300×9
3	H-350×175×7×11	H-350×175×7×11	H-350×175×9×14	RHS-300×9
2	H-396×199×7×11	H-400×200×8×13	H-400×200×8×13	RHS-300×9
1	H-400×200×8×13	H-400×200×8×13	H-390×200×10×16	RHS-300×9

Wide-flange sections are used for beams and hollow square sections are used for columns. Steel material type is SN400B for beams and BCR295 for columns. Section shapes are given in Table 1.

3. MODELING FEATURES

3.1 General modeling

The building specimen is numerically simulated by PC-ANSR analysis program, using a three-dimensional model composed of various frame members, such as beams, columns, beam-to-column panel zones, column base plates, and others (Fig. 2). Slab diaphragm is adopted by using truss bars, thus in-plane displacements of all nodes at the same floor level are equal. Composite action of the steel beam and concrete slab is taken into account. Column-base is modeled as elastic rotational spring.

The beam-to-column panel zone tends to deform in shape of parallelogram where one diagonal direction is in tension and the other is in compression; besides, right angles at the joints between beam/column-end and panel remains right angles (Fig. 3). Shear strain causes the panel to rotate at certain angle; thus the panel can be considered to work as a rotational spring.

3.2 Modeling of column hinges

3.2.1 Fiber method approach

Fiber method approach was employed in this study, where the column end is modeled as a 'fiber hinge' composed of two rigid plates connected by fibers distributed over the cross section (Fig. 4). The hinge zone is modeled to have a zero length, which means its two end nodes must have the same coordinates. Its rotation characteristic is defined by considering finite length of buckling zone.

The nonlinear stress-strain properties of 'fiber element' which are based on this finite length is illustrated in Fig. 5, where σ_y^+ and σ_y^- represent nominal yield stress due to tension and nominal buckling stress due to compression, respectively; ε_1, ε_2, ε_3 are negative strains associated with each gradually reduced buckling stiffness of the element; and α, β, γ are factors used to define the stresses corresponding to some control points on the curve.

The first zone O-A is associated with the initial loading of the element which approaches the critical buckling stress (assumed to be equal to yield stress) at point A. Zone A-B is characterized by a decreasing load accompanied by element shortening and buckling.

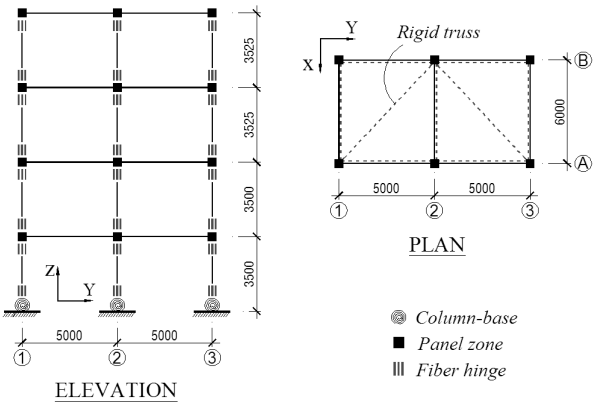


Figure 2 Three-Dimensional Analytical Model

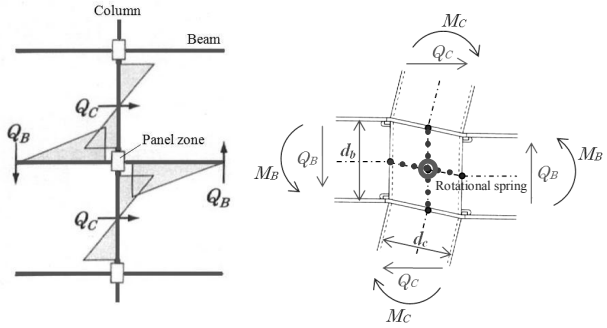

Figure 3 Beam-to-Column Panel Zone Model

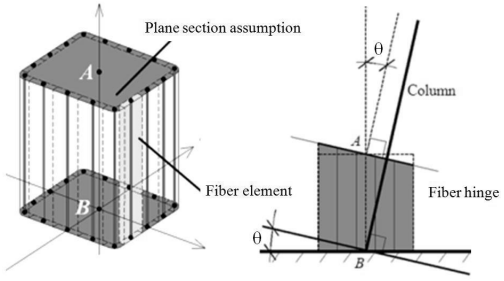

Figure 4 Column Hinge Modeled by Fiber Elements

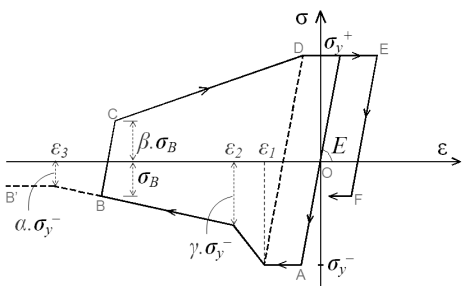

Figure 5 Hysteretic Behavior of Fiber Elements

Zone B-C-D is the compression unloading and tensile loading of the fiber element. Subsequent hysteretic loops have the same characteristic except that the consecutive peak compressive stresses are reduced due to deterioration caused by the previous inelastic cycling of the material. Hence, the compressive yield stress at point F, where the element begins to yield in compression, is set equal to the value of compressive stress at point B. Point B is named for the reversal location of the curve when the element shortening stops. This location changes per load cycle. Accordingly, the curve continues to approach point B and thereafter along zone B-B'.

3.2.2 Influence of fiber hinges on column stiffness

Fiber hinges are added at both top and bottom ends of every column. At each floor level, columns are considered to work as the model shown in Fig. 6, where both column ends are ideally restrained from rotation but top end allowed to translate. In such manner, the column (length *L*) is supposed to consist of two cantilever column portions joining at the inflection point which generally locates at the mid-height of the column.

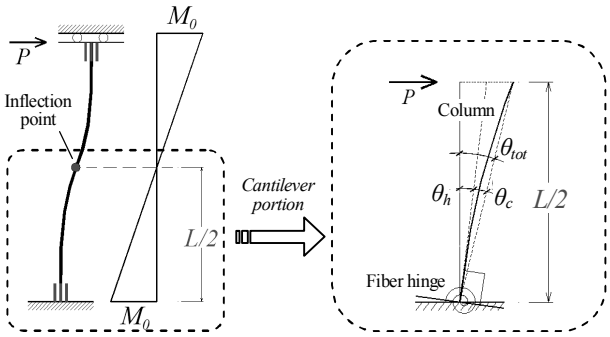

Figure 6 Column Modeling

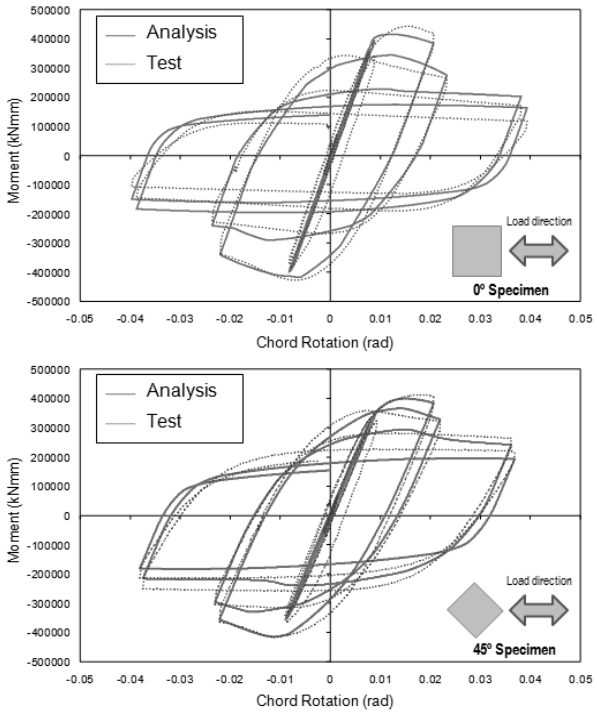

Figure 7 Cantilever Column M-θ Curves

Finite length *l* of the hinge evidently changes column bending stiffness. Thus, the column needs to be stiffened in order to eliminate the additional flexibility due to fiber hinges. By equating the deflection of the cantilever portion (length *L/2*) induced by both hinge rotation and column elastic rotation with theoretical value, the following formula which is used to stiffen the column by increasing its Young's modulus of elasticity to a fictitious value, *E',* is obtained, where *E* is original Young's modulus, *L* is the full column length and *l* is the finite length of fiber element. The effect of this stiffness modification is shown up on the moment vs. chord rotation relationship of the cantilever column (Fig. 7). The analytical results almost match the experimental data.

$$E' = E.\frac{L/2}{L/2 - 3l} = E.\frac{L}{L - 6l} \quad (1)$$

Moreover, the base plate also affects stiffness of the columns in the first story. To evaluate the effect of base plate on column flexibility, the following check is carried out. A base plate with rotational stiffness of α times column stiffness (EI/L) is added to bottom end of the column (Fig. 8-a). Location of the inflection point in terms of α is plotted in Fig. 8-b, indicating that the error of the model created by assuming inflection point at mid-height of column is insignificant as long as the rotational stiffness of the base plate is much larger than column stiffness, as the actual model. This also indicates that fiber method approach can be used as long as the inflection point is close to the middle.

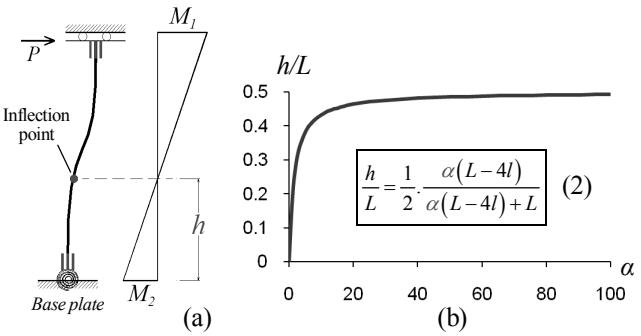

Figure 8 Influence of Fiber Hinges on Column

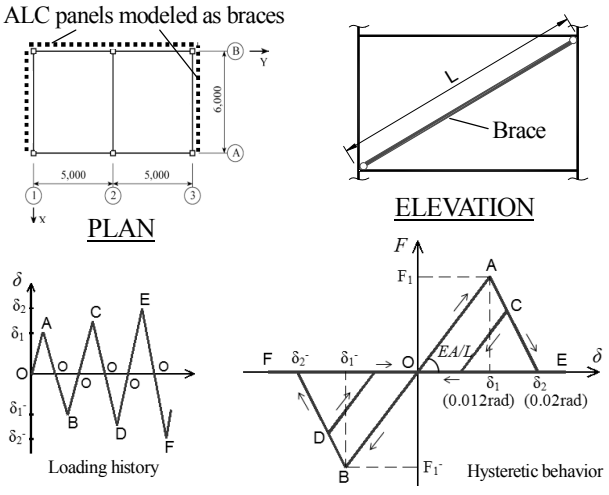

Figure 9 Modeling of Non-Structural Components

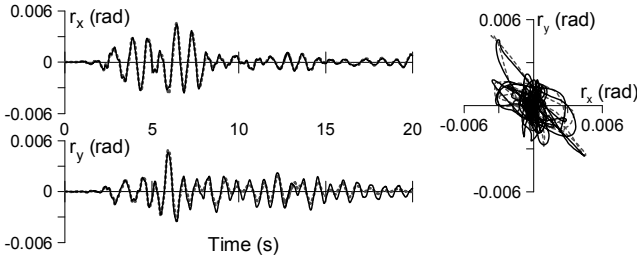
3.3 Modeling of non-structural components

Non-structural components are simulated using braces added on three external frames of the building, with slip behavior so as to degrade resistant capacity after the story drift angle overpassed 0.012 rad and be completely damaged under the story drift angle of 0.02 rad, as shown in Fig. 9. These components contribute about 10% lateral stiffness at each story. Elastic stiffness of non-structural components on each story which is determined by the subtraction of frame stiffness from stiffness of the whole building is then distributed to each brace.

4. TIME-HISTORY ANALYSES

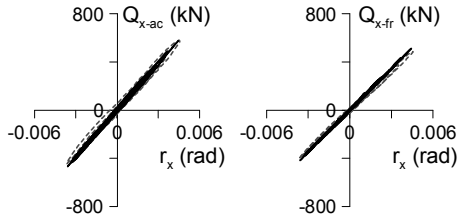
Rayleigh damping is considered in the analyses, and damping ratio of 2% is assigned to cover the first two fundamental modes in both X and Y directions. It is noteworthy that due to counting for stiffness of nonstructural components, the obtained vibration periods (shown in Table 2) are consistent with those from the free vibration test of the building specimen which are 0.80 sec in X direction and 0.76 sec in Y direction.

Table 2 Fundamental Periods [sec]



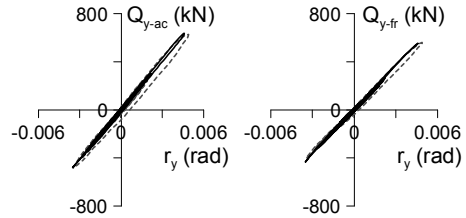
Mode	X-dir.	Y-dir.
1	0.79	0.76
2	0.25	0.24

Actual acceleration records measured on the shaking table during the test are adopted as the input acceleration in the analyses. EW, NS and UD components are used for the X, Y and Z directions, respectively. Three analysis cases of excitation levels, including 20%, 60% and 100% Takatori ground motions, are presented.



Subjected to the motion of 20% Takatori record, the building has worked elastically. The ground motion which is equal to Level-1 design earthquake is not strong enough to separate the base plate away from the stiff foundation. There is hence little likelihood that pre-tension force of anchor bolts is overcome. Thus, the column base under this elastic load case is considered to be very stiff. By using such manner, the analysis output almost agrees with that recorded in the experiment, as shown in Fig. 10.

Fig. 10-a shows the time-history curves of story drift angle in the first story level in X and Y directions, respectively. Fig. 10-b,c shows the story shear (Q) vs. story drift angle (r) relation of the first story. In those plots, solid lines stand for the analytical results, and broken lines show the experimental records provided by the Building Collapse Simulation Working Group. Those figures show good agreement between the analytical results and experimental records.



Under the 60% Takatori ground motion which is 1.5 times larger than the Japanese Level-2 design earthquake (i.e. peak ground velocity at 0.75 m/s), the building performed inelastic behavior. The recorded maximum elongation of anchor bolts reaches up to 0.85 mm, large enough for the

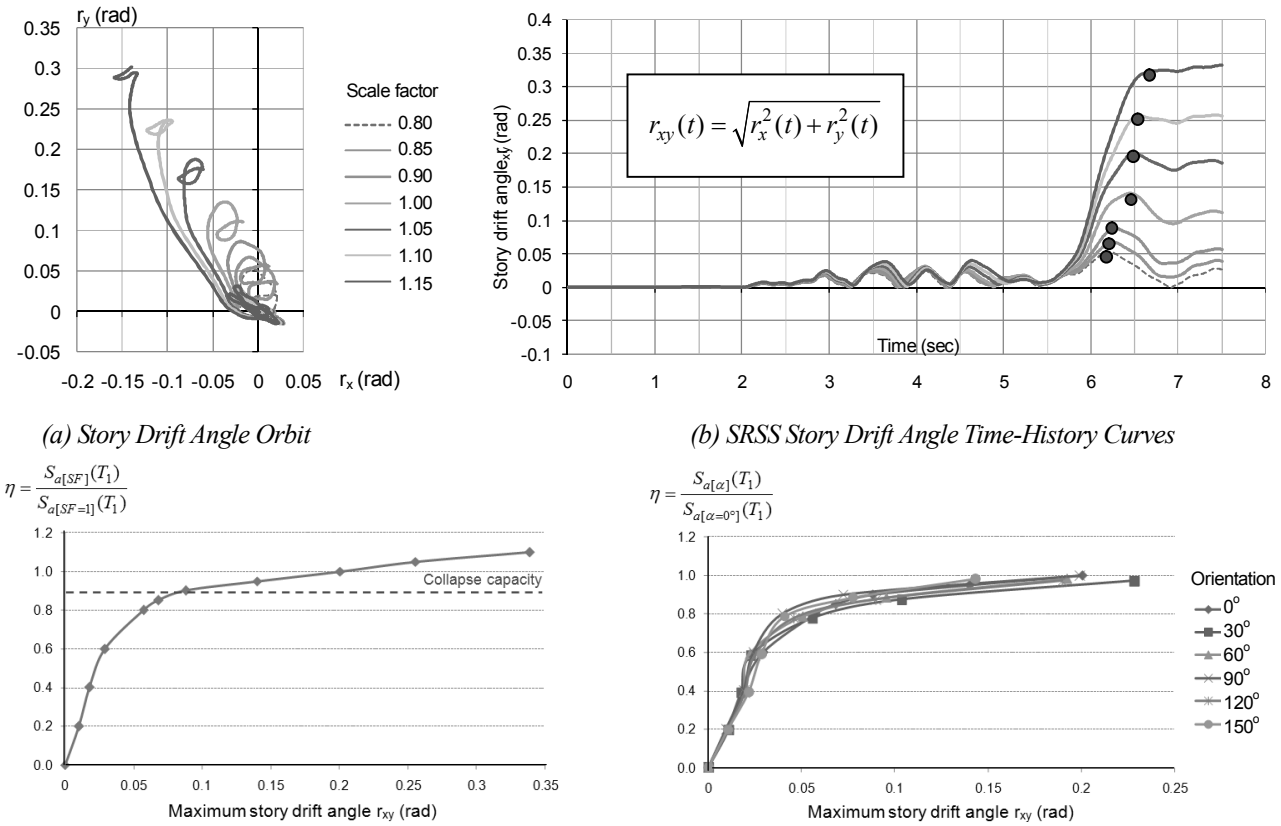
Figure 12 Time-History Analysis Results (100% Takatori Excitation Level, 1st Story)

separation of base plate to occur. Hence, elastic rotational stiffness is assigned for column base plate when analyzing this case. Fig. 11 shows good correspondence between the analytical results and experimental records.

Since non-structural components are taken into account in this study, the analytical model is capable of capturing the difference between the *acceleration-based story shear* (Q_{ac}) obtained from story acceleration times story mass and the *frame-based story shear* (Q_{fr}) obtained from summation of column restoring forces, demonstrating the certain contribution of non-structural components in lateral stiffness of the building. The effect of non-structural components in carrying lateral forces shows up evidently, in which, for instance, the peak Q_{ac} in Y direction is much larger than peak Q_{fr}.



The collapse occurred when the building was subjected to the 100% Takatori ground motion which is 2.5 times larger than Level-2 design earthquake (i.e. peak ground velocity at 1.28 m/s). Fig. 12-a,b shows the analytical results for the collapse excitation level in the same arrangement as those of 60% Takatori presented above. Fig. 12-c,d shows the moment (M) vs. rotation (θ) relation of the column at the A-2 row in the first story. Fig. 12-e shows the moment ($_pM$) - shear angle (γ) relation of the beam-to-column panel in Y direction at the A-2 row in the second floor. The model shows good accuracy of story drift angle time-history curves in comparison with experimental data. Target collapse story drift angle of the first story in either X or Y direction is almost achieved, which is 0.080 rad and 0.186 rad, respectively. Deterioration of column strength due to local buckling characterized by negative slope in the plot of story shear vs. story drift angle relation (Fig. 12-a) also shows up significantly, leading the specimen to collapse.

5. COLLAPSE CAPACITY

Having recently emerged as a powerful means to study the collapse behavior of structures, 'Incremental Dynamic Analysis' involves performing a series of nonlinear dynamic analyses in which the intensity of the ground motion selected for the collapse investigation is incrementally increased until the global collapse capacity of the structure is attained. It also involves plotting a measure of the ground motion intensity (e.g. spectral acceleration at the fundamental natural period of the structure) against a response parameter (e.g. peak story drift ratio), namely Incremental Dynamic Analysis (IDA) curve.

Incremental dynamic analysis is carried out to the analytical model. Peak story drift angle per scale factor is marked by red circles in Fig. 13-a,b. The IDA curve is shown in Fig. 13-c, in which the abscissa indicates peak story drift ratio that normally obtained from the first story, and the ordinate stands for normalized spectral acceleration at fundamental natural period $S_a(T_1)$ (also equal to scale factor), which is the ratio of $S_{a[SF]}(T_1)$ in case of scaled ground motion to $S_{a[SF=1]}(T_1)$ in case of non-scaled motion.

The global collapse capacity is considered reached when the curve in this plot becomes flat. That is, when a small increase in the ground motion intensity generates a large increase in the structural response. However, since infinity is not a possible numerical result, FEMA 350 (2000) suggested the 20% tangent slope approach, in which the last point on the curve with a tangent slope equal to 20% of the slope in the elastic region is defined to be the capacity point. Using the 20% tangent slope approach, the collapse capacity is estimated to be corresponding to the scale factor of approximately 0.90, where the tangent slope of the IDA

(b) SRSS Story Drift Angle Time-History Curves

(c) IDA Curve (Original Case)

(d) IDA Curves (Varied Cases of Orientations)

Figure 13 Incremental Dynamic Analysis Results

curve is five times smaller than its elastic slope.

The collapse capacity of the building specimen under various propagating directions of the 1.0×Takatori ground motion is also investigated. The EW and NS components of the Takatori record which are used previously for X and Y directions are rotated at an angle of α with respect to the original ones. SRSS story drift angle (r_{xy}) and SRSS spectral acceleration are adopted, in which SRSS stands for square root of sum of squares of the parameters in X and Y directions at specific time. The IDA curves for those cases are shown in Fig. 13-d, in which the normalized spectral acceleration is the ratio of spectral acceleration obtained from the direction-rotated ground motion to spectral acceleration estimated from the original ground motion. Results from the curves show that collapse capacity of the building specimen under various load cases is almost equivalent to the original case (i.e. α = 0). It thus can be concluded that the building likely collapses under any direction of the 1.0×Takatori ground motion.

6. CONCLUSIONS

Numerical simulation and collapse dynamic analysis of the E-Defense four-story steel building were summarized in this paper. Followings are some concluding remarks:

(1) Fiber element based method which is adopted in the study is a simple approach but takes effect in modeling local buckling at the column ends, one of the major reasons of building collapse.

(2) The analytical model is successful in simulating dynamic inelastic response and collapse manner of the building which is supposed to be the deterioration of column strength due to local buckling.

(3) Collapse capacity of the building specimen is estimated at approximately 0.9 times the original Takatori ground motion.

Abstract: A steel concentrically braced frame (CBF) is an efficient, stiff building system. However, CBFs may exhibit limited ductility and poor seismic behavior due to brace buckling and low cycle fatigue. An alternative building frame system known as a Self-Centering CBF (SC-CBF) has been extensively tested at the Lehigh University NEES Equipment Site. The SC-CBF increases the ductility capacity of the CBF system by allowing the frame to rock on its base. Post-tensioning bars run vertically along the height of the SC-CBF to self-center the structure leaving no residual drift. The SC-CBF building system is designed using a performance based design procedure that limits the yielding of the post-tensioning (PT) bars under the design basis earthquake but permits significant yielding of the PT bars under intense ground motion such as the maximum considered earthquake in the US (with about a 2500 year return period). Because aftershocks may occur before repairs can be completed it is also desirable to know how the SC-CBF with yielded PT bars will perform. Experimental results show the SC-CBF system performs well in intense earthquake ground motions at the maximum considered earthquake demand level. Results also indicate that the SC-CBF system performs well after the PT bars yield when subjected to a strong aftershock at the design basis earthquake level (475 year return period).

1. INTRODUCTION

Steel concentrically braced frames (CBFs) are an efficient, stiff building frame system which may have limited ductility capacity and poor seismic behavior due to brace buckling and low cycle fatigue. An alternative building frame system (Roke et al., 2006) that retains the high stiffness of a CBF at low levels of lateral load but has significantly increased ductility capacity is being developed at Lehigh University. This new system is called the Self-Centering Concentrically Braced Frame (SC-CBF). The SC-CBF increases the ductility capacity of the building system through rocking of the braced frame on its base. Post-tensioning (PT) bars run vertically along the height of the SC-CBF to self-center the structure leaving little or no residual drift. A schematic of this system is shown in Figure 1 and a typical cyclic hysteresis plot is shown in Figure 2.

A 4 story 0.6 scale SC-CBF was tested using the hybrid simulation technique at the Lehigh University NEES Equipment Site. The SC-CBF was subjected to a total of 31 ground motions at the design basis earthquake (DBE) and maximum considered earthquake (MCE) demand levels. The DBE and MCE are defined by FEMA 450 (FEMA 2003). The DBE corresponds to an event with an approximately 475 year return period while the MCE corresponds to an event with an approximately 2500 year return period. A ground motion record from the 1995 Kobe earthquake at 0.9 scale was used in simulations. The SC-CBF frame was also subjected to "aftershock" earthquake ground motions. An aftershock ground motion record was run twice after yielding the PT bars. Yielding of the PT bars reduced the initial PT force below the design PT bar force. This paper gives a description of the SC-CBF building system and system behavior, describes the laboratory test structure, and presents laboratory testing results from the MCE and aftershock hybrid simulations.

2. SC-CBF BUILDING SYSTEM

2.1 System Behavior

The behavior of the SC-CBF system for the configuration discussed in this paper is shown schematically in Figure 3. Other configurations have been studied and are discussed by Roke et al. (2006, 2009, 2010), Eatherton et al. (2010), and Ma et al. (2010). As shown in Figure 3a gravity loads from each floor are carried by gravity columns

located adjacent to the SC-CBF frame columns. Lateral loads are transferred to the SC-CBF frame through friction lateral load bearings.

The initial lateral load resisting behavior of the SC-CBF frame is similar to a conventional CBF. At low levels of lateral force the frame deforms elastically as shown in Figure 3(b). At higher levels of lateral load the "tension" column decompresses or lifts up and the SC-CBF rotates about the base of the "compression" column. This rocking behavior is shown in Figure 3(c). The initial overturning moment resistance is provided by the prestress force in the vertical PT bars, the friction lateral load bearings, and the weight of the SC-CBF.

The post-decompression lateral translation behavior is largely rigid body rotation. Once the lateral load is removed the force in the PT bars acts as a restoring overturning moment to self-center the SC-CBF. The rocking action of the SC-CBF (and yielding of the PT bars if the seismic demands are high enough) limits the internal frame forces that develop due to earthquake loading. The post-decompression stiffness of the frame is controlled by the amount and location of the PT bars. A distribution strut may be used in the top story to spread out the PT force over multiple stories.

2.2 Limit States and Performance Based Design

There are four primary limit states for the SC-CBF system: (1) decompression, (2) PT bar yielding, (3) significant frame member yielding and (4) frame member failure. Decompression is controlled by the initial prestress force in the PT steel. The occurrence of PT bar yielding is affected by the initial PT prestress force and the deformation demands imposed by a seismic event. Frame member yielding and failure are primarily controlled by member strength and ductility capacity.

In performance based design there are two levels of seismic demand that are considered, the DBE and the MCE. The performance objective for the DBE is immediate occupancy (IO) while the performance objective for the MCE is collapse prevention (CP). The four primary limits states are reconsidered in light of these performance objectives. The performance objectives and primary limit states are summarized in Figure 4. Decompression and uplift of the SC-CBF columns does not cause structural damage if the column base is detailed properly and friction lateral load bearings are used. Therefore the decompression limit state does not affect IO. Yielding of the PT steel reduces the initial prestress force and affects the performance of the structure in aftershocks. While this damage should be repaired by replacing or restressing the PT bars, PT bar yielding does not compromise the safety of the structure and is considered acceptable for IO. It should be noted that the consequence of PT yielding is determined by the PT steel used. Some PT strand and anchorage systems may not be ductile. Some high strength PT bar and anchorage systems have large ductility (Perez et al. 2003). The PT steel used in this study of the SC-CBF system was a PT bar system that can develop ductile behavior.

Small amount of yielding in the frame members (beams, braces, columns, and struts) may not have a significant effect on self-centering behavior of the structure but significant yielding of the frame members may affect IO. Significant yielding of frame members may require repair or the structure may be condemned due to residual drift. Significant member yielding should not occur under the DBE. Yielding of the frame members can be controlled by allowing the PT steel to act as a fuse to limit the amount of force that can be transmitted to the frame members. The performance based design approach for the SC-CBF system uses capacity design principles to keep the frame members essentially elastic at lateral load levels that cause PT bar yielding. See Roke et al. (2010) for more details on the SC-CBF performance based design procedure.

Failure of the frame members by fracture or buckling indicates the onset of collapse of the SC-CBF and should not occur except in very rare seismic events well beyond the MCE. This limit state can be controlled through yielding of the PT bars and the ductility capacity available in the members.

3. LABORATORY HYBRID SIMULATIONS

3.1 Design of Prototype Test Structure

The SC-CBF system and performance based design procedure (Roke et al., 2010) was evaluated through hybrid simulation of a scaled prototype structure. The scale factor was chosen as 0.6 to meet laboratory constraints. This prototype structure, shown in Figure 5, is 6 bays in length and width. Each bay is 5.49 m wide. There are four stories above grade and one basement story. The story heights above grade are 2.74 m for the first story and 2.29 m for the upper three stories. There are four SC-CBFs in each orthogonal direction. Each of these four SC-CBFs carries $1/4^{th}$ of the seismic mass of the test structure due to symmetry.

The prototype structure was assumed to be located at a stiff soil site in Van Nuys, California for the purpose of seismic design and analysis. Since $1/4^{th}$ of the mass of the prototype structure is tributary to each SC-CBF only one frame with two adjacent gravity columns was physically placed in the laboratory. The rest of the prototype structure was modeled numerically. The physical response of the SC-CBF and numerical response of the prototype structure are combined using the well known hybrid simulation technique ("*Hybrid Simulation*", 2008).

The laboratory test substructure consisted of one SC-CBF frame with an adjacent gravity column on each side and six high-strength vertical post-tensioning bars. The SC-CBF will carry $1/4^{th}$ of the seismic mass of the prototype structure. The seismic masses for $1/4^{th}$ of the prototype structure (lumped at each floor) are 135900 kg, 134800 kg, 134800 kg, and 142200 kg from the first floor to the roof, respectively. The total gravity loads carried by $1/4^{th}$ of the gravity load system for the structure are, from the first floor to the roof, 1495 kN, 1484 kN, 1484 kN, and 1556 kN.

The members of the laboratory substructure were designed using the performance based design procedure described in Roke et al. (2010). The members were fabricated from A992 steel and the AISC section sizes are: W10x112 SC-CBF columns, W12x50 beams, W8x67 gravity columns, W8x48 braces for the first, second and third stories, and W8x58 for the fourth story. The distribution strut at the fourth story was a W8x48 and the strut at the base of the frame between the SC-CBF columns was a W8x67, both made of A992 steel. The PT steel was six, 25.4 mm diameter bars. The ultimate strength of each bar, published by the manufacturer, was 567 kN. The yield strength for the PT steel was taken as 454 kN. The initial prestress force in each PT bar for the MCE tests varied from approximately 178-200 kN. The initial PT force for the aftershock tests was substantially less.

The friction lateral load bearings (shown in Figure 6) are located at each floor and are comprised of a brass wearing plate on the SC-CBF column side and a hot-rolled steel "knuckle" on the gravity column side. There is a small gap between the two elements of the friction lateral load bearing. The design value for the coefficient of friction for the friction lateral load bearings was 0.45.

3.2 Maximum Considered Earthquakes

Five different MCE level ground motions were selected to examine the performance of the prototype SC-CBF structure. Ground motions at the DBE level were also used but they are not included in this paper. See Roke et al. (2010) and Sause et al., (2010) for more information on the performance of the prototype SC-CBF structure subjected to DBE level ground motions. Hybrid simulation of the five MCE ground motions was used to couple the response of the laboratory substructure and the rest of the prototype structure. Raleigh damping was used in the hybrid simulation with 2% in the first mode and 5% in the second mode, respectively. A summary of the records used is shown in Table 1. The laboratory testing results for the five MCE records are shown in Tables 2-5.

In addition to the five MCE ground motions a record from the 1995 Kobe, Japan earthquake was included in the hybrid simulations. This record is identified as tak090 and produces a roof drift response well above the mean roof drift response. See Roke et al. (2010) for more details on the mean roof drift response of the prototype structure. The record was scaled by 0.9 because of laboratory constraints. The results of this tak090 hybrid simulation are included in Tables 2-6. The roof drift time-history response is shown in Figure 7 while Figure 8 shows the overturning moment versus the roof drift and the overturning moment versus the gap that develops at the column base.

As shown in Table 2 the MCE ground motions produce a roof drift response greater than 1%. The tak090 produced a significantly greater roof drift response (3.85%). Only records cap000 and tak090 caused yielding of the PT bars. The time history plot of the PT bar force for tak090 is shown in Figure 9. The base shear (V_b) response for all of the MCE records is greater than or equal to 2.9 times the design base shear (V_D). The base shear response to the tak090 record is 4.3 times the design base shear. The overturning moment (OM) varies from 10275 kN-m to 19857 kN-m. The two records that cause yielding in the PT bars (cap000 and tak090) both had maximum overturning moments greater than 14000 kN-m.

The maximum interstory drift for each story and MCE ground motion record is shown in Table 3. All of the stories had an interstory drift greater than 1%, where tak090 had the largest interstory drift at 3.88%.

Normalized brace, and distribution strut forces are given in Tables 4 and 5. The maximum absolute value of the member force was normalized by the factored axial force design demand (see Roke et al. (2010) for more information on this calculation). Three braces exceeded the factored design demand for the tak090 ground motion. The normalized fourth story distribution strut ratio exceeds 1.0 for tak090 only. No yielding of the braces or distribution strut was observed throughout testing.

3.3 Aftershock Earthquakes

Intense earthquakes, such as a MCE, may yield the PT bars. If the PT bars yield then some or all of the initial prestress force may be lost. Yielding of the PT bars and loss of prestress force will affect the performance of the SC-CBF during an aftershock.

There were two aftershock hybrid simulation tests done at Lehigh University. The first aftershock test followed a partial simulation of tak090 that was aborted before completing the test. The PT bars yielded during the aborted tak090 simulation and the total prestress force was reduced to 60-65% of the design prestress force. The SC-CBF was then subjected to an aftershock hybrid simulation. After the first aftershock simulation the prestress force in the PT bars was reduced much further by yielding the PR bars even more. This time yielding of the PT bars was achieved by displacing the frame to a large roof drift in a controlled manner. The prestress force in each bar was reduced to a small value. Some bars were completely slack with a small gap (a few millimeters or less) between the anchor plate and the foundation anchorage. This was followed by the second aftershock simulation.

The ground motion record for the aftershocks was a DBE ground motion record from the 1994 Northridge earthquake (Santa Susana station, 090 component). The scale factor for this ground motion was 2.49 and a plot of the pseudo-acceleration response spectra can be seen in Figure 10.

Hybrid simulations were completed for the two aftershock cases (ReducedPT force and SmallPT force) and the results compared with testing results from a case where the prestess force in the PT bars was near the design value. These results are summarized in Tables 6-9.

The maximum roof drift (shown in Table 6) increased only slightly to 0.79% in the ReducedPT case when compared with the DesignPT. The SmallPT case, however, increased to 0.99% drift when compared to the DesignPT case. This is a 27% increase in roof drift compared with

the DesignPT case even though the total roof drift is not significant (<1%). The maximum base shear went up for the ReducedPT case by 5.4% compared to the DesignPT, but the base shear for the SmallPT case stayed about the same. The overturning moment decreased by 10% for the ReducedPT case when compared with the DesignPT and the SmallPT case decreased by 34.8% compared with the DesignPT case.

The maximum interstory drift shown in Table 7 increases for the ReducedPT case by 0.04-0.08% for each story when compared with the DesignPT case and by 0.12-0.29% for each story for the SmallPT case when compared with the DesignPT case.

Normalized brace and distribution strut forces can be found in Tables 8 and 9. The maximum absolute value of the member force was normalized by the factored axial force design demand (see Roke et al. (2010) for more information on this calculation). The maximum normalized brace forces increased for stories 1 and 3 but decreased for stories 2 and 4 for the ReducedPT case when compared with the DesignPT case. The SmallPT normalized brace forces decreased for all stories when compared with the DesignPT case. Normalized distribution strut forces decreased for the ReducedPT case and even more for the SmallPT case when compared to the DesignPT case. This is expected as the force in the distribution strut is primarily influenced by the force in the PT bars.

4. SUMMARY AND CONCLUSIONS

The SC-CBF system performed well during laboratory hybrid simulations at the MCE seismic demand level with only two ground motion records (cap000, tak090) yielding the PT bars. Yielding of the PT bars results in a loss of prestress force. Significant aftershock ground motions may follow a MCE level earthquake. The aftershock performance of the SC-CBF system was studied in laboratory hybrid simulations after yielding of the PT bars reduced the total initial prestress force to 60-65% of the design prestress force and then later additional yielding reduced the initial prestress force in the PT bars to a small value. The "damaged" frame was subjected to a DBE level aftershock ground motion at each reduced level of PT prestress force. The SC-CBF system performed well in the hybrid aftershock simulations. The test data indicates that the aftershock performance of a damaged SC-CBF is adequate, but more studies should be done. The study documented here was limited and does not address all possible outcomes. Further studies of the aftershock performance of a SC-CBF system could lead to recommendations on how quickly a SC-CBF structure should be repaired after an earthquake and what precautions should be taken regarding immediate occupancy.

Abstract: Special Concentrically Braced Frames are used for seismic design. During small frequent events, their strength and stiffness assure serviceable performance, but inelastic tensile yield and post-buckling compressive deformations of the brace dominate performance during large seismic events. Inelastic deformations of the brace place significant secondary inelastic deformation demands on beams, columns, and connections, which significantly affect the seismic performance. Performance based concepts which require accurate prediction of elastic and inelastic deformations as well as yield mechanisms and failure modes of the system are sometimes used. However. computer models commonly used in practice seldom capture the full range of SCBF behavior. An improved model for the OpenSees computer program is developed to accurately predict seismic performance. This proposed model is somewhat more complex than models currently used in design practice, but it is relatively simple and is suitable for a wide range of practical applications. The model is based upon prior experimental research and is used for both nonlinear pushover and dynamic analyses. The model parameters are based upon the member sizes, properties and connection designs. The model is compared to experimental results and computer predictions commonly used in practice. Errors in theoretical predictions from the various models are compared to experimental data. The proposed model provides accurate simulation of global behavior, while retaining simplicity and providing reasonable predictions for many local behaviors.

1. INTRODUCTION

Special concentrically braced frames (SCBFs) are widely used for lateral-load resistance of buildings. They provide the strength and stiffness needed for an economical system that easily meets serviceability limit states for performance based seismic design (PBSD). During large, infrequent earthquakes, SCBFs must assure life safety and collapse prevention PBSD limit states, and this requires prediction of the inelastic behavior. As a result, theoretical models for PBSD must reliably predict both elastic and inelastic performance. However, current modeling methods seldom accurately predict these full behavior, yield mechanisms, and failure modes.

The inelastic seismic response of SCBFs is dominated by compressive buckling, tensile yielding and post-buckling behavior of the braces [Popov et al. 1976]. The braces are typically connected to beams and columns through gusset plate connections, which must tolerate large inelastic deformations and end rotations associated with brace buckling, while sustaining the full axial resistance of the brace. Gusset plate connections and beam and column framing members provide boundary conditions to the brace, and therefore influence its resistance and deformation capacity. Proper design of the connections may significantly improve the response and deformation capacity of the frames [Lehman and Roeder 2008]. However, in many analyses for structural design, the gusset plate connection is simulated as pinned or rigid joints. These approximations may limit the accuracy of the stiffness and resistance predicted by the computer simulation, and they commonly lead to erroneous predictions of the deformation capacity and failure modes of the system.

Since the seismic behavior of SCBFs is quite complex, some very detailed computer models have been developed to accurately predict their performance [Huang and Mahin 2010, Shaw etal. 2010, Yoo 2006, Yoo et al. 2008-2009]. These models have invariability employed a relatively fine mesh of nonlinear shell or 3-dimensional brick elements. Some analyses modeled only braces or their connections [Huang and Mahin 2010, Shaw etal. 2010], while others evaluated individual braced bays or multi-story single-bay CBFs [Yoo 2006, Yoo et al. 2008-2009]. Accurate models must include large deformation theory for simulation of both local and global buckling, and some studies extended the models to include consideration of initiation of cracking and fracture based upon the strains, components of strains, or stress-strain history computed in the analyses [Huang and Mahin 2010, Shaw etal. 2010, Yoo et al. 2008-2009]. The effort required to develop these models is substantial, since some had more than 20,000 shell elements and a much larger number of degrees of freedom. Nonlinear analyses

of these complex models required considerable computing time with the analyses required several days to complete a cyclic load history. Nevertheless, these complex models provide accurate representation of global and local behavior of the system, and numerous comparisons are made between local and global behavior in analysis and experiments. However, these complex models are too time consuming and expensive for typical professional practice, and further they are not suitable for completing nonlinear static and dynamic analysis for PBD of larger braced frame systems.

Simpler methods are needed for nonlinear dynamic analysis and practical evaluation of the nonlinear performance of large structural systems. Unfortunately, most simple models result in significant loss in accuracy in predictions of SCBF performance. A simplified but relatively accurate nonlinear method is developed for the OpenSees computer program and evaluated in this paper. It utilizes basic concepts of engineering mechanics to provide properties of key components of the analytical model, and these concepts are based upon observed performance of braced frames in past experimental research. The accuracy of the proposed model is verified by comparison to past experimental results, and comparisons are made with other common computer models to show that the proposed model provides improves accuracy over current methods and permits reliable prediction of seismic performance of SCBF systems.

2. Observed Behavior from Experimental Research

The proposed model is based upon behavior observed in prior experiments, and therefore a brief review of prior experimental research is required. A number of experiments have been performed on braces, gusset plate connections and other components of SCBFs. However, research shows that component tests do not accurately reflect SCBF system behavior due to the complex interactions of the brace with connections and other framing members during cyclic inelastic deformation [Lehman and Roeder 2008]. A more limited base of test data is available for SCBF system tests. A series of single-story and multi-story braced frame tests, which focus on the influence of the gusset plate design on the overall cyclic lateral response of SCBFs, were conducted at University of Washington (UW) and National Center for Research on Earthquake Engineering (NCREE) in Taipei, Taiwan.

Thirty single-story frame specimens such as illustrated in Fig. 1a were tested at the UW. These steel frames had no slab and had somewhat idealized boundary conditions, but they were tested with a wide range of gusset plate configurations, design strategies, brace types and configurations. Three 2-story and three 3-story SCBFs as illustrated in Figs. 2b and 2c were tested at the NCREE Laboratory in Taiwan. These frames included composite floor slabs with realistic test boundary conditions. Several variations of connection design and brace type were tested, but a major goal of these multi-story tests were to provide confirmation of analytical models and design methods that could not be obtained from the single-story single-bay tests. An extensive body of local and global data is available from these tests, and this data was used for development, calibration and verification of the proposed model.

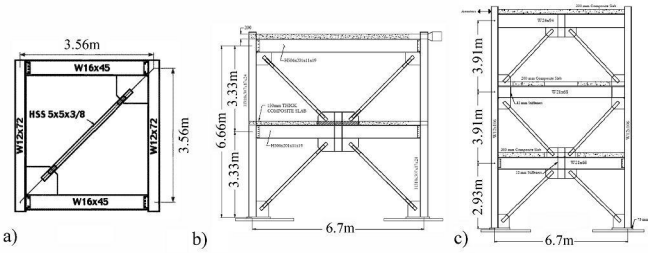

Figure 1. Typical Test Specimens; a) Single-Story Single Bay SCBF, b) Two-Story Single-Bay SCBF, and c) Three-Story Single-Bay SCBF

A number of important observations were made from this experimental research, and a number of important recommendations and observations can be noted. These include:

- Extensive local yielding must be expected in the beam and column adjacent to the gusset plate.
- Extensive inelastic deformation of the gusset plate must be expected, but it should occur after initial yielding and buckling of the brace to maximize SCBF inelastic deformation capacity. Gusset plate yielding reduces local buckling, deformation in the beams and columns adjacent to the gusset plate, and damage to the welds. Different methods are available for permitting and accommodating gusset plate deformation. The 2tp linear clearance shown in Fig. 2a works well with tapered gusset plate connections, but if often leads to larger, thicker gusset plates, which may significantly reduce the inelastic deformation capacity of the system. The 8tp elliptical clearance model shown in Fig. 2b often permits smaller, more compact gusset plates, which provides increased inelastic deformation capacity and reduces the size of the relatively rigid connection stiffness zone and the damage to welds, beams and columns adjacent to the gusset. This 6tp horizontal clearance zone shown in Fig. 2c works better than alternatives at the midspan gusset, because the bottom flange of the beam provides less restrain to the gusset than that provided when two edges are restrained by the beam and column at corner gusset connections.
- The strength and stiffness of the gusset plate connection must be adequate to develop the expected resistance of the brace, but excess strength and stiffness concentrates the inelastic deformation into a short length of the brace and causes early brace fracture.
- Tapered gusset plates behave a bit differently than rectangular gussets. They may provide good end rotational capacity for the brace, but they also result in thicker gussets or greater inelastic demands on the gusset plate and the welds.
- Wide flange braces achieve larger inelastic deformations

than HSS tubes, but they do this at the cost of increased deformation demands on the gusset plate connection.

These observations all affect the inelastic response of SCBF system, and the proposed computer model or any other model that accurately predicts SCBF performance must be capable of incorporating these and other behaviors.

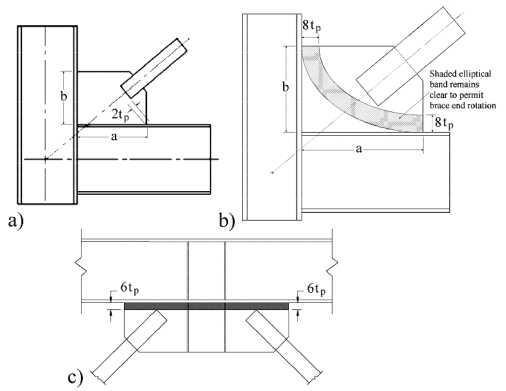

Figure 2. Variations in Gusset Plate Connections; a) Current 2tp Linear Clearance, b) Elliptical Clearance, and c) Horizontal Clearance for Midspan Gussets

A wide range of analyses including the full nonlinear shell element analyses as well as the simplified analyses described in this paper were performed on each of the 36 test specimens. The specimens cover a wide range of analytical parameters, and a group of 14 specimens, which reflect the full range of observed performance, were selected to demonstrate the effect of all parameters on the accuracy and viability of the various computer models. The analyses will include and verify the important observations from the experimental study for these 14 SCBF frames, and critical data for these specimens is defined in Figs 3a to 3c and Tables 1 and 2.

The 14 specimens included 9 single-story single-bay frames (HSS1, HSS2, HSS5, HSS7, HSS10, HSS11, HSS12, HSS17 and WF23) as described in Table 1. HSS 5x5x3/8 brace tube were adopted for all of the HSS specimens. HSS1 and HSS12 were included because they used the current AISC design practice. They employed the 2tp linear clearance, and as a result had larger gusset plates. The two specimens had different failure modes, and the size and thickness of gusset plates strongly influence system performance. HSS2 and HSS5 were specimens designed with thinner more compact gusset plates by the elliptical clearance method, but different clearance values were employed. HSS10 and HSS17 had a tapered gusset plate, which clearly have different behavior than rectangular gussets. HSS7 and HSS11 employed the elliptical clearance model but the gusset plate was thicker than the minimum required, and HSS11 also had heavier beams than required. Strength and stiffness of the connection and framing members strongly influences SCBF performance. WF23 had a wide flange brace, and wide flange braces can sustain larger inelastic deformations and place greater inelastic demands on the connections than HSS tubes. These parameters address key conclusions noted from the experimental research [Johnson 2005, Herman 2006, Kotulka 2007, Powell 2009]. The ability of computer models to capture these differences is important.

Three 2-story single bay frames (TCBF1-HSS, -WF and -TG) and two 3-story single-bay frames (TCBF2-HSS and -WF) were included in the analytical study as shown in Table 2. These multi-story frame tests permit evaluation of more variation in braces and connections, composite floor slabs, different boundary conditions, and the ability to predict multi-story effects. Specimens TCBF1-HSS, -WF and -TG were tested by using a single set of framing using Taiwanese hot rolled shapes, H506x201x11x9 for beams and H318x307x17x24 for columns as shown in Fig. 2b. Two different types of braces, HSS- and WF-sections, with gussets designed by the 8-tp elliptical clearance model, were evaluated in TCBF1-HSS and -WF tests. TCBF1-TG had tapered gusset plates with 2-tp linear clearance. Specimens TCBF2-HSS and –WF employed another set of beam and column framing with US shapes as shown in Fig 1c, and it had mid-span gusset connections with the 6-tp horizontal clearance (Figure 2b). The braces and gusset plates were replaced between the tests for all multi-story frames. Lateral cyclic loads were only applied at the top level of concrete slab through the load beams, and the framing members were reused through entire phase. Only the braces and gusset plates were replaced between the tests. Additional details of the test setup and dimensions may be found elsewhere [Clark 2009, Lumpkin 2009].

3. Computer modeling of SCBFs

Tensile yielding, buckling and post-buckling behavior of the brace are highly nonlinear and key elements in the seismic response of the SCBF system. Significant deformation and yielding are also required in the gusset plate connections, and local yielding of the beams and columns adjacent to the gusset plate are invariably noted in experiments. To simulate these complex behaviors, the typical continuum finite element analysis such as the detail nonlinear shell element model described earlier has been used. However, these complex finite element simulations are always computational costly and time consuming. Further, large structural systems would require so many elements and degrees of frame, that analysis this complex modeling impractical for nonlinear dynamic analysis of complete systems. A proposed model of the concentrically braced frame was developed in OpenSees framework [OpenSees], which was a simplified discrete model that enabled accurate representation of SCBF behavior. Similar OpenSees models have been used in other recent research, however different models of connection performance were employed [Uriz and Mahin 2008]. The force-based nonlinear beam-column element with four integration points was the primary element in the proposed model. The sections were created using fiber sections, which enable the creation of the various steel cross sections with an assumption of the plane remains plane. The Giuffre-Menegotto-Pinto model with the Steel02 material was the nonlinear constitutive law used for all members. The OpenSees model also was used to evaluate nonlinear models with pinned or rigid joints at the brace-beam-column connections.

3.1 Simulation of Brace buckling behavior

Modeling the cyclic inelastic behavior of braces, including buckling in compression, yielding in tension and post-buckling behavior, must be included in the analysis of SCBF system performance. The proposed OpenSees model in this analytical research built upon the modeling approach developed by Gunnarson in a prior analytical study [Gunnarsson 2004]. This prior work showed that accurate simulation of brace buckling behavior is achieved with ten or more nonlinear beam-column elements using fiber sections along the length of the brace. The fiber sections consisted of several quadrilateral patches provided in the OpenSees program that allow for variability of the cross-section. The mesh of fibers within each quadrilateral patch is defined by the number of subdivisions (fibers) in both directions of each patch. Prior study also showed that accurate predictions of AISC buckling capacity are achieved with initial imperfection of 1/500 of the length of the brace in the shape of sine function, and verified the approach for different cross-sections and end conditions [Gunnarsson 2004, AISC 2005].

The required number of the fibers through the cross-section of the brace was investigated, and 4-by-4 fibers for each of eight quadrilateral patches to form the tube section, as shown in Fig. 3a, were found to converge accurately on brace performance. For wide-flange braces, the 2-by-10 fibers were used for each flange and web, and the finer mesh of fibers was arranged in the buckling direction of the cross-section as shown in Fig. 3b. The material properties were based upon measured properties noted for each test specimen, and 1% strain hardening was used for the brace elements. The brace was invariably stiffer and stronger at each end due to the overlap length of the gusset and net section reinforcement commonly required at the gusset. This increased local strength and stiffness was modeled, and reduced deformation with little local yielding occurred in this portion of the brace. To represent the complex cross-section at these locations, an increased strength element was used at each end of the brace. To accomplish this, the yield stress and initial stiffness of the steel in this local area were multiplied by 3 to assure that the local region remaining elastic. This ratio was deemed to be appropriate because the Whitmore width of the gusset should have somewhat more area than the brace, and net section reinforced further increased the local strength and stiffness. To capture large deformations of the SCBF system, the structural analysis used the co-rotational coordinate transformation, which performs an exact geometric transformation of element stiffness and resisting force from the local coordinate system into the global coordinate system.

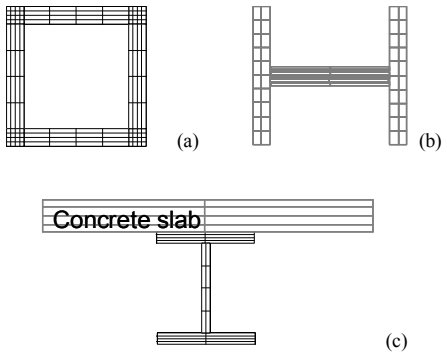

Figure 3. Fiber sections of brace and composite beam members; a) HSS tube brace, b) Wide-flange brace, and c) composite beam.

3.2 Modeling of framing components

Significant local yielding in beam and column members adjacent to gusset plate connections occur in SCBF experiments. As a result, the nonlinear behavior of all beam and column members also employed beam-column elements combined with fiber sections using 2-by-4 fibers for each flange and web. More fibers were arranged in the bending direction in the cross-section as depicted in Fig. 5. The single-story single-bay frames and columns of multi-story frames were steel members without composite action. However, the beams in the multi-story test frames were composite member. To consider the composite effect of the concrete slabs in the simulation of the multi-story frame specimens, 2 by 4 fibers representing concrete behavior

were used in the fiber section of the composite beam as illustrated in Fig. 3c. The true dimensions of the slab in the specimens were used in the model, and an elastic material model, which did not develop tensile stress, was used for representing the concrete behavior.

3.3 Beam-Column Connections.

Beam column connections were commonly shear plate or shear tab connections for beam-column joints without gusset plates attached. Shear tab connections were bare-steel in the single-story single-bay test specimens and with slabs in multi-story specimens. A zero-length nonlinear spring element using the moment-rotation model developed by Liu [2000] was useded to estimate the initial rotational stiffness and the maximum positive and negative moment capacity for the shear tab connections with and without slabs. This model considers composite action for shear tabs with composite slabs bearing against the face of the column. Beam-column connections at beam-column-brace connections were usually welded-flange welded-web connections. As a resulted, they were treated as fully restrained connections with the simplified pinned or fixed connection models. The brace was either pinned or rigidly fixed to the beam-column joint with the simplified pinned or fixed connection models, since these assumptions are common in practice.

3.4 Proposed model of gusset plate connections

Gusset plate connections in the real structures are neither pinned nor fixed joints, and these connections have a significant effect on the stiffness, resistance and inelastic deformation capacity of the SCBF system. Hence, accurate simulation of these connections is required. A wide of alternatives were considered in developing an accurate simulation. To simulate the nonlinear out-of-plane rotational behavior of the gusset plate connections, single and multiple springs along the brace axial direction at and beyond the end of the brace were considered and investigated. Various initial rotational spring stiffness, from pinned to rigid joints, and with different yield strength of the nonlinear springs were evaluated. It was found that increased initial spring stiffness increased the predicted buckling capacity of the brace. Hence, the correct estimate of the gusset plate stiffness is required to accurately predicting the buckling capacity of the brace.

The results showed that the multiple spring model provided similar analytical responses with the single nonlinear spring model but frequently caused convergence problems. Ultimately, simplified single-spring models which were placed at the ends of the brace were selected. Rigid links from the work point of the connection to the spring at the end of the brace and to the partial dimensions of the gusset were employed because of the relative in-plane rigidity of the gusset and the limited deformation occurring at the beam and the column attached to the gusset plate. Figure 4 shows a schematic of the proposed model for the connections. The stiffness of the zero-length nonlinear rotational spring element at the end of the brace simulated the out-of-plane deformational stiffness of the connection. Therefore the stiffness of this rotational spring was based upon the geometry and properties of the gusset plate. This initial out-of-plane rotational stiffness of the nonlinear rotational springs is a rational estimate of gusset stiffness and it is based upon a prior continuum finite element study by Yoo [2006].

$$K_{cal}^{rotational} = \frac{E}{L_{ave}}\left(\frac{W_w t^3}{12}\right) \qquad \text{(Eq. 1)}$$

where E is Young's modulus of steel, Ww is the Whitmore width defined by a 45° projection angle, Lave is the average of L1, L2 and L3 as shown in Figure 4, and t is the thickness of the gusset plate. The analyses showed that using the plastic moment capacity of the Whitmore cross-section with a 45° projection angle as the yield resistance for the rotational spring model led to the best prediction of the post-buckling compressive resisting strength of the frame.

These parameters are somewhat empirical terms, but they are also consistent with basic engineering mechanics. Gusset plates are designed for stress levels averaged over the Whitmore width of the gusset, and so this width represents the portion of the gusset that is considered effective in resisting the loads and deformations of the brace. The rotational stiffness in Eq. 1 is effectively the EI/L of the gusset, and EI/L is the rotational stiffness of a cantilever beam with the properties of the gusset. The stiffness is affected by the thickness and properties of the gusset, and the Whitmore width will be affected by tapered gusset plates, since the actual width of a tapered gusset is used if the actual width is smaller than the Whitmore width.

The gusset plate is relatively rigid against in-plane deformation, and therefore rigid links are used to simulate this rigidity in the proposed improved model. The rigid zone extends from the work point of the connection to the physical end of the brace and the physical end of the gusset as it extends up the column. However, it only extends out to 75% of the dimension "a" on the beam (see Fig. 2a and 2b) to permit some limited deformation within the "rigid" zone. The adopted rigid link at the ends of the brace makes the brace length identical to the specimens, and provides the most accurate estimate of brace buckling resistance. Experiments show that some in-plane deformation of the gusset occurs due to diagonal stresses and deformation, and therefore the ideal rigid zone is somewhat smaller than the full size of gusset, since this permits more beam and column deformation. The analytical results of the study showed that using smaller rigid zone on the beams and columns results in smaller compressive resisting strength of the frame in the post-buckling level, and the adopted size of rigid zone on the beams and columns defined above was the size found to best represent the experimental behavior for all test specimens. Tapered gussets have smaller dimensions "a" and "b" than rectangular gussets, and hence greater deformation is permitted. The analytical results also confirmed that the fiber elements joining to the rigid links on

the beams and columns permit yielding that reflects the local yielding observed in experiments. The combined effect of these modeling attributes led to significant improvements in the predicted performance of the SCBF systems.

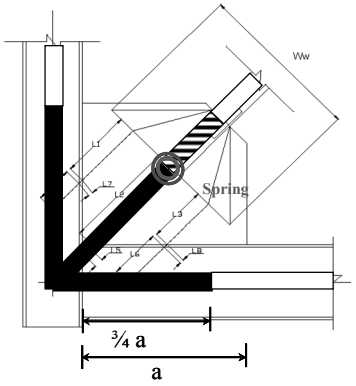

Figure 4. A schematic of the gusset plate connection model

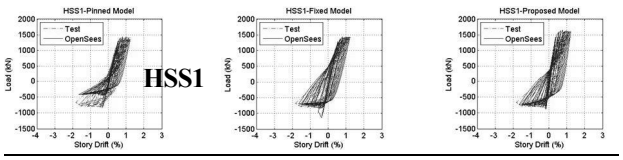
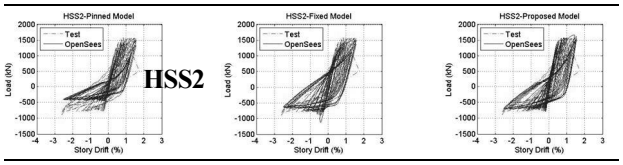
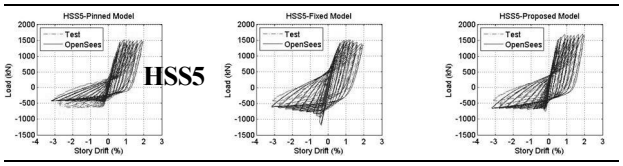
3.5 Alternate models

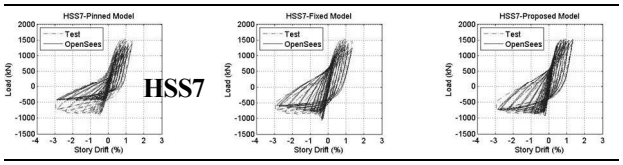
While the proposed improved model is simpler than the complex shell element models described earlier, they are a bit more complex that models commonly used in engineering practice. In most cases, shear plate connections are analyzed as pin connections for practical analytical studies. Beam-column connections may be modeled as rigid connections for beam-column connections at gusset plate connections or fully restrained beam-column joints. Brace buckling may be modeled through nonlinear elements, but the ends of the brace are either pinned or fixed to be work point of the beam column joint. Two alternate connections with these simplified assumptions are depicted in the top of Table 3. The two alternate connections reflect the variation that is expected in practice, and they are compared to theoretical predictions with the proposed improved model to demonstrate the effect of variations in analytical model on the accuracy of the predicted results. The OpenSees beam and column modeling was similar for all analytical models. While the pinned and fixed models included in the study use simplified assumptions of the connections, they continue to employ the full benefits of nonlinear modeling and analysis provided by OpenSees, even though many commonly used computer programs has significantly less capabilities for simulating material and geometric nonlinearities.

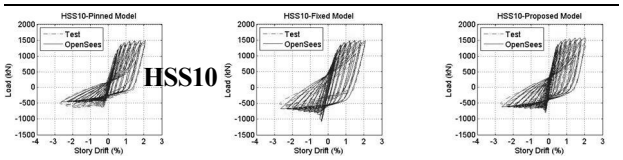
4. Simulation results

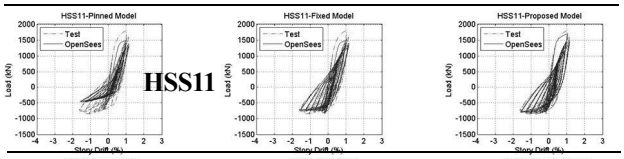


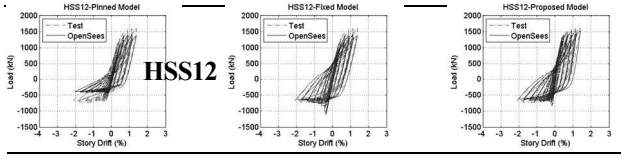


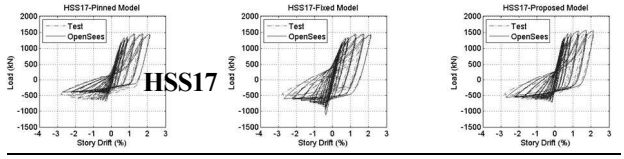


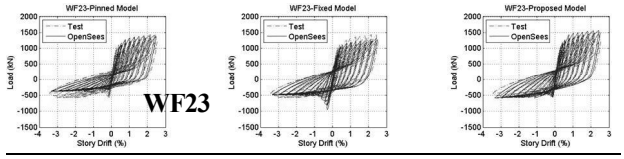












The proposed models was compare to the test results of the 14 experiments and to the analytical results obtained with pinned brace joint and fixed brace joint models to demonstrate the relative accuracy of the different theoretical predictions.

4.1 Single story frames

The 9 single-story single-bay frames were analyzed with the proposed improved model as well as nonlinear models with pinned and fixed brace joints, and the results of the global response are given in Table 3. The pinned model always significantly underestimated the buckling capacity of the brace. The fixed model always significantly overestimated the brace buckling capacity, and it also predicted more dramatic loss of resistance during post-buckling deformation. The proposed model consistently provided a more accurate prediction of the buckling capacity of the brace due to using the real length of the brace and proper modeling of the gusset plate connection. It should be emphasized that the basic frame modeling was the same for the different analytical models. Moreover, the proposed model simulates the post-buckling behavior with reasonable accuracy for all specimens due to both of the appropriate modeling of the brace and rigid links on the beams and columns adjacent to the gusset plate connections. All models provided similar predictions of tensile resistance and stiffness of the frame. They overestimated or underestimated the tensile resistance with similar errors and frequency.

A number of individual differences and comparisons are noted. HSS1 was designed by the 2tp linear clearance method with current design provisions and had a relatively large gusset plate and rigid-length effect. The improved proposed model slightly overestimated the initial stiffness and tensile strength of the frame. The pinned and fixed joint models, which excluded the rigid off-set, better captured the initial stiffness and the tensile strength of the frame, but had significant error in the compressive resistance. HSS2 was designed with the elliptical-clearance model and had smaller gusset plates comparing with HSS1. This resulted in more accurate estimates of stiffness and compressive and tensile resistance than the pinned or fixed joint models. HSS5 had thin gusset plates with 8tp-elliptical-clearance gusset plates, which provided greater ductility and deformation capacity than other specimens. The proposed model slightly overestimated the initial stiffness and the tensile strength compared to the traditional models. HSS7 and HSS 11 had thick gusset plates of 7/8 inches and the proposed improved model provided consistently better estimates of stiffness and resistance. HSS10 had tapered gusset plates that led to shorter rigid lengths on the beams and columns, and the proposed model had better estimates of compressive behavior than pinned and fixed joint models. The tensile resistance was again overestimated by a modest amount. HSS12 had exactly the same dimensions of specimen HSS1 but using the CJP welding at the gusset to beam and column connections, but avoided the early weld fracture noted with HSS1. As a result, the proposed model more accurately predict the behavior of the specimen. HSS17 had thin and tapered gusset plates, and the proposed model again predicted the overall behavior of the frame more accurately than other models. WF23 had wide-flange brace with thin gusset plate designed by the 8tp elliptical clearance model. The proposed model accurately predicted the buckling capacity and the post-buckling behavior of the brace, but overestimated the strength with the brace in tension.

4.2 Multi-story frames

After the development of the proposed model, the multi-story frames were tested, and they were used to further verify the proposed model. The composite effect of the concrete slab was included in the model except the block-out regions which was used for the installation of the gusset plate connections due to the reuse of the framing system, as shown in Fig. 1. The global and individual story hysteretic responses were compared with test results in Tables 4.

TCBF1-HSS was a two-story with rectangular HSS braces. Table 4 shows that the proposed model accurately predicted the hysteretic behavior of the specimens not only at the roof level but also the individual story responses. The proposed model accurately estimated the stiffness distribution of the multi-story specimen, as shown in Table 4. The 3-story single-bay frames were also analyzed and comparisons. TCBF2-HSS was tested first, and the proposed model accurately represented the initial stiffness, lateral resistance and the distribution of stiffness and deformation over the height of the frame, as shown in Table 4. The comparisons of other multi-story specimens, TCBF1-WF, TCBF1-TG and TCBF2-WF, had similar trend, which are not shown in this paper due to the length limit of the conference paper.

Table 4. Analytical and experimental responses of the multi-story frames

3rd-story	--	

The errors in prediction of the overall energy dissipation, maximum lateral resistance and buckling capacity of the frames were calculated to further demonstrate the relative accuracy of the various models. These comparisons are shown in Table 5. The energy dissipation of the analytical and experimental cyclic responses was calculated by integrating and accumulating the areas of every hysteretic cycles of the frames. The analyses and experiments were displacement controlled, and so the applied story drift was identical between the experimental and analytical responses. As a result, the errors of the energy dissipation reflect the accumulated errors of the predicted resistance of the frames. Through all

specimens, the average errors of the energy dissipation were around 13% by using the proposed model, and 42% and 20% by using pinned and fixed model, respectively. In terms of the maximum resistance of the frames, the proposed model consistently provided a better estimate than the pinned and fixed joint models. The pinned joint consistently underestimated the compressive resistance, while the fixed joint model consistently overestimated the compressive resistance. The proposed model slightly overestimated the resistance with the frame having very thin gusset plates. Moreover, the proposed model provided significantly better estimates of buckling and post-buckling behavior than the pinned and fixed joint models for the single-story frames. For multi-story frames, the pinned joint models provided relatively poor estimates, while the proposed model and the fixed joint model were relatively comparable. In general, the proposed model best represented the experimental response for all single-story to multi-story frames.

5. Local Comparison

The ability to predict local behaviors is another important test of finite element analysis. The complex nonlinear shell element analyses provide accurate predictions of local behavior including local yield and local buckling and distortions. OpenSees analyses clearly are not capable of capturing some of these local effects, because the plane-sections-remain-plane constraint effective restrains deformations so that most local buckling and distortion cannot occur. However, local yielding is observed in the beams and columns adjacent to the gusset plate, and the extent of the computed yielding is clearly approximately proportional to that observed in the tests.

Midspan out-of-plane deflection of the brace is a key element of the local responses of the SCBF systems, and it is more easily captured and documented in the OpenSees analysis. This out-of-plane deformation is an important parameter, because it is closely related to the fracture potential of the brace. The OpenSees models employ the assumption that plane-sections-remain-plane, and therefore, they cannot capture the local buckling behavior observed at the midspan of the brace during experiments. Therefore OpenSees models would be expected to always slightly underestimate the amount of the midspan deflections measured during the test. Table 6 provides comparisons of the maximum analytical and experimental out-of-plane displacement of the within the single-story one-bay tests. The story drift for the experiment and analysis are identical for all models at this comparison point. The basic model with fixed joints always predicted smaller out-of-plane deformations than the pinned joint model and the proposed model, due to the more rigid boundary condition of the braces. The proposed model and the pinned joint model were relatively comparable. However, the proposed model having real brace length in the analysis would predict closer deformed shapes of the out-of-plane deflection along the braces. Through the series of the single-story one-bay tests, the proposed model enabled to accurately predict the out-of-plane deformations for the specimens with normal rectangular gussets, while have relatively larger errors for the specimens having tapered gusset plates, HSS10 and HSS17, and that having larger beam, HSS11.

Table 6. Experimental and analytical mid-span out-of-plane deflections of the braces

6. Summary and Conclusions

This paper has addressed the nonlinear finite element analysis of the seismic performance of the the SCBF system. A simplified improved model was proposed and the computed results were compared to experimental results and the computed for nonlinear models more commonly used in analysis. The proposed model consisted of beam-column, rigid-length and spring-type elements, and they enabled accurate simulation of the cyclic behavior of the braced frames with minimal computing cost and time. The model includes the effects of buckling, post-buckling and tensile-yielding behaviors of the frames, and it was verified through a great number of specimens using various types of braces and gusset plates.

The computed analytical results varied significantly with different models. Pinned and fixed end brace models are commonly used in practice for simulation of braced frame performance. However, both of these models resulted in significantly different and inaccurate analytical responses comparing with experimental results through a great number of specimens. The fixed end brace model significantly overestimated the compressive resistance of the brace and the deterioration of resistance in post-buckling deformation, but it underestimated some local deformations such as the out-of-plane deformation of the brace. The pinned end brace models significantly underestimated the compressive resistance of the brace, and sometimes overestimated local deformations such as the out-of-plane deformation of the brace. All models provided good but similar variability in accuracy in predicting stiffness and tensile resistance.

The proposed improved model provided significantly more accurate estimates of compressive capacity of the brace and post buckling deformation. It provided good estimate of the distribution of deformation between stories of multi-story frames. It consistently provided reasonable accuracy through the wide range of parameters considered in the experimental program.

Using real length of the brace and appropriate boundary conditions helped the proposed model accurately estimate the buckling capacity of the brace in the structures. Moreover, modeling the proper rigid off-set on the beams and columns at the gusset plate connections significantly affected the simulations of the tensile strength and post-buckling behavior of the frame. Based on the analytical investigation, besides the buckling capacity of the braces, the post-buckling behavior of the frames was also accurately predicted by the proposed model due to the proper rigid off-set of beams and columns. In terms of the tensile strength, the frames with thick gusset plates were accurately predicted by the proposed model, while that with thin gusset plate, 3/8-inche plate, were slightly overestimated. In the comparisons of energy dissipation and lateral resisting forces, the traditional model with pin-ended braces had poorest accuracy. In terms of comparisons of the midspan out-of-plane deflections of the brace, the basic model with fixed brace joints had poorest accuracy. In general, the proposed improved model always gave the consistently highest-accuracy and more reliable predictions in both of the global and local response levels.

Abstract: Steel concentric braced frames (CBFs) are widely used as systems to resist lateral loads induced from wind and seismic loading. Recent research on full-scale CBF subassemblages has shown that current design provisions fall short of the design intent. Additionally, the effect of imposed out-of-plane deformation on the system has never been evaluated experimentally in this manner. This paper describes the design, test setup and experimental results of two tests performed on a two-story, one-bay by one-bay CBFs, an HSS buckling-brace system in a single-story X-configuration, and a buckling-restrained braced frame (BRBF) in a single-diagonal configuration. The design of the gusset plates for the HSS braces followed a balanced design procedure with an elliptical clearance to permit out-of-plane rotation due to brace buckling. The HSS braces fractured at 2% story drift. The BRBF gusset plate design followed current U.S. design standards, and the BRB cores fractured at 3.5% story drift prior to any instability.

1. INTRODUCTION

Concentric braced frames (CBFs) are widely used as systems to resist lateral loads induced from seismic loading. In high seismic regions, special concentric braced frames (SCBFs) are used. Recent research on full-scale CBF subassemblages has shown that current design provisions fall short of the design intent (Chen et al. 2004, Mahin et al. 2004). Subsequent research has evaluated improvements to the connection design (Yoo et al. 2008). The results have been used to develop a design methodology to balance the multiple yield mechanisms of the frame, most importantly the brace and the gusset plate, to maximize the drift capacity. The process further evaluates all potential failure modes to ensure the desired mechanism occurs and all others are suppressed. This research has resulted in more rational design and detailing rules for SCBFs.

Prior tests performed on braced frames were planar, single and multi-story specimens. The current paper focuses on the full, three-dimensional response of a two-story, one-bay by one-bay large-scale CBF structure that was tested using the MAST laboratory at the University of Minnesota as part of the NSF-funded project entitled "International Hybrid Simulation of Tomorrow's Braced Frame Systems" through the NEES research program. The test specimen simulated the corner bay of a two-story building system braced in two orthogonal directions. The first test used conventional HSS diagonal braces in a single-story X-configuration in each story. The second test used buckling restrained braces (BRBs) in a single diagonal configuration.

The objectives of the test were: (1) to examine the large-displacement, bi-directional behavior of CBFs and BRBFs, (2) to examine the applicability of the latest design and detailing rules for these systems, (3) to examine the behavior of columns shared by two orthogonal braces, (4) to examine the effect of gusset plates framing into the column web, and (5) to examine the effect of composite concrete slabs on the behavior of CBFs and BRBFs.

2. EXPERIMENTAL PROGRAM

2.1 Specimen Description

Two specimens were tested in this research program. Both were nearly full-scale, one-bay by one-bay, two-story frames with braces in two orthogonal bays and framing into a "shared" column. Buckling HSS braces were used in the first test while the second test used BRBs. Fig. 1(a) and 1(b) show the second and third floor plan, respectively, of both test specimens. The braced frames occur along grid lines A and 1 as indicated by the dashed lines near the girders. Note that column A-1 is the "shared" column as the two orthogonal braced bents frame into this column. The second floor deck consists of 51 mm thick ribbed metal deck topped by 83 mm of normal weight concrete for a total depth of 135

mm as in typical steel buildings. The third floor slab will be used to transfer the load from the loading beam into the test specimen and as such, required a 254 mm thick concrete slab.

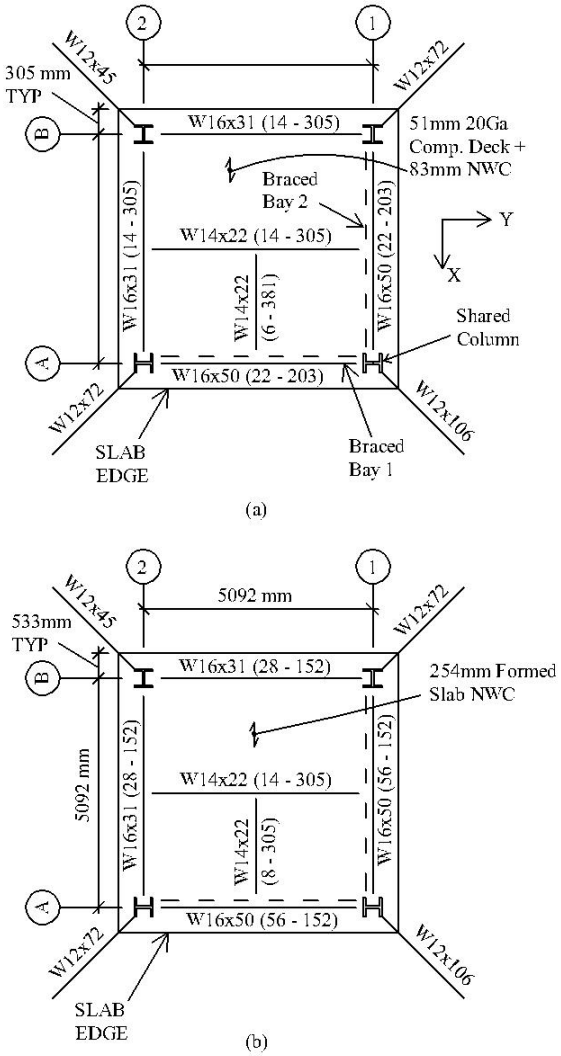

Figure 1. Test specimen floor plans: (a) second floor; (b) third floor plan.

The braced frame elevations for the buckling brace frame and the BRBF are shown in Fig. 2(a) and 2(b), respectively. The beam connections in each braced bay are welded flange – welded web (WFWW) connections with demand-critical welds, while those in the other two bays are simple shear connections. The buckling braces were A500B HSS3x3x1/4 while the BRB cores were 300 MPa steel with a design maximum adjusted brace force of 979 kN at 3% story drift. A photo of the test setup showing the strongwalls, crosshead and the first specimen is shown in Fig. 3.

2.2 Specimen Design

The sizes of the HSS buckling braces and BRBs in the test specimen were determined based on the capacity of the MAST lab strongfloor and force actuator system while ensuring that sizes which are typical of current construction could be used. The size of the braces chosen is typical of the upper stories in a mid to high-rise building or the lower stories of a low-rise building. The design of the test frame members followed current design practice based on the AISC Seismic Provisions (AISC 2005b), ASCE 7 (ASCE 2005), and a procedure shown by Lopez and Sabelli (2004).

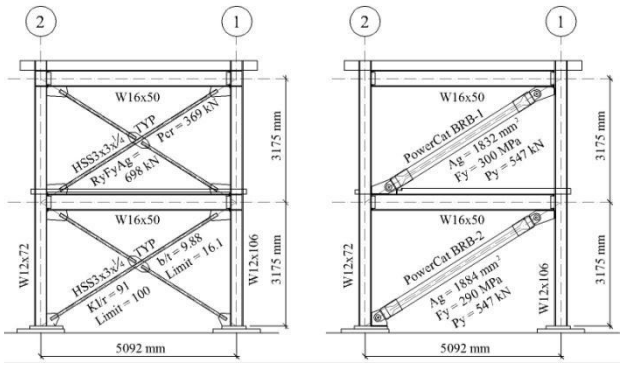

Figure 2. Braced frame elevations: (a) buckling brace frame; (b) buckling-restrained braced frame.

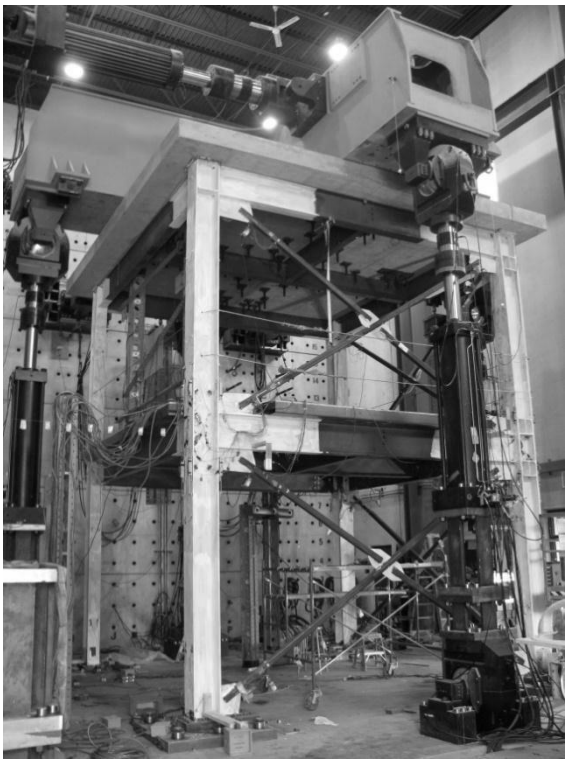

Figure 3. Photo of first test specimen in MAST lab

The beams and columns were designed to resist the maximum expected BRB force at $2.0\Delta_{bm}$, where Δ_{bm} is the brace axial deformation corresponding to the design story drift, in combination with the gravity load using the applicable load combinations. The frame beams and columns conform to the strong-column weak-beam philosophy. The demand on the shared column was found assuming 100% of the brace and beam capacities were realized in one direction while 30% of the capacities of these

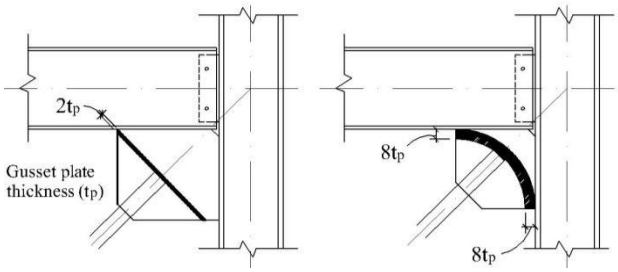
elements were realized in the orthogonal direction.

2.3 Gusset Plate Design

2.3.1 Buckling brace test specimen gusset design

Current seismic design rules (AISC 2005b) require the bracing connection to develop the strength of the brace while accommodating the rotation associated with out-of-plane brace buckling. As shown in Fig. 4(a), accommodation of the rotational capacity is generally accomplished through a linear clearance model, whereby the brace is terminated a distance $2t_p$ before the line of restraint, where t_p is the thickness of the gusset plate. This requirement can result in large buckling lengths of the gusset plate, and consequently, lead to heavy and overly stiff connections that have a detrimental effect on the behavior of the system (Roeder and Lehman 2009).

Based on tests at the University of Washington (UW) of over 30 one-bay, one-story planar CBFs, a new clearance model has been developed that when combined with the proposed balanced design procedure (Roeder et. al. 2005), results in thinner and smaller gusset plates. These thinner gusset plates have been shown to reliably accommodate large out-of-plane gusset rotations at the brace ends and sustain the tensile strength of the brace. This clearance model, called the elliptical clearance model, is shown in Fig. 4(b). A clearance of $8t_p$ has been shown to be the most efficient.



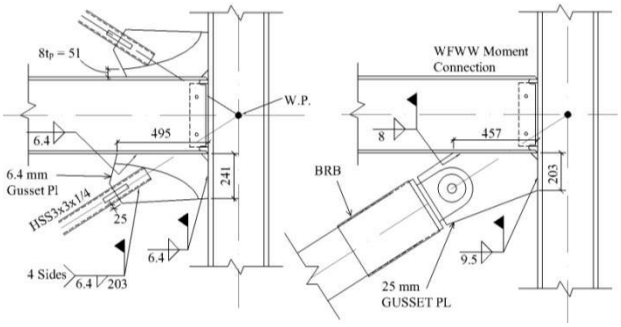


Figure 4. Clearance models: (a) currently used clearance, per AISC, $2t_p$ and (b) proposed 8tp elliptical clearance model.

The balance factors in the balanced design method are used in a similar manner to the AISC resistance factors except that they are used to achieve ductility and inelastic deformation capacity rather than strength. Smaller balance factors indicate that the exceedance of the considered limit state would cause significant deterioration of strength, stiffness and ductility, and/or that the capacity prediction is less reliable.

An example of a typical gusset design for the buckling brace frame is shown in Figure 5(a). It should be noted that the welds connecting the gusset plate to the beams and columns are sized to resist the strength of the gusset plate and not the forces that result from application of the Uniform Force Method (UFM). The buckling lengths of the gusset plates were computed as the average centroidal length and the two lengths at the extreme points of the Whitmore width. An effective length factor, K, of 0.65 was used.

2.3.2 BRBF gusset design

Because BRBs are generally not expected to deform out-of-plane, the clearance model for CBFs does not apply to BRBFs. Given that much less research has been performed on gusset plates for this system, it was decided that the gusset plates in the BRBF specimen would be designed according to the current standards using the uniform force method and the limit states outlined in AISC (2005a) instead of the balanced design approach. Figure 5(b) shows a typical gusset detail used in the BRBF test specimen.

(a) (b)

Figure 5. Gusset plate details: (a) buckling brace test specimen; (b) BRBF test specimen

2.4 Loading Protocol

Cyclic displacements were applied in each horizontal direction at the top floor while rotation of the crosshead about the vertical axis was maintained at zero to prevent torsional deformation from occurring. Free rotation about both horizontal axes was permitted. To limit the differences between the uni-directional tests performed at UW and those performed here, the same uni-directional displacement histories was used in the current tests that were used in the tests at UW.

The determination of the bi-directional qualities of the bi-directional loading protocol was facilitated by nonlinear time-history analyses of prototype braced frame buildings. Three and 6-story single diagonal BRBF buildings were designed and simultaneously subjected to the X and Y-component of 10 ground motions from the SAC program.

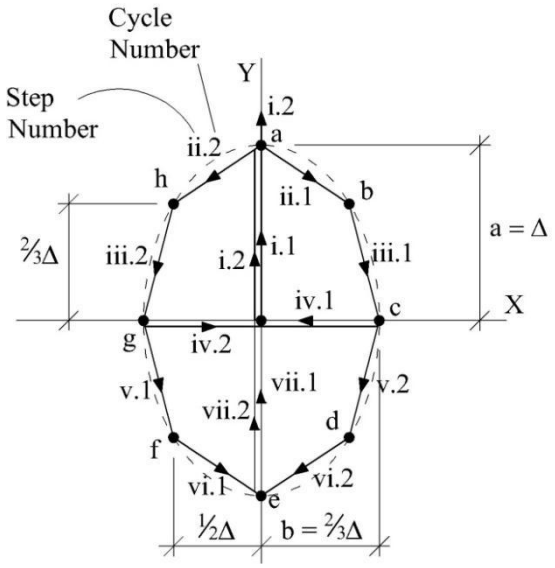
Using rainflow cycle counting, the ratio of the frame damage (cumulative plastic deformation) in X and Y was found for each case and a ratio of 1.5 was chosen. The final displacement-controlled protocol is shown in Figure 6.

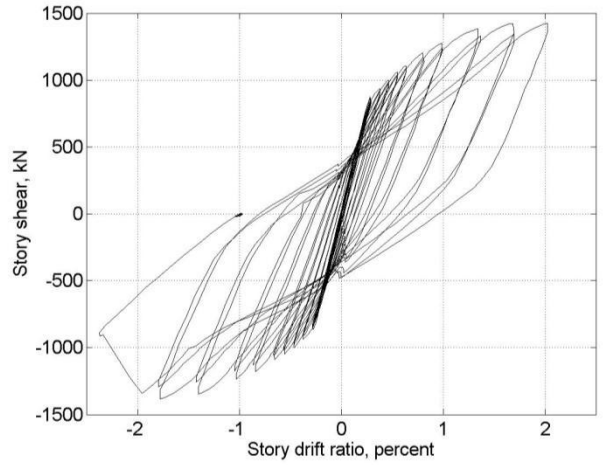
3. EXPERIMENTAL RESULTS

3.1 Buckling Brace Test Results

As discussed earlier, the test specimen was loaded according to Figure 6, where the Y-direction corresponds to that shown in the floor plans in Figure 1. Figure 7 shows the story shear – story drift ratio response for the second floor of each orthogonal braced bent. The top discontinuous brace at the 2nd story fractured during the first negative drift excursion at approximately 2% story drift following the first positive excursion. This drift ratio at fracture is consistent

with that observed in two previous tests of a similar single-story X-configuration at UW and those tested by Tremblay et al (2003). After fracture, the test specimen was unloaded in this frame's direction and uni-directional loading was applied to the specimen in the other direction continuing from the drift at which fracture occurred. The test proceeded until the top discontinuous brace in Braced Bay 2 was deemed close to fracture at approximately 1.7% story drift. The test was stopped prior to brace fracture in this bent to prevent damage to the frame as this frame was to be used again for the BRBF test.





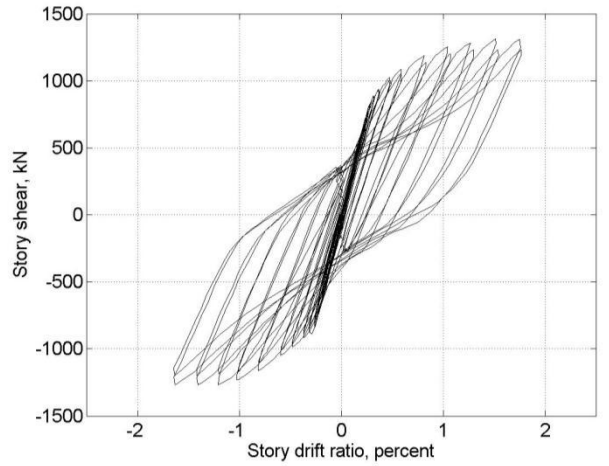


Figure 6. Bi-directional loading protocol "cloverleaf"

Based on brace strain gauge data, and global and local force-deformation curves, brace buckling occurred simultaneously in the discontinuous braces in the 1st and 2nd story of Braced Bay 1 at 0.25% story drift. Yielding of the braces occurred at 0.37% story drift. In the orthogonal direction, brace buckling occurred at 0.22% story drift and yielding at 0.36% story drift. Due to a number of factors including brace end connection stiffness and initial imperfections, brace buckling and subsequent brace damage occurred in only one half of the discontinuous brace while the continuous brace buckled in reverse curvature with the tension brace acting as a lateral support.

Prior to brace fracture there was extensive yielding in the gusset plates due to brace axial force and gusset plate bending due to brace buckling. This type of behavior was intended as part of the balanced design philosophy of maximizing energy dissipation and encouraging other yielding mechanisms beyond brace yielding. Slight gusset plate yielding was visually observed (flaking of whitewash) at approximately 0.23% story drift in the corner gussets just prior to brace buckling. Figure 8 shows a typical gusset yielding pattern in the corner gusset plates at 2% story drift. This pattern was typical of these joints. Additionally, frame action (opening and closing of the joint) cause additional yielding and deformation in the gusset as seen in the diagonal yield pattern originating at the intersection of the bottom beam flange and column flange shown in Figure 8.

(a)

(b)

Figure 7. Buckling brace test 2nd story hysteretic curves: (a) Braced Bay 1 (Y-direction); (b) Braced Bay 2 (X-direction)

Column yielding initiated at the base of the three braced frame columns at approximately 0.46% story drift and continued to spread at the bases as the story drift increased. Figure 9 shows the yielding at the base of the column in Braced Bay 1 at 2% story drift. Additionally, the web of the beam on the second floor of Braced Bay 1 at the shared column side yielded and deformed at the instant of brace fracture. Up to that point, only limited yielding was observed at this location.

3.1 BRBF Test Results

The BBRB followed the same loading protocol as the first test with the exception of the principal loading direction. Based on the beam web damage described previously, it was decided to make Braced Bay 2 the principal loading direction. Additionally, a web doubler plate with the same thickness as the beam web was attached to the damaged beam web to ensure that would not be the weak link in the BRBF test. It should also be noted that there were initial lateral frame deformations of 50 mm in the Y direction and

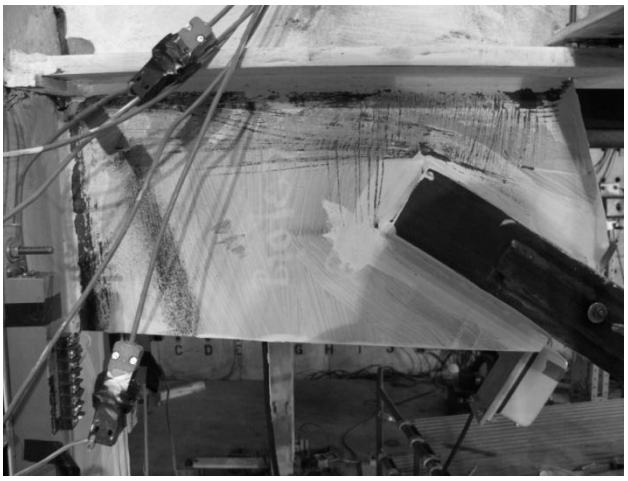

Figure 8. Gusset plate yielding, buckling brace test, 2% story drift

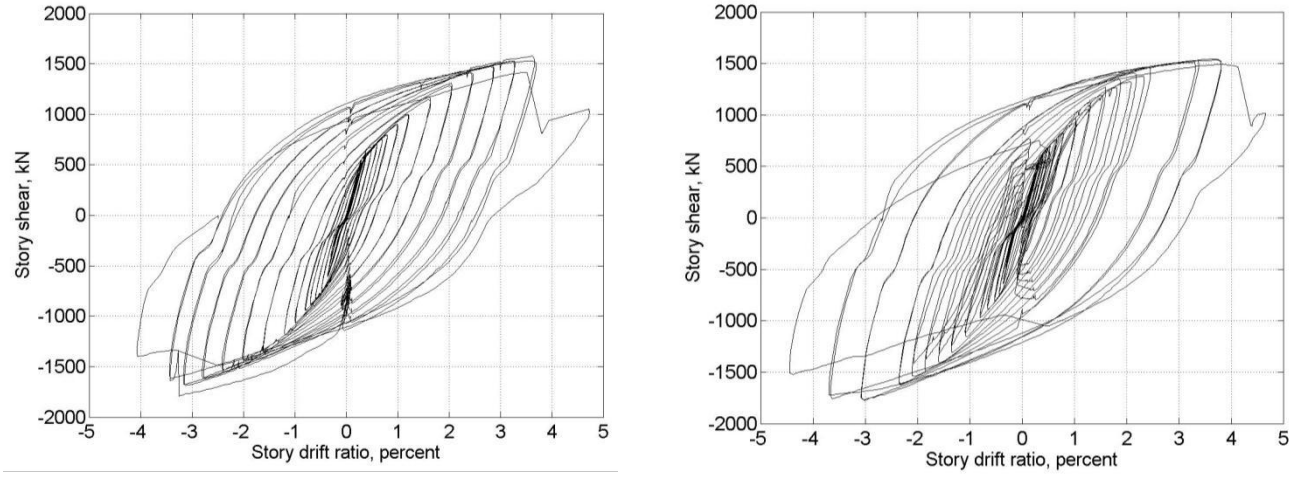
Figure 9. Column and gusset plate yielding at base, buckling brace test, 2% story drift



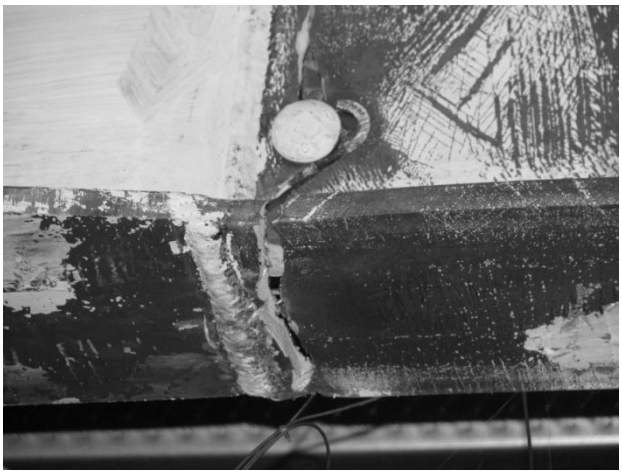
25 mm in the X direction due to the permanent frame deformation from the first test. The drifts reported below are relative to the initial permanent deformation.

Figure 10 shows the story shear – story drift ratio response for the second floor of each orthogonal braced bent. Yielding of the BRB cores occurred at approximately 0.33% story drift ration in each direction. In the Y-direction, the BRB core fractured at approximately 3.5% average roof drift ratio (RDR) while in the X-direction, the BRB core fractured at 4.1% RDR. The BRBs in the first story did not fracture as the first story columns resisted a larger amount of the story shear than the second story columns due to the base fixity. After core fracture, the load resisted by each frame was reduced by approximately 40%. The test was continued after core fracture and the frame stiffness remained the same due to the stiffness of the moment frame and the fact that the stiffness of the BRBs at this point was practically zero due to yielding of the BRB core.

At -3.2% RDR, the bottom flange in the second floor beam attached to the shared column in Braced Bay 2 (X-direction) fractured suddenly just outside of the CJP as shown in Figure 11. This occurred after the web at this location exhibited ductile tearing that extended through more than half of the beam web. This tearing was initiated at the erection bolt holes at the beam splice three feet away from the centerline of the column.

As shown in Figure 13, the web and bottom flange of the third floor beam at the shared column side in Braced Bay 1 also exhibited considerable yielding, local buckling and ductile tearing. The tear occurred at the edge of the gusset plate and extended completely through the bottom flange up to approximately ¾ of the beam depth. The braced frame columns yielded considerably at the base and above and below the second and third floor joints. Additionally, local buckling occurred at the base of the two frame columns that the BRBs framed into. This occurred on the side opposite of the gusset plates as shown in Figure 12(b). Column flange and web yielding can also be seen in this photo.

Limited gusset plate yielding was observed and was confined to a localized area approximately one inch square near the gusset-column reentrant corner. Weld tearing occurred in the second and third floor gusset plates at the gusset-column weld. These tears propagated through the total length of the weld and were due to frame action as they initiated when the brace was in compression and the joint



(a) (b)

Figure 12. BRBF test photos, -3.2% story drift: (a) gusset weld tear at column; (b) column local buckling and yielding

was opening. Preliminary analysis indicates that this tearing had limited effect on the overall frame behavior but further analysis is required to fully quantify this.

The BRBs were connected to the gusset plates with pins which limited the amount of moment transferred between these two elements. As a result of fabrication and fit-up tolerances, which require the hole to be slightly larger than the pin, and yielding of the pin and steel in the vicinity of the pinhole, there was a reduction in frame stiffness as the BRBs underwent a change in the sign of the axial force. This can be seen clearly in the hysteretic curves shown in Figure 10. Additional damage occurring in the frame included panel zone yielding in the columns, tearing at the bolt holes that connected the gravity beams to the braced frame columns, and beam web yielding near the end of the gusset plates. Second floor composite slab damage was limited to hairline cracks around the braced frame columns but were more indicative of shrinkage cracks than flexural cracks.

Figure 13. BRBF test photos, -3.6% story drift: beam web and bottom flange tear at edge of gusset plate

4. CONCLUSIONS AND FUTURE WORK

The out-of-plane loading appeared to have negligible effect on the frame behavior. The HSS braces fractured at 2% story drift which is consistent with previous tests performed on a similar frame loaded uni-directionally at UW. There was considerable gusset plate yielding in the first test which was expected as gusset plate yielding was specifically designed for and deemed a desirable secondary yielding mechanism. Additionally, the elliptical clearance method provided adequate rotation capability of the gusset plates while providing a much more compact design than the $2t_p$ linear offset method most commonly used in practice today.

Similar to the first test, the out-of-plane deformation appeared to have minimal effect on the BRBF behavior. The BRB cores fractured at 3.5 and 4% story drift and no instabilities occurred in the BRB prior to fracture. As BRBs are proprietary and are detailed differently, especially at the ends, this type of behavior may not be typical of all BRBs. Indeed, instabilities have been shown to occur at the end of the BRBs in previous tests that have not been subjected to out-of-plane deformation (Mahin et al. 2004). Frame action, as opposed to brace action, had a dominating effect on the demands on the gusset-frame welds. Approximately half of the gusset to column welds tore completely through along their lengths as a result of the joint opening.

Work is ongoing to further analyze the test results with

the goals of better quantification of the effect of out-of-plane deformation on the system, the effect of the concrete floor slab, and the demands on the shared column due to bi-directional effects. To aid in this work, 3D finite element models will be developed and calibrated to the test results and parametric studies shall be performed.

Abstract: The static stability capacity is the main index to measure the whole mechanical performance of single-layer latticed shells. A new damage assessment method of single-layer latticed shells was presented by performing static stability analysis once before and once after subjecting the shell to earthquakes, and the damage index is calculated from a perspective of the static stability capacity degradation incurred by earthquakes. The method has a solid theoretical basis and can be easily implemented. Compared with other methods to assess the damage of single-layer latticed shells, the examples show that the method has a high precision especially when the shells near collapse.

1. INTRODUCTION

The damage assessment has been one of the key and difficult problems in the earthquake engineering. The state of structural damage is usually described by a damage index D because of its simplicity and effectiveness. A rational damage index should be in the range of [0,1], and a value of zero represents no damage while a damage index value of one corresponds to collapse. The damage indices can be broadly divided into two classes (Ghobarah et al. 1999): strength-based damage indices; and response-based damage indices. The latter has been widely used, which can also be divided into two types according to the calculating method: (1) The damage indices are calculated by the damage parameters such as stresses, displacements and energy, etc. The well-known Park-Ang damage model (Park and Ang, 1985) is a typical example of this approach. (2) The damage indices are calculated from a perspective of the degradation of structural performance such as stiffness and frequency. One of the typical example is the method presented by the authors (Ghobarah et al. 1999), the basic procedure of which is to perform pushover analysis for the structure before and after subjecting the structure to the earthquake, then the damage index is calculated according to the stiffness degradation:

$$D=1-(K_{final}/K_{initial}) \quad (1)$$

where $K_{initial}$ is the initial slope of the base shear-top deflection relationship resulting from the pushover analysis of the structure before subjecting it to the earthquake and K_{final} is the initial slope of the same relationship but after subjecting the frame to the earthquake. This method and the modified version have been widely used in the damage assessment of frame structures.

Most of the damage assessment methods are about the multi-story structures. In the research of the damage assessment of single-layer latticed shells, the authors (Zhi et al. 2007)presented a fitted damage index with the span, strains, nodal displacements and yielded members ratio as the damage parameters. The authors (Du et al. 2007) evaluated the damage of single-layer latticed domes with the Park-Ang damage index. The authors (Kato and Nakazawa 2010) presented discrete damage values of a single-layer latticed dome and the substructure with the maximum displacement and acceleration as the damage parameters. It can be seen that all the available methods are of the first kind of response-based damage assessment methods, and there are no assessment methods of the second kind. A new damage assessment method of single-layer latticed shells was presented in the paper by performing static stability analysis twice: once before and once after subjecting the shell to earthquakes, and the damage index is calculated in this method from a perspective of the static stability capacity degradation incurred by earthquakes.

2. BASIC PRINCIPLES

2.1 Word Processing

The design of the most single-layer latticed shells are controlled by the static stability capacity, so the static stability capacity is the main index to measure the whole

mechanical performance of single-layer latticed shells. It is rational and effective to calculate the damage index from a perspective of the static stability capacity degradation incurred by earthquakes. Similar to the method presented by Ghobarah, the method is to perform static stability analysis for the shell twice: once before subjecting the shell to the earthquake and once after subjecting the shell to the earthquake. The load-displacement curves are shown in Fig.1, where P_i and P_f are the static stability capacities of the shell under dead load P_0 before and after the earthquake. Unlike the method presented by Ghobarah, if the shell does not collapse after the earthquake, then the static stability capacity will at least be the self weight P_0 (including the self weight of members and the super dead load) of the shell, so the influence of P_0 should be removed when the damage index is calculated by the method. Similar to Equation 1, the damage index D can be calculated as follows:

$$D=1-(P_f-P_0)/(P_i-P_0)=(P_i-P_f)/(P_i-P_0) \quad (2)$$

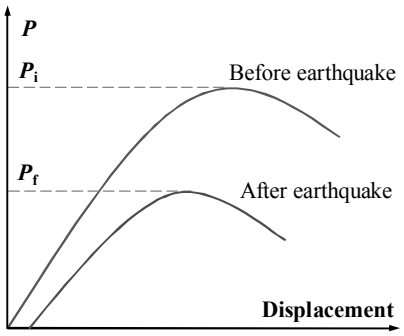

Figure 1 Load vs. Displacement Curve

If the load P is expressed by the load factor F , i.e., introducing the equations $P_i = P_0F_i$ and $P_f = P_0F_f$ into the equation above, a new form of it is:

$$D=(F_i-F_f)/(F_i-1) \quad (3)$$

3. APPLICATION IN SINGLE-LAYER SPHERICAL DOME

3.1 Model

A single-layer latticed dome shown in Fig.2 is taken as the numerical example, and the span and height of the dome are 40m and 8m, respectively. All the periphery nodes are pin-supported, and the material is the ideal elasto-plastic model with the yield stress of 235MPa and Young's modulus of 2.06e5MPa.

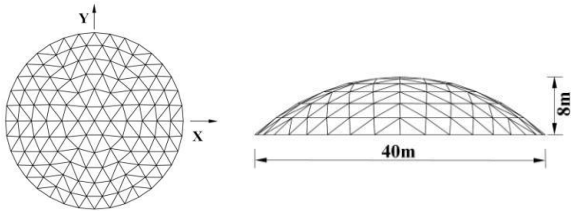

Figure 2 Single-Layer Latticed Dome

The members section arrangement has a great influence on the static stability performance of the single-layer latticed shells, and a rational section arrangement should make sure most members work together to bear the loads, thus a relatively high static stability capacity will be achieved. After comparison of the static stability performance of some domes with different section arrangements, the radial and hoop members section are determined as Ø114×4mm and the others are determined as Ø108×3.5mm. The basic eigenvalue buckling mode is taken as initial geometry imperfection applied to the dome, and the maximum imperfection value is taken as 1/300 of the span. Both geometric and material nonlinearity are included in the analysis. The static buckling shape of the dome before earthquake is shown in Fig.3, in which the yielded members are depicted with blue lines and the red dot denotes the node with maximum vertical displacement in the buckling shape.

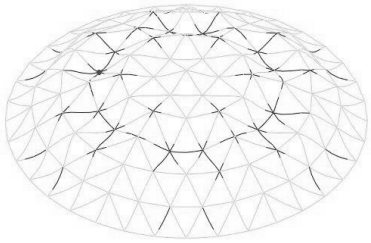

Figure 3 Static Buckling Shape and Yielded Members (scale 30)

The load factor-vertical displacement curve of the node is depicted in Fig.4, from which the static stability capacity factor can be drawn as 6.831.

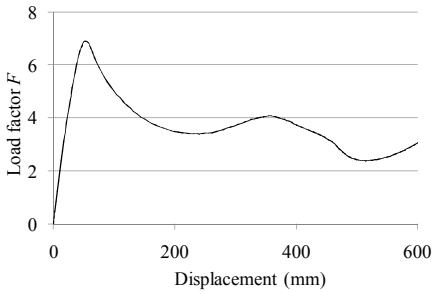

Figure 4 Load Factor vs.Vertical Displacement Curve

3.2 Seismic Time History Analysis and Static Stability Analysis

The FEA software ABAQUS 6.9-1 is used to do the time history and static stability analysis, and Both geometric and material nonlinearity are considered in the analysis. All the members are meshed with 4 beam elements-B31 with the section type of PIPE. The Riks arc-length method is used to do the static stability analysis, and restart technology is used to do the static stability analysis after earthquake in order to import the damage state into the beginning of the second static stability analysis. The default Hilber-Hughes-Taylor implicit integration algorithm in ABAQUS/Standard is used to do the time history analysis. Self weight of members is automatically considered by the

software, and super dead load of 0.5kN/m^2 is converted to nodal masses. Rayleigh damping ratio is taken as 0.02 and the damping coefficients are computed by the WLS method presented by the authors (Yang et al. 2010).

To learn the yield extent of the members, plastic strains of eight member section points are outputted, which is shown in Fig.5, and 1P is used to denote the members in which at least one section point enter into plastic stage, and 8P denote the members in which all the eight section points enter into plastic stage.

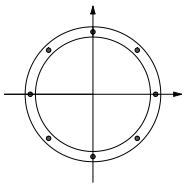

Figure 5 Section Points

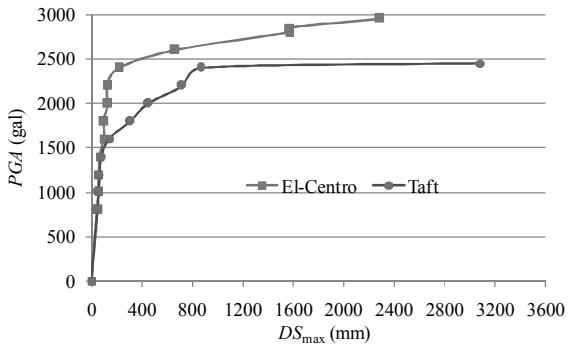
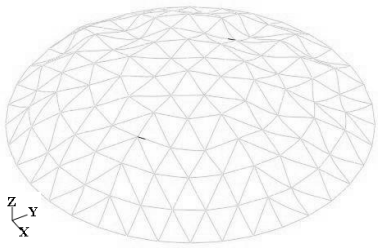
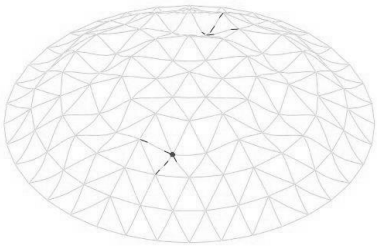
Three dimensional El-Centro and Taft earthquake acceleration records are selected as the input excitations. The accelerations are scaled to different PGA in order to learn damage states of the dome under the earthquakes with different intensities. The dome is unloaded after the earthquake, then the second static stability analysis is performed.

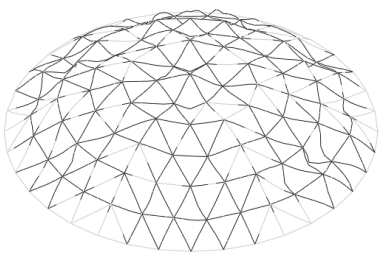
3.3 Analyses Result

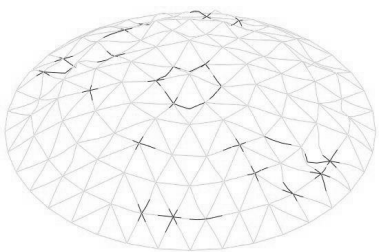
The maximum nodal vertical displacement DS_{max} during the time histories are shown in Fig.6.











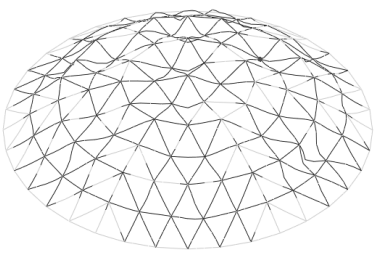


Figure 6 PGA vs. DS_{max} Curves

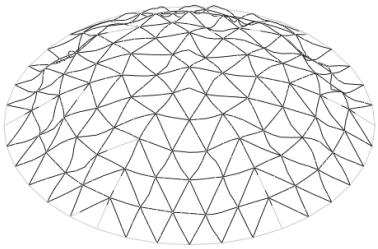
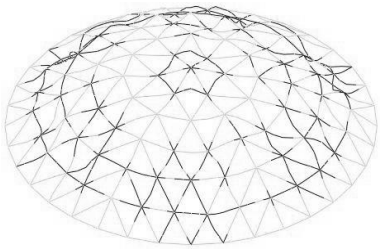
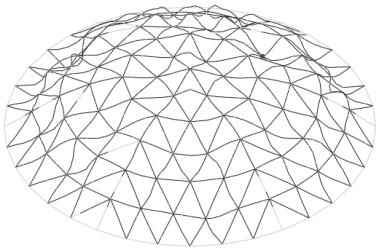
To learn damage states of the dome clearly, the shape and the second buckling shape coupled with the yielded members distribution after the El-Centro and Taft earthquakes with different PGA are shown in Table.1 and Table.2, in which the red dots denote the nodes with maximum vertical displacements in the buckling shape, and the numbers under each deformed shape denote the scaled times of the displacements. The 1P and 8P members are depicted with blue lines in the figures, and there are no 8P members after both earthquakes with the PGA as 800gal, so the figures are vacant in the corresponding grids. All the deformed shape have the same axis as the one depicted in the first figure.

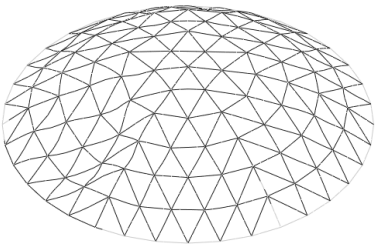
Table 1 Dome Damage under El-Centro Earthquake and Second Buckling State

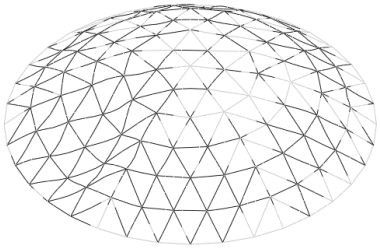
PGA (gal)	Shape and 1P members distribution(blue lines)	Shape and 8P members distribution(blue lines)	Buckling shape and 1P members distribution(blue lines)
800	 80	No 8P members	 30
1600	 30	 30	 20

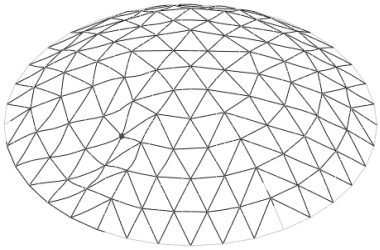


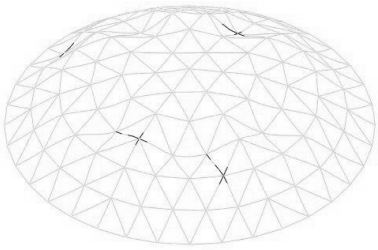


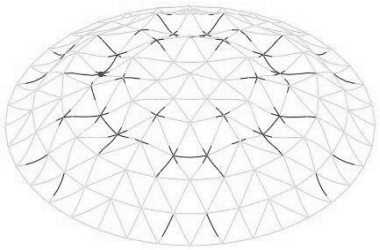


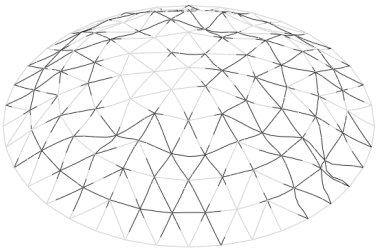


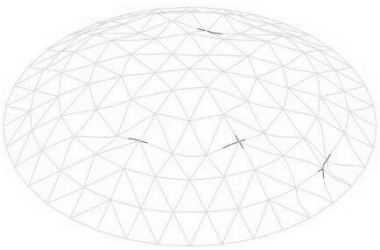


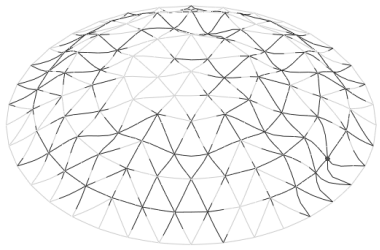


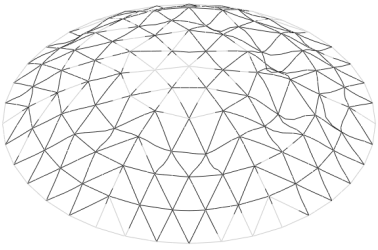


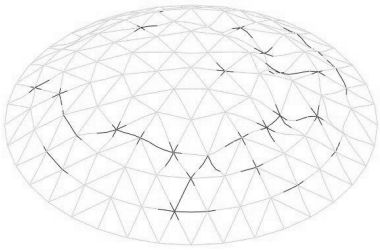


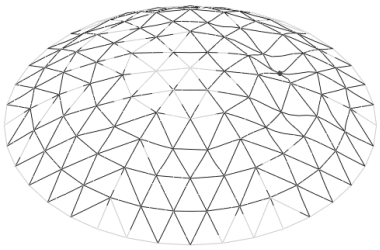


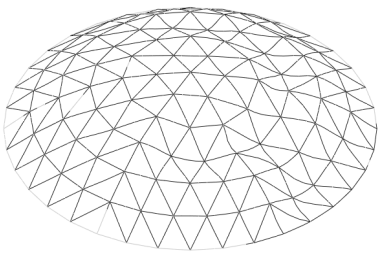


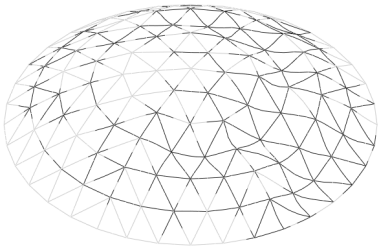


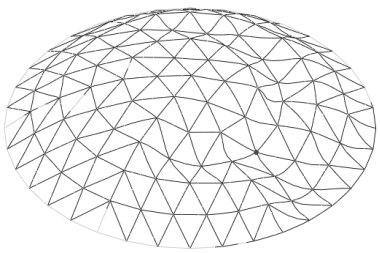












2400	 10	 10	 5
2950	 1	 1	 1

Table 2 Dome Damage under Taft Earthquake and Second Buckling State

PGA (gal)	Shape and 1P members distribution(blue lines)	Shape and 8P members distribution(blue lines)	Buckling shape and 1P members distribution(blue lines)

The static stability load factor vs. displacement curves before and after earthquakes with different PGA are depicted in Fig.7 and Fig.8, in which PGA=0 denotes the first static stability curve before earthquakes. Fig.9 shows the static stability capacity factors after earthquakes with different PGA.

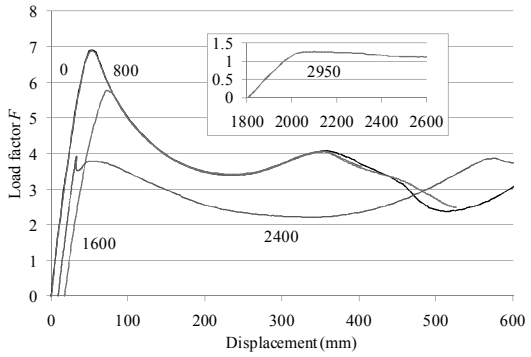

Figure 7 F vs. Displacement Curves (El-Centro)

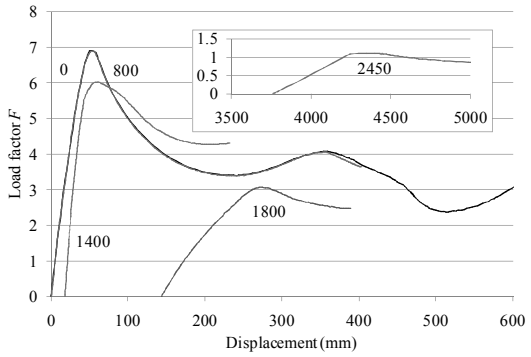

Figure 8 F vs. Displacement Curves (Taft)

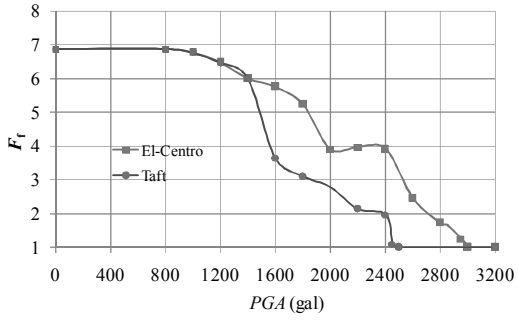

Figure 9 F_f vs. PGA Curves

PGA_y and PGA_c are used to denote the PGA when the dome yields and collapses, respectively. The PGA_y for both El-Centro and Taft earthquakes are 800gal, and the PGA_c are 3000gal and 2500gal, respectively. It can be seen from the figures above that when PGA is less than PGA_y, the dome remains elastic after the earthquakes and the static stability capacity will not reduce; and when PGA is equal to PGA_y, only a few members of the dome yield after the earthquakes, so F_f almost equals F_i; and when PGA is greater than PGA_y and less than PGA_c, the DS_{max}, the quantity of 1P and 8P members increase gradually on the whole with the increase of PGA, while F_f almost decrease gradually with the increase of PGA, and when PGA is close to PGA_c, almost all the dome members yield and the quantity ratio of 8P members to all the members is also high; when PGA is equal to or greater than PGA_c, the dome collapse. It can also be seen that the shape after the earthquakes is similar to the static buckling shape after the earthquakes, which shows that buckling of the dome follow the shape and damage state incurred by the earthquakes. Through comparing the figures in the last row of the two tables, it can be seen that the severe damaged area after the earthquake and the buckling area of the dome under the El-Centro motion are larger than those under the Taft motion, which shows that different ground motions may inflict more or less damage areas on the dome.

There is a hardening phenomenon (Vamvatsikos and Cornell 2002) that need to be noted in Fig.6 and Fig.9 with the El-Centro earthquake. The DS_{max} and F_f curves deviate from the original developing trend when PGA reaches 1100gal, thus making the DS_{max} and the F_f non-monotonic functions of the PGA. This is called hardening which is a frequent phenomenon in the incremental dynamic analysis(IDA) of frame structures (Vamvatsikos and Cornell 2002) and spatial structures (Yang et al. 2010), whereas it needs further research about whether there is a correlation between the reverse of maximum displacement and that of static stability capacity when domes harden.

3.4 Damage Assessment of the Dome

By Substituting F_f in Fig.9 and F_i=6.887 into the Equation 3, the damage index D under El-Centro and Taft earthquakes can be calculated, which is shown in Fig.10.

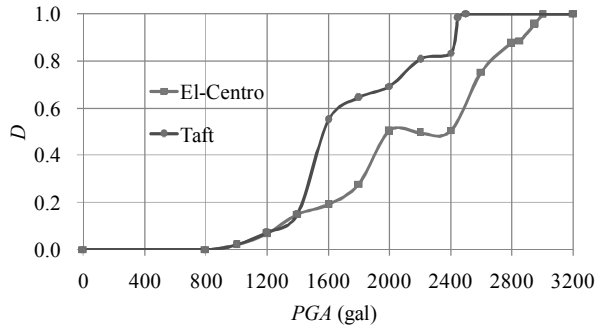

Figure 10 *D* vs. PGA Curves

When PGA is less than PGA_y, the dome remains elastic after the earthquakes and *D* equals zero; and when PGA is equal to or greater than PGA_y and less than PGA_c, *D* increases on the whole with the increase of PGA except the occasional hardening of the dome, and *D* converges to one when the PGA approaches PGA_c; and when PGA is equal to or greater than PGA_c, the dome collapse, so *D* is taken as one. Therefore, compared with the other damage assessment methods of single-layer latticed domes, the most advantage of the method is the high precision especially when the dome nears collapse.

3.5 Damage Assessment of the Dome under Other Ground Motions

The damage assessment of the dome under other ground motions in Table.3 is presented in Fig.11.

Table 3 Ground Motions

4. APPLICATION IN SINGLE-LAYER CYLINDRICAL SHELL

4.1 Model

The geometry of the single-layer cylindrical latticed shell is shown in Fig.12, where the length *L*, span *B* and height *f* of the shell are 40m, 20m and 5m, respectively.

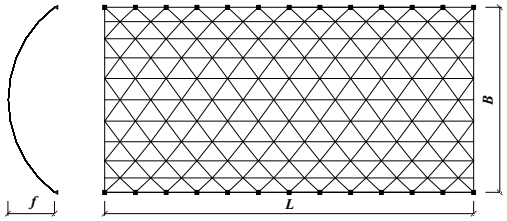

Figure 12 Single-Layer Cylindrical Latticed Shell

All the longitudinal edge nodes are pin-supported, and the diagonal members are of the section Ø159×5,while other members Ø89×4. The material is the same as the one for the spherical dome. Fig.13 shows the basic eigenvalue buckling mode of the shell, which is applied to the shell as initial geometry imperfection with the maximum value as *B*/300.

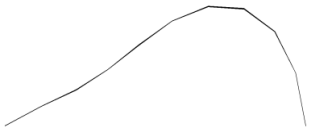

Figure 13 Basic Eigenvalue Buckling Mode

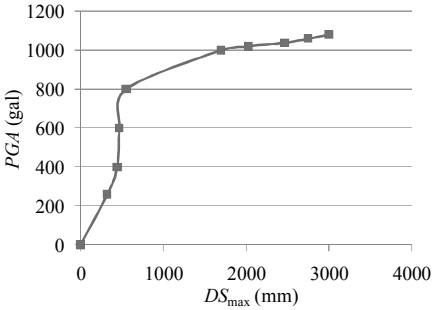
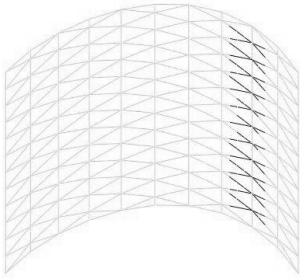
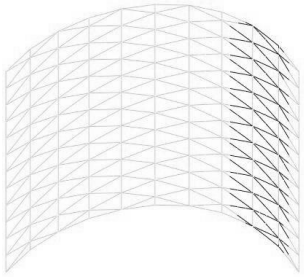
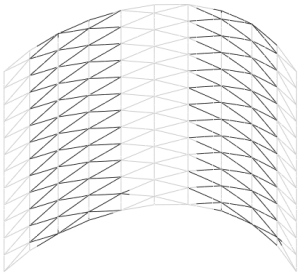
4.2 Analyses Result

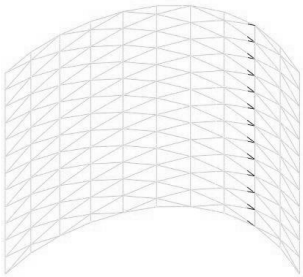
The three dimensional Northridge ground motions is selected as the input excitations. The analysis procedure is the same as presented above. Fig.14 shows the maximum nodal vertical displacement DS_{max} during the time history with different PGA.

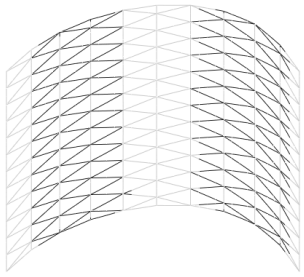


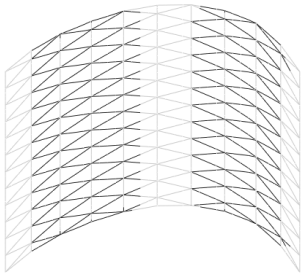


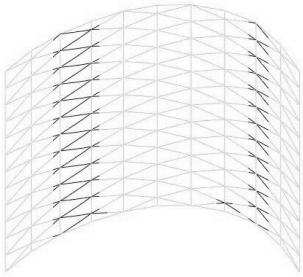


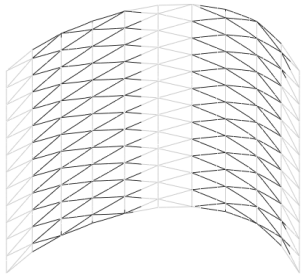


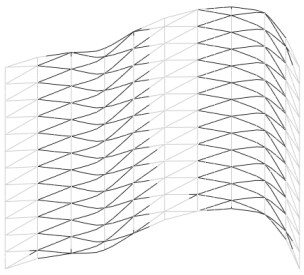


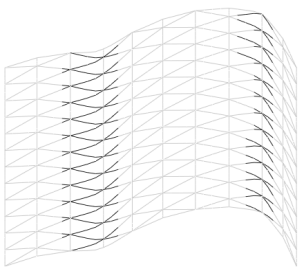












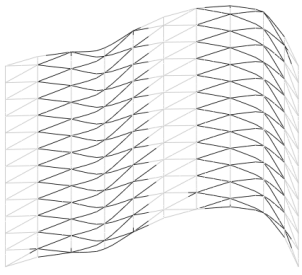


Figure 14 PGA vs. DS_{max} Curve

Table.4 presents the damage states of the shell after Northridge earthquake and the second buckling shapes and yielded members.

Table 4 Shell Damage under Northridge Earthquake and Second Buckling State

PGA (gal)	Shape and 1P members distribution(blue lines)	Shape and 8P members distribution(blue lines)	Buckling shape and 1P members distribution(blue lines)
260		No 8P members	
600			
800			
1080			

The figures in Table.4 show that the longitudinal supported single-layer cylindrical shell has a very distinct one way mechanical characteristics, and with the span direction as the main force bearing direction, the damages are almost the same along the longitudinal direction. The same damage feature of the shell can also be observed under other ground motions.

Fig.15 shows the static stability load factor F vs. displacement curves before and after Northridge earthquake with different PGA.

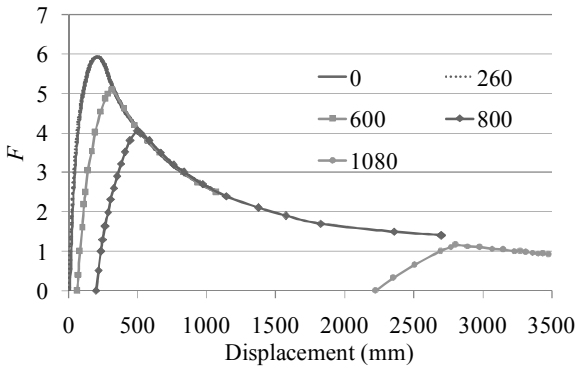

Figure 15 F vs. Displacement Curves

4.3 Damage Assessment of the Shell

Fig.16 shows the damage index under Northridge earthquake with different PGA.

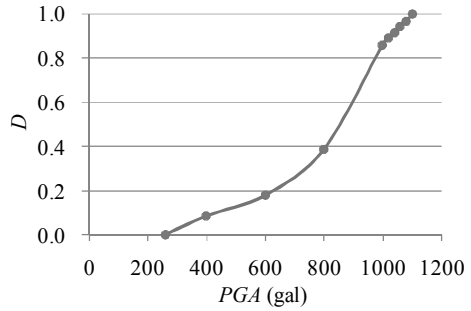

Figure 16 *D* vs. PGA Curve

4.4 Damage Assessment of the Shell under Other Ground Motions

The damage assessment of the shell under other 4 ground motions in Table.5 is presented in Fig.17.

Table 5 Ground Motions

ID	name	M	Year	Recording Station
1	Kocaeli, Turkey	7.5	1999	Yarimca
2	Chi-Chi, Taiwan	7.6	1999	TCU065
3	Imperial Valley-06	6.5	1979	Chihuahua
4	Kocaeli, Turkey	7.5	1999	Izmit

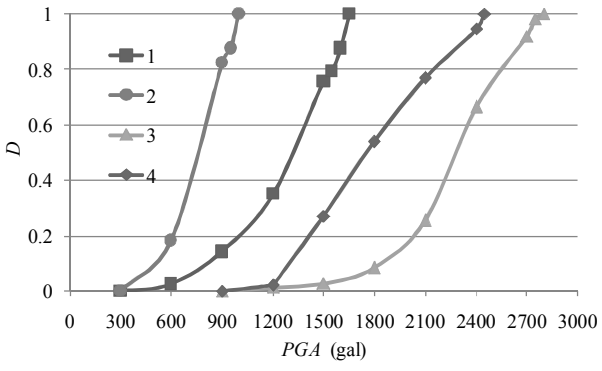

Figure 17 *D* vs. PGA Curves

Compared with the damage state of the spherical domes under earthquakes, the damage index D vs. PGA curves of cylindrical shells are more straightforward with less backward curves, which is mainly due to the simple and one way mechanical characteristics of the longitudinal supported cylindrical shell.

5. SUMMARY OF THE METHOD

The general formula of the method is as follows:

$$D=\begin{cases}0, & PGA<PGA_{\mathrm{y}}\\ \left(F_{\mathrm{i}}-F_{\mathrm{f}}\right)/\left(F_{\mathrm{i}}-1\right), & PGA_{\mathrm{y}}\le PGA<PGA_{c}\\ 1, & PGA\ge PGA_{c}\end{cases} \quad (4)$$

The method is of the second kind of response-based damage assessment methods, and it avoids the calculation of damage parameters and only needs static stability analysis before and after the earthquake, so it is easily implemented and the calculation is simple.

6. CONCLUSIONS

A new damage assessment method of single-layer latticed shells was presented by performing static stability analysis twice. The method has a solid theoretical basis and can be easily implemented. Compared with the other methods to assess the damage of single-layer latticed shells, the example shows that the method has a high precision especially when the shell near collapse.

Abstract: A moment frame with bracing elements is one of efficient seismic-resistant structural system used in elastic design. However, when the seismic input is larger than the buckling strength of the braces, the braces first undergo overall buckling and subsequent local buckling; further, concentration of plastic strain in the local buckling zone leads to brace fracture. The authors have previously proposed a brace fracture prediction method. In this study, they carry out time-history response analyses for braced frames using the proposed method and investigate the fatigue distribution in different types of frames, by taking into account the effect of brace fracture.

1. INTRODUCTION

In elastic design, a building structure with a braced frame is considered to be an efficient and economical system. However, in elasto-plastic design, under large earthquake the brace causes buckling and their hysteresis are unstable. In this case, the strength of the structure is commonly evaluated by ductility index or time-history response analysis. Including post-buckling many researchers have proposed the use of a hysteresis model for simulating the brace behavior; for instance, the method proposed by Shibata and Wakabayashi (1982) have been used to develop a hysteresis model for the accurate simulation of buckling behavior.

Goel (1989) and Takeuchi (2006) et al. indicated that once braces undergo overall buckling and subsequent local buckling, a large plastic strain is induced to the limited position, and this leads to brace fracture. Since the abovementioned Shibata and Wakabayashi hysteresis model does not take into account this fracture phenomenon, it cannot be used for the accurate simulation of brace behavior. Kanvinde and Deierlein (2007) reported that brace fracture can be assessed by micro-finite element analysis. This analysis, however, is not suitable for large-scale structures because it consumes long time and the result depends on the finite division method. Kanao and Nakashima et al. (2004) reported the dynamic response of the braced frame considering the brace fracture condition determined by the maximum response. However, brace fracture is not unambiguous determined by the maximum response, the results are evaluated under a hypothetical theory. Mukaide and Tada et al. (2010) investigated the seismic response of a tubular braced frame using a collaborative pseudo dynamic test. The results of this investigation increase the reliability of the brace fracture estimation. However, this proposed method can only simulate an experimented particular braced frame. On the other hand, the authors have proposed a brace fracture prediction method by taking into account a strain concentration ratio in the local buckling zone which is an increasing index between the entire strain and the local strain, without carrying out micro-finite element analysis. However, their accuracy was reported not necessarily precise (Mukaide and Tada et al. 2010).

In this study, the equation of strain concentration ratio is re-constructed and to improve the brace fracture prediction accuracy. Time history analysis program is constituted using the improved strain concentration ratio. The proposed analysis algorithm is applied to predict the dynamic response behavior and energy dissipation performance of six types of braced frames considering brace fracture.

2. BRACE FRACTURE PREDICTION METHOD

In the case of circular-tube braces, after local buckling, the local strain in the buckling zone becomes markedly higher than that in the other zones, and this leads to fracture. In this study, we develop a practical model for predicting the local strain transition and fracture in circular-tube braces on the basis of fatigue curves, by postulating a simplified hinge zone model. In this model, the plastic hinge is assumed to occupy the center of the circular-tube brace during overall buckling, as shown in Figure 1. The length of the plastic zone, L_h, is calculated using Eq. (1):

$$L_h = L\left(1-\left(\frac{S}{Z}\right)\right) \tag{1}$$

where L is the total length of the circular brace; S, the section modulus of the circular-tube; and Z, the plastic section modulus of the circular-tube. The hinge angle, θ_h, is calculated using Eq. (2), and the normalized deformation amplitude for the braces, $\Delta\varepsilon_n$, on the compression side is assessed by using Eq. (3), which includes a term for the maximum normalized tensile deformation, ε_{ntm}, observed before compression.

$$\theta_h = \cos^{-1}\left(1-\Delta\varepsilon_n\right) \tag{2}$$

$$\Delta\varepsilon_n = \varepsilon_{ntm} - \varepsilon_n \tag{3}$$

Here, the normalized deformation, ε_n, is defined as the ratio of the longitudinal displacement, δ, to the total length of the brace, L, as shown in Eq. (4).

$$\varepsilon_n = \delta / L \tag{4}$$

The local strain in the hinge zone, ε_h, is calculated by the average approximation shown in Eq. (5):

$$\varepsilon_h = \frac{\theta_h D}{L_h} = \frac{\theta_h D}{L\left(1-\left(\frac{S}{Z}\right)\right)} \fallingdotseq \frac{\theta_h D}{L\left(1-\frac{\pi}{4}\right)} \tag{5}$$

where D is the circular-tube diameter. The deformation of the circular-tube after local buckling is modeled in Figure 2. The relation in Eq. (6) defines the normalized deformation initiated by local buckling, ε_{lb}, according to previously reported experimental data (Ogawa et al. 1995). The hinge angle corresponding to local buckling θ_{lb} is calculated using Eq. (7), which is identical to Eq. (2).

$$\varepsilon_{lb} = 0.0683\varepsilon_y^{-0.39}\left(\frac{D}{t}\right)^{-1.39} \tag{6}$$

$$\theta_{lb} = \cos^{-1}\left(1-\varepsilon_{lb}\right) \tag{7}$$

where ε_y, the yield strain, and t, the circular-tube thickness. The hinge angle increment $\Delta\theta_h$ in the local buckling zone can be calculated using Eq. (8):

$$\Delta\theta_h = \theta_h - \theta_{lb} \qquad (\theta_h > \theta_{lb}) \tag{8}$$

The angle in the local buckling zone φ_h itself is calculated from Eq. (9) by using $\Delta\theta_h$ at which local buckling occurs, as shown in Figure 2:

$$\varphi_h = \cos^{-1}\left(\cos\Delta\theta_h - \frac{D\sin\Delta\theta_h}{l_p}\right) \tag{9}$$

where l_p is the half-amplitude of the local buckling wave; all the other variables have been defined previously. l_p is derived on the basis of the classical theory of buckling using Eq. (10) (Timoshenko et al. 1963), where ν_p is the plastic Poisson's ratio with a value of 0.5.

$$l_p = \pi\sqrt[4]{\frac{D^2t^2}{48\left(1-\nu_p^2\right)}} = \pi\sqrt{\frac{Dt}{6}} \tag{10}$$

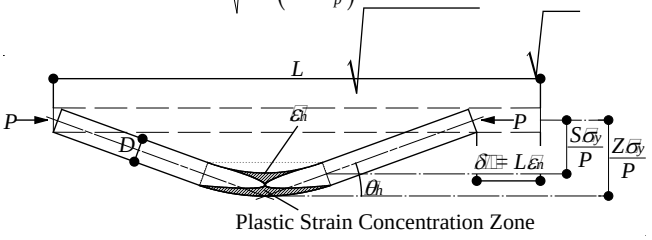

Figure 1 Overall Buckling of Circular-tube Brace

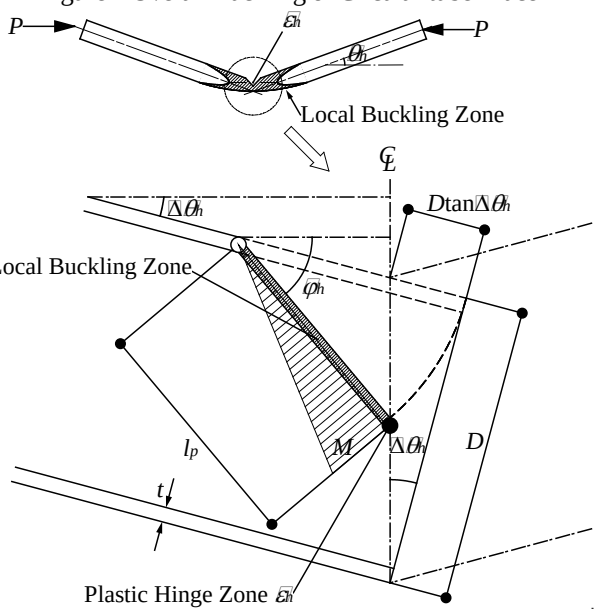

Figure 2 Local Buckling of Circular-tube Brace

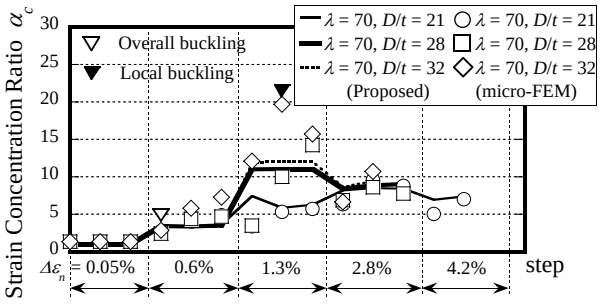

Figure 3 Strain Concentration Ratio

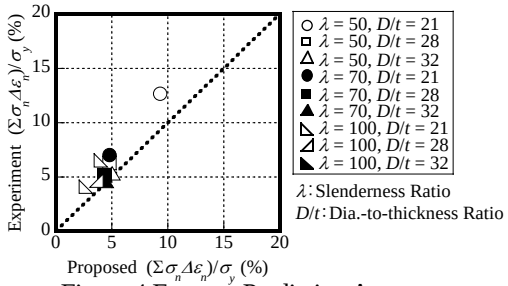

Figure 4 Fracture Prediction Accuracy

The strain in the hinge zone ε_h is expressed as the sum of overall and local buckling, as shown in Eq. (11):

$$\varepsilon_h = \frac{\varphi_h t}{2l_p\left(1-\frac{S_l}{Z_l}\right)} + \frac{\theta_{lb} D}{L\left(1-\frac{S}{Z}\right)} = \frac{3\sqrt{6}\varphi_h}{2\pi\sqrt{\frac{D}{t}}} + \frac{\theta_{lb} D}{L\left(1-\frac{\pi}{4}\right)} \quad (11)$$

where S_l and Z_l are the section modulus and plastic section modulus in the local buckling zone, respectively. Here, the local buckling zone is assumed to be rectangular, and the ratio of the abovementioned section moduli (S_l/Z_l) is 2/3. Thus, we assess the local strain in the local buckling zone before and during overall buckling, as well as that during the local buckling process. Therefore, the strain concentration ratio, α_c, is defined as shown in Eq. (12) at the bottom of this page. Here, ε_{cr} (= σ_{cr}/E) is the normalized axial deformation corresponding to overall buckling; σ_{cr}, the overall buckling stress; and E, the elastic modulus of steel. All the other variables used in this equation have been defined previously. Eq. (12) can be employed to calculate the local strain in the plastic hinge zone on the basis of the total normalized deformation. The strain concentration ratios increase drastically after local buckling and are large for specimens with a large diameter-to-thickness ratio; this trend is consistent with that observed in the experimental results. Figure 3 shows the plots drawn using the values calculated from Eq. (12) in accordance with the proposed method. These plots are in good agreement with those obtained by reconstituted micro-FEM analysis results as similar as Takeuchi and Suzuki et al. (2006) reported. By making use of this strain concentration ratio, the local strain transition can be evaluated from the ε_n value determined from Eqs. (3) and (4), and the instant of fracture can be determined by comparing the cumulative local plastic strain $\Sigma\Delta\varepsilon_{hp}$ and average plastic strain amplitude $\Delta\varepsilon_{hp}$ with the experimental fatigue curve as Eq. (13) (Saeki et al. 1995).

Table 1 Frame Type

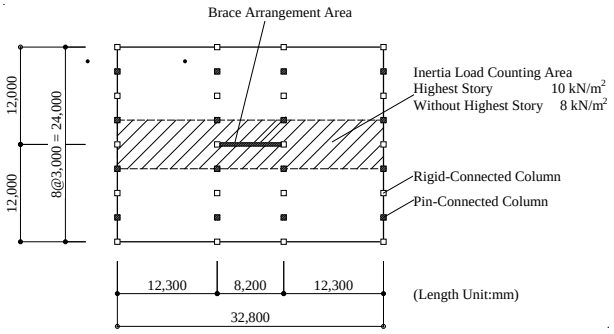

Figure 5 Typical Floor Plan of the Assumed Building

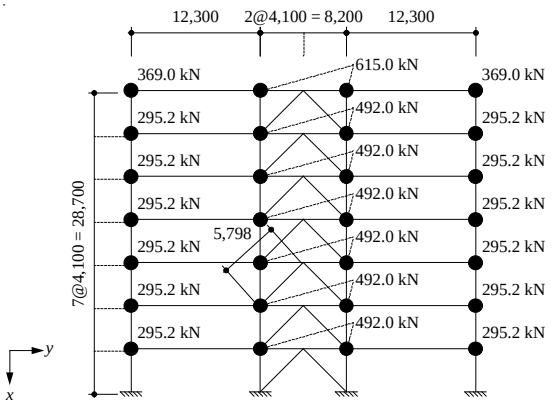

Figure 6 Assumed Inertia Load and Member Size

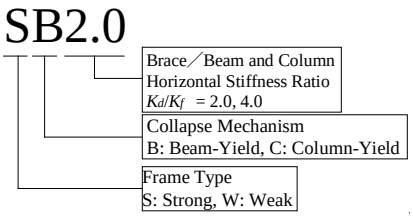

Figure 7 Frame Type Label

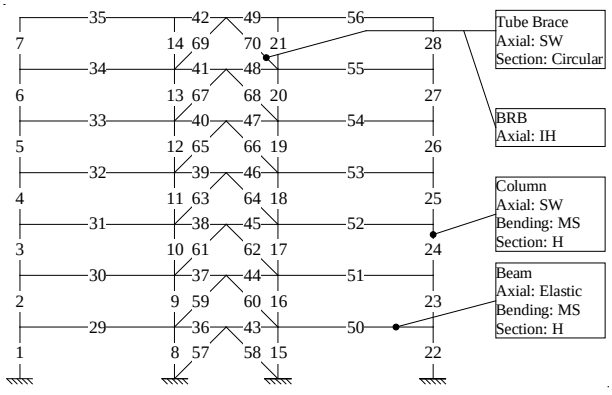

Figure 8 Frame-Member Number and Model

$$\alpha_c = \frac{\Delta\varepsilon_h}{\Delta\varepsilon_n} = \begin{cases} 1.0 & (\Delta\varepsilon_n < \varepsilon_{cr}, \text{ Prebuckling stage and tensile stage}) \\ \dfrac{\theta_h D}{L\left(1-\frac{\pi}{4}\right)\Delta\varepsilon_n} & (\varepsilon_{cr} < \Delta\varepsilon_n < \varepsilon_{lb}, \text{ Overall buckling stage}) \\ \dfrac{3\sqrt{6}\varphi_h}{2\pi\sqrt{\frac{D}{t}}\Delta\varepsilon_n} + \dfrac{\theta_{lb} D}{L\left(1-\frac{\pi}{4}\right)\Delta\varepsilon_n} & (\varepsilon_{lb} < \Delta\varepsilon_n, \text{ Local buckling stage}) \end{cases} \quad (12)$$

$$\sum \Delta\varepsilon_{hp} = 3857\overline{\Delta\varepsilon_{hp}}^{-1.13} \quad (13)$$

In Figure 4, the cumulative dissipation energy $\Sigma(\sigma_n \Delta\varepsilon_n/\sigma_y)$ determined from the proposed method is compared with the experimentally determined value. The estimates obtained by the proposed method are by and large consistent with the experimental results, and hence, this method is considered suitable for fracture prediction.

3. ANALYSIS MODEL OF BRACED FRAME

Figures 5 and 6 show a plane-frame model of a seven-story building with a rigid frame that includes braces. The black mark column in Figure 5 represents a pin-ended column that can support only the dead load, while the white mark column can withstand the dead load and the lateral seismic force; the plans of all the seven stories are designed to be similar. Thus, a dead load equivalent to that in one-half of the shaded area and an inertial mass equivalent to that in the shaded area are applied to the plane frame. The different types of models used in this study are listed in Table 1. The models are designated as SB, SC, WB, and WC; here, S, W, B, and C stand for high-strength frame, low-strength frame, beam-yield type, and column-yield type, respectively. The member size of the S-type frames is decided on the basis of the data available for normal buildings in Japan, while that of the W-type frames is decided from the data available for buildings in the United States. The plastic section modulus ratio, Z_{bp}/Z_{cp}, for the B-type frames is lesser than 1.0, while that for the C-type frames is greater than 1.0. Table 2 shows the frame parameters; the plastic section modulus of the S- and W-frames is set to 0.8 for the beam-yield type and 2.0 for the column-yield type. The lateral stiffness ratio between the brace and the frame, K_d/K_f, is set to 2.0 and 4.0 for the S- and W-type frames, respectively. Figure 7 shows the building types, and Table 3 lists the mechanical properties of steel. The natural period is in the range 0.72–1.08 s (0.025*H*–0.038*H*) for the S-type frame and 0.90–1.71 s (0.03*H*–0.06*H*) for the W-type frame (*H* denotes the building height in meters) as shown in Table 4. A circular-tube brace and a buckling-restrained brace (BRB) are used for the analysis. Here, the strength of a BRB pair is

equivalent to that of a circular-tube brace on the tensile side, and the instant of fracture for the BRB is defined on the basis of the method developed by Takeuchi and Ida et al (2008).

The member index and element type model for each frame are shown in Figure 8. A multi-spring element is added to both ends of the beam and column members, and the axial stiffness of all the members is defined on the basis of the numerical model proposed by Shibata and Wakabayashi (SW Model) as Figure 9; these members undergo fracture at the point where the cumulative value and average value of local strain calculated from Eq. (12) meets the fatigue curve of Eq. (13). After a given member is fractured, its stiffness decreases to 1/1000 of the original value and the stress reduces to 0. The multi-spring model (MS Model) is modeled from 16 elasto-plastic springs as Figure 10, and it plays the role of a plastic hinge when the spring at the end of the web undergoes plastic deformation, and the post-yield tangent modulus is approximately 1/60 of strain-hardening tangent modulus provided in Table 3. The hysteresis curve for the BRB is simulated by using the isotropic hardening model (IH Model) as Figure 11. Assuming the earthquake magnitude as 7, the input seismic acceleration is 2.5 times that of an artificial seismic wave BCJ-L2 developed by Building Center of Japan, as shown in Figure 12. The structural damping factor h has a value of 0.02 taking into account 1st and 2nd vibration mode as Rayleigh damping.

4. RESPONSE OF BRACED FRAME TAKING INTO ACCOUNT BRACE FRACTURE

4.1 Effect of Brace Fracture

The response behavior of the braced frame determined from the time-history response analysis (discussed in Section 3) is compared with that determined on the basis of a no

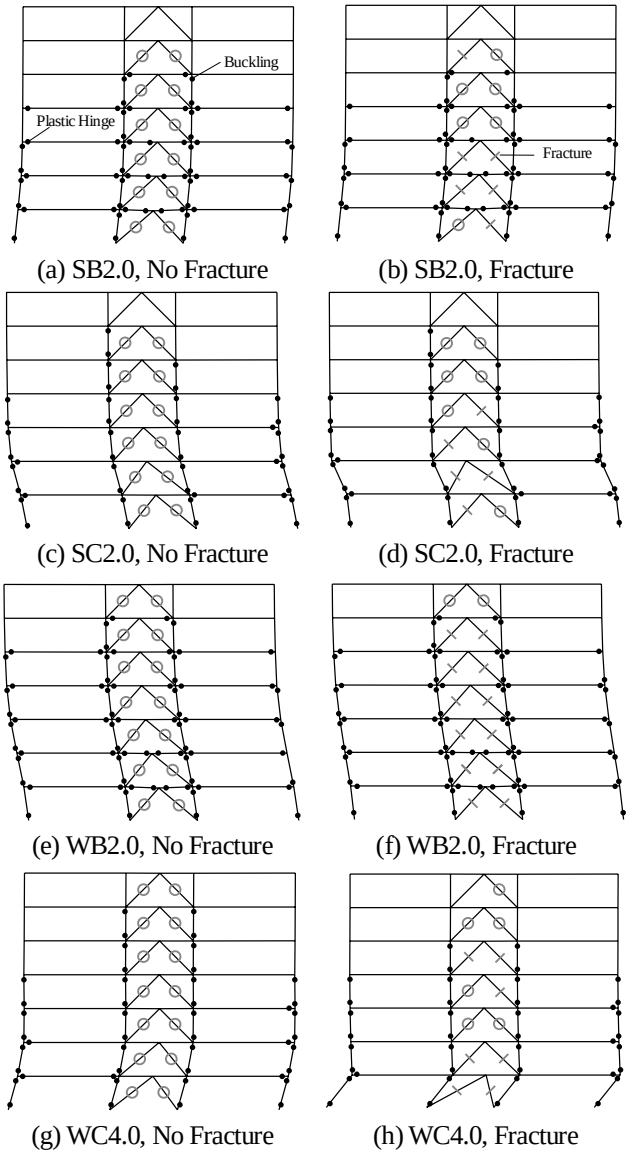

Figure 13 Collapse Mechanism

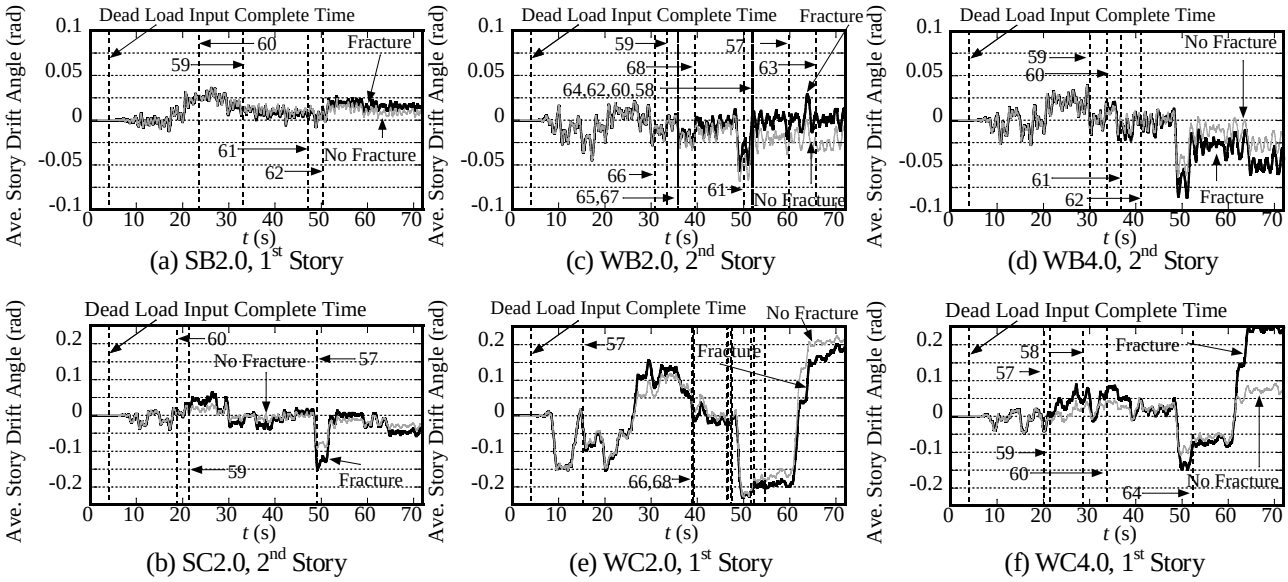

Figure 14 Average Story Drift Angle

fracture analysis, in which the effect of brace fracture is ignored. Figures 13 (a)–(h) show the models for the yielding mechanism, displacement response, and buckling and fracture braces. In this figure, the black points represent the plastic hinge, and the circles at the midpoint of the brace indicate buckling; further, the slash marks indicate the areas of fracture. Figure 14 shows that the time-history of the average story drift angle. SB2.0, which is shown in Figures 13(a) and (b), indicates that buckling occurs in 12 braces up to the first six stories and that six braces suffer fracture. However, there is no significant difference between the average story drift angle determined by the no fracture analysis and the fracture analysis. The collapse mode in SB2.0 is of the beam-yield type. The collapse mode of SB2.0 is dominated by the beam-yield since plastic hinge formation is initiated first at the beam ends and then at the column end. SC2.0 shown in Figures 13(c) and (d) indicates that the member number of the fracture brace is smaller than that of SB2.0. The average story drift angle in the second story is larger in the fracture analysis than in the no fracture analysis, and thus, the damage is concentrated in this story. The collapse mode of SC2.0 is dominated by the column-yield, and the main frame is almost elastic. The collapse mode of WC2.0 is dominated by the beam-yield, as in the case of SB2.0. The fracture-member number for WC2.0 is greater than that for SB2.0 and SC2.0. On the other hand, the difference between the average story drift angle determined by the no fracture and fracture analyses in this case is less significant than that in the case of SB2.0 and SC2.0. Figures 13(g) and (h) show the results obtained for WC4.0: all braces except for the 69th member undergo buckling, and seven braces up to the fifth story undergo fracture. The number of fracture braces in WC4.0 is greater than that in SC2.0. The average story drift angle in the fracture analysis is considerably larger than that in the no fracture analysis; further, according to the fracture analysis, the first story collapses. From the abovementioned observations, it is apparent that there is a significant difference between the behavior of the column-yield-type frames in the no fracture and fracture analyses and that the damage concentrates in a certain story.

4.2 Effect on Maximum Story Drift Angle

Models in which circular-tube braces are replaced with BRBs are studied. Figure 15 shows the maximum story drift angle in each case. The difference between the drift angle in the no fracture and fracture analyses is small in the case of SB2.0, as shown in Figure 15(a), and the maximum story drift angle of SB2.0 using BRB distributes more uniformly. In the case of SC2.0, the maximum story drift angle at the second story is 1.6 times higher in the fracture analysis than in the no fracture analysis, as shown in Figure 15(b). On the other hand, when a BRB is used for SC2.0, the damage at second story is reduced. The difference between the maximum story drift angle in the fracture and no fracture analyses is not very significant in the case of WB2.0, as shown in Figure 15(c), and the use of BRB for WB2.0 does not prevent damage concentration. However, the energy distribution determined by the fracture method differs significantly from that determined by the no fracture analysis. The difference between the maximum story drift angle in the case of WC2.0 is similar to that in the case of SC2.0, as shown in Figure 15(d). The difference between the maximum story drift angle determined by the no fracture and fracture analyses is more significant in the case of WB4.0 than in the case of WB2.0, as shown in Figure 15(e). In the case of WC4.0, the maximum story drift angle at the first story is dramatically higher in the fracture analysis than in the no fracture analysis, as shown in Figure 15(f).

4.3 Hysteresis in Each Member

Figure 16 shows the normalized force-deformation curves for the circular-tube brace and the BRB in a given story; these curves indicate a significant difference between the results of the no fracture and fracture analyses. Here, the normalized force is the value obtained when the force is divided by the initial section area. Brace energy dissipation

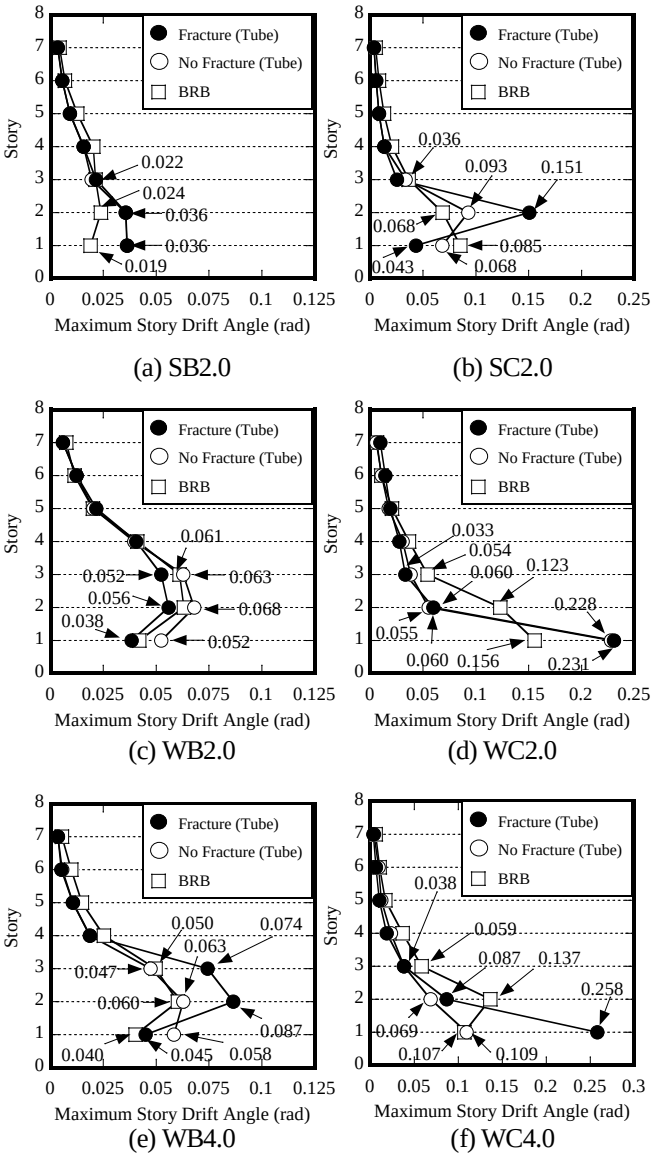

Figure 15 Maximum Story Drift Angle

ceases after the instant of fracture, as shown in Figures 16(a)–(d). Among these four cases, the difference between the results of the no fracture and fracture analyses is the most prominent for SC2.0, as shown in Figure 16(b). On the other hand, the hysteresis curve for the BRB represented in Figures 16(e) and (f) indicates the isotropic hardening behavior of SB2.0 and SC2.0; energy dissipation in the BRBs in these models is greater than that for the circular-tube brace. In addition, fracture does not occur in any of the BRBs in the models considered in this study.

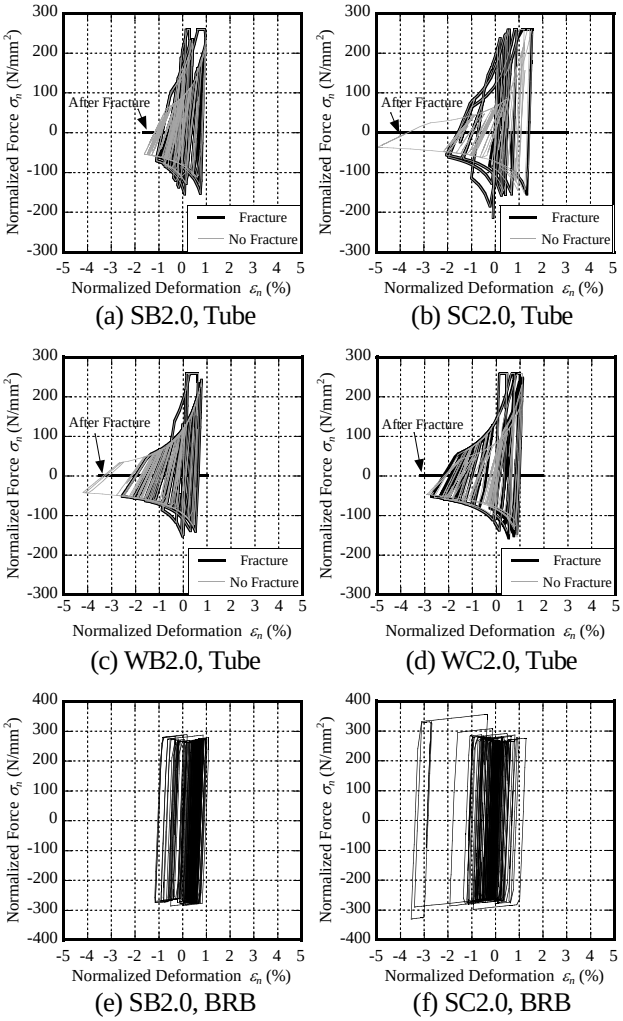

Figure 17 shows the relationship between the non-dimensional bending moment and the relative rotational angle for SB2.0, WC2.0, and WC4.0. The average bending moment M_{ave} and the relative rotational angle θ_{eq} are defined as shown in Eq. (14).

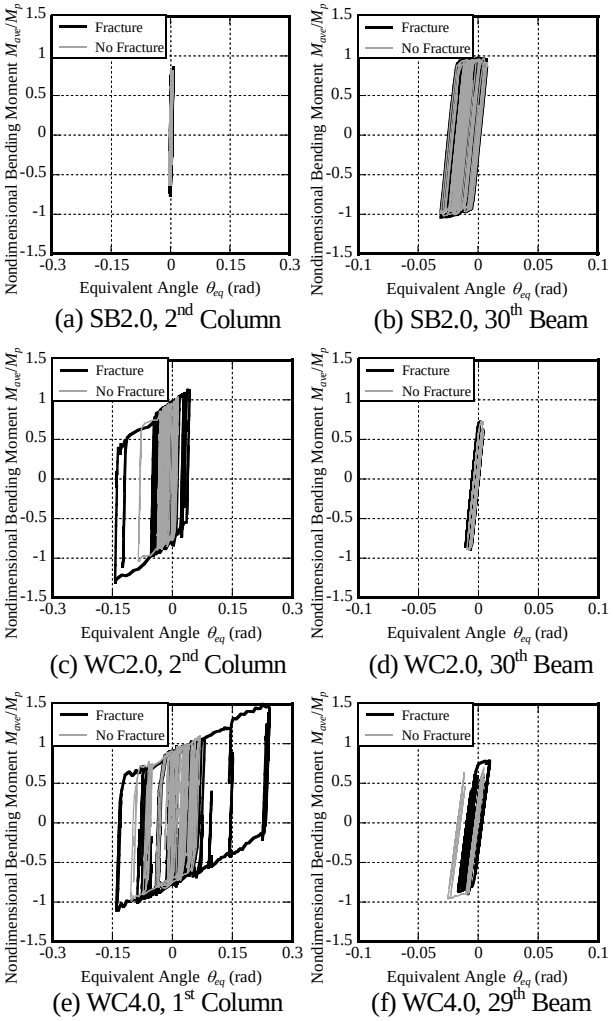
$$\begin{cases} M_{ave} = \dfrac{M_j + M_i}{2} \\ \theta_{eq} = \dfrac{\left(v_j - v_i\right)}{L} + \dfrac{\theta_j + \theta_i}{2} \end{cases} \tag{14}$$

Here, M_i and M_j are the bending moments; v_i and v_j, the transverse displacements; and θ_i and θ_j, the rotational angles at each end of the member. M_p is the plastic bending moment, which is defined as the product of the plastic section modulus and the yield stress. Since SB2.0 is of the beam-yield type, the energy dissipation in the beam is greater than that in the column, and the difference between the results of the no fracture and fracture analyses of the circular-tube braced frame is not significant as shown in Figures 17(a) and (b). On the other hand, since WC2.0 and WC4.0 are of the column-yield type, the energy dissipation in the column is considerably greater than that in the beam, as shown in Figures 17(c)–(f). From the calculation results, we come to the following conclusion: if the braced frame is of the column-yield type and the brace strength is high, the difference between the results of the no fracture and fracture analyses is significant.

5. EVALUATION OF ENERGY DISSIPATION PERFORMANCE OF BRACED FRAME ON THE BASIS OF BRACE FRACTURE

In this section, we describe the evaluation of the energy dissipation (CED) performance for each analysis case. The



(a) SB2.0, Tube (b) SC2.0, Tube

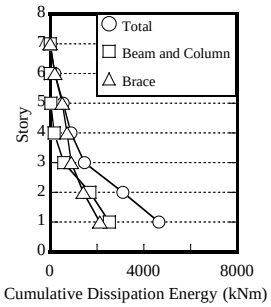
(c) WC2.0, 2nd Column (d) WC2.0, 30th Beam

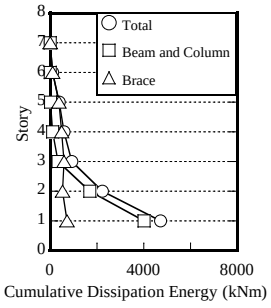
(e) WC4.0, 1st Column (f) WC4.0, 29th Beam

Figure 17 Beam and Column Hysteresis Curve



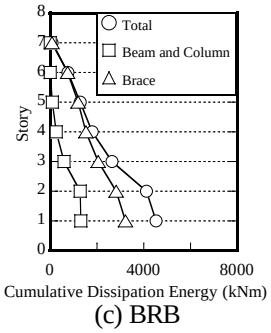
CED of the beam and column, W_{pf}, and that of the brace, W_{pb}, are defined as follows.

$$\begin{cases} W_{pf} = \int M_{ave}\theta_{eq}d\theta \\ W_{pb} = \int_V \sigma_{eq}\varepsilon_{eq}d\varepsilon_{eq} \end{cases} \quad (15)$$



The total CED is evaluated as the sum of W_{pf} and W_{pb}. Figures 18(a)–(c) show the effect of brace fracture on the CED in the case of WC4.0. Because the CED in the brace ceases after the instant of fracture, as shown in Figure 18(b), the CED for the beam and column determined by the fracture analysis is greater than that determined by the no fracture analysis, as shown in Figure 18(a). In contrast, the CED in the BRB is greater than that in the beam and column, and the CED distribution ratio for the beam and column is much lesser than that for the circular-tube braced frame. There is no notable difference between the total CED in the BRB frame at each story and that in the circular-tube braced frame; however, the energy dissipation in the BRB frame is more uniform than that in the circular-tube frame.

The CED distribution in the beam and column and that in the brace are shown in Figures 19(a)–(i). The CED distribution in the brace is not more than 30–40% of that in the circular-tube braced frame, as shown in Figures 19(a)–(f). In particular, in the case of WC4.0, the CED distribution estimated by the fracture analysis is markedly smaller than that determined by the no fracture analysis, indicating the collapse of the first or second story. In this case, the CED distribution in the beam and column determined by the fracture analysis increases and becomes 70–90% of that determined by the no fracture analysis.



The fatigue characteristic at the point of intersection of the beam and column indicate that an increase in the CED distribution in the beam and column may lead to fracture at the point of intersection and a consequent degradation of the seismic performance of the braced frame. On the other hand, the CED distribution in the brace is higher than that in the beam and column in the case of the BRB frame, and hence, very less damage is caused to the beam and column. The CED distribution in each frame is more uniform in the case

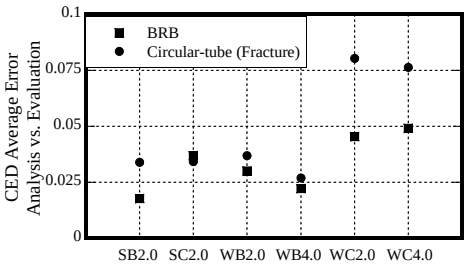

Figure 21 CED Average Errors
(Analysis vs Evaluation)

of WB2.0 and WC4.0 than in the case of WC2.0, at each story. There is no significant difference between the maximum story drift angle for the circular-tube braced frame and the BRB frame in the case of WB2.0; however, there is a significant difference between the CED distribution in the column and beam and that in the brace.

The damage distribution at each story is related to the CED. Akiyama (1999) proposed a method to predict the CED distribution. In the present study, the plastic level exceeds the allowable limit predicted on the basis of Akiyama's method.

For trial, we applied Akiyama's method to the frame result by taking into account the brace fracture. The CED distribution at each story is defined as shown in Eq. (16).

$$\frac{W_{pi}}{W_p} = \frac{s_i p_i^{-n}}{\sum_{j=1}^{N} s_j p_j^{-n}} \tag{16}$$

Here, W_{pi} is the CED at the i^{th} story, and W_p is the total CED of all the stories. n denotes the damage concentration index, whose value is 4 for the beam-yield type and 8 for the column-yield type. The values of s_i and p_i are calculated using Eq. (17).

$$\begin{cases} s_i = \left(\sum_{j=i}^{N} m_i \Big/ M \right) A_i \left(k_1 / k_i \right) \\ p_i = \left(\alpha_i / \alpha_1 A_i \right) \end{cases} \tag{17}$$

Here, M is the total mass; m_i, mass of the i^{th} story, α_i, the yield shear force coefficient; A_i, the shear force coefficient ratio; and k_i, the horizontal stiffness of the frame at each story.

The evaluated CED ratio values are plotted in Figure 20 (dashed line) along with the values calculated by the time-history response analysis. In the assumed building models, the damage is normally concentrated at the second story. In all the models, the evaluated CED ratio is smaller than that determined by the response analysis, and the accuracy of the evaluated value decreases up to the third story. This is because the stiffness and strength defined on the basis of the elastic situation are used for the evaluation. The CED average errors between the evaluated value and the response analysis value are compared, as shown in Figure 21. The CED average errors for the BRB frame are closer to 1.0 than is the value for the circular-tube braced frame, and thus, it apparent that the accuracy between the evaluated and response-analysis value is stronger for the BRB frame than for the ordinary braced frame. The accuracy for the column-yield-type frames is weaker than that for the beam-yield-type frames.

6. CONCLUSIONS

In this study, we carried out the time-history response analysis to determine the instant of brace fracture, on the basis of the strain concentration ratio, and investigate the dynamic behavior and energy response behavior of braced frames. Following are the conclusions of this study.

1) If the braced frame is of the column-yield type and the brace stiffness and strength are high, the damage concentrates at a certain story, and the maximum story drift angle response evaluated from the time-history analysis by taking into account brace fracture is significant higher than that in the no fracture case. Generally, the damage concentration is reduced when circular-tube braces are replaced with BRBs; however, in column-yield types, the use of BRBs does not guarantee damage mitigation. In this study, the braced frame is highly robust to damage when the strength of the beam and column is high and the braced-frame collapse is of the beam-yield type.

2) The maximum story drift angle for some BRBs is almost equal to that of a circular-tube braced frame. However, there is a significant difference between the energy dissipation distribution in the beam and column and that in the brace; as a result, the damage in the beam and column is mitigated.

3) The energy dissipation distribution in the assumed braced frames is evaluated by Akiyama's method; the estimation accuracy decreases owing to the effect of buckling and fracture. This is because the stiffness and strength are significantly different from those in the initial condition. On the other hand, the estimation accuracy for the BRB frames is lower than that for the circular-tube braced frame, and the evaluated value is effective in case of the beam-yield-type frames at a certain level.

4) The ultimate strength of a braced frame subjected to an extremely large earthquake can be assessed and compared with that determined by the proposed time-history analysis program.

Abstract: Synthetic earthquake ground motions are commonly used tools in earthquake engineering and hazard mapping. These ground motions are often generated to match the characteristics of recorded ground motions. In this paper, the effectiveness of multiple synthetic ground motions was evaluated based their similarity to recorded motions in inducing structure damage. Using a calibrated damage potential indicator, the damage potential of synthetic ground motions generated using four different physical models was compared to the historically recorded ground motions at corresponding sites. It was concluded that synthetic ground motions are able to produce damage to North American light frame wood buildings similar to that produced by their recorded counterparts; but the damage prediction potential varies with the generating model, target structural type, ground motion intensity, and site parameters.

1. INTRODUCTION

For a particular structure, the damage induced by an earthquake is a function of the ground motion, the building site, and the properties of the building system. One of the simplest indicators that combine ground motion intensities and building response characteristics is spectral acceleration at a building's natural period. Despite its wide use in design codes and simplified seismic calculations, spectral acceleration is most accurate for linear systems since it is developed using a linear oscillator and is not the best candidate for damage prediction of nonlinear systems (e.g. Elenas and Meskouris, 2001). Many past research studies have realized that in order to capture the damage to buildings caused by a given earthquake ground motion, nonlinear characteristics of the building should be taken into account (Krawinkler and Nassar, 1990, Atkinson and Goda, 2010, Sunasaka et al., 2003). Work by Bazzurro and Luco (2003) investigated non-stationary characteristics of seismic ground motion and concluded that a damage indicator that incorporates both ground motion and nonlinear building properties is desirable for quantifying the damage potential of ground motions.

Synthetic ground motion generation is an important component in seismic risk research, including seismic hazard mapping, because it supplements the relatively sparse worldwide database of strong ground motions. Recent mapping studies are moving beyond simply providing some measure of seismic intensity, and toward predicting building performance (e.g. Atkinson and Goda, 2010, Hall et al. 1995). Therefore it is important from an applicability standpoint that synthetic ground motions induce similar levels of damage to the built environment as do comparable recorded ground motions. A number of studies on generating synthetic ground motion have focused on characteristics of the generated ground motions themselves, essentially comparing waveforms and spectral acceleration (e.g. Hartzell et al., 2005, Frankel 2009, Liu et al. 2004, and Zeng et al. 1994). There have been studies that applied both synthetic and recorded ground motions in analysis of building structures (e.g. Jalayer et al. 2004), but to date there have been few direct comparisons of the damage caused to a particular building type as the result of recorded versus synthetic ground motions (e.g. Bazzurro et al. 2004). This relative absence provided the impetus for this study.

2. SYNTHETIC GROUND MOTION MODELS

Four synthetic ground motion models were investigated in this study. For simplicity, these models were named in this study after their authors as "Artf" for Frankel (2009), "Hart" for Hartzell et al. (2005), "Pliu" for Liu et al. (2004), and "Zeng" for Zeng et al. (1994). Detailed information about and suitable applications of these models can be found in the publications of the original studies. A brief comparison of the characteristics and properties of these models is presented in Table 1.

Table 1 Synthetic ground motion models

Synthetic motion model	Artf	Hart	Pliu	Zeng
Green's functions	Plane layered full wave theory at low frequencies; stochastic at high frequencies	Plane layered full wave theory	Plane layered full wave theory	Plane layered full wave theory
Source Distribution	Uniform size distribution; non-overlapping sources	Fractal size distribution; non-overlapping sources	Uniform size distribution; non-overlapping sources	Fractal size distribution; overlapping sources
Slip Distribution	k^{-2}, with x and y correlation lengths	k^{-2}, with variable corner wavelength	k^{-2}, with x and y correlation lengths and Cauchy amplitude distribution	Based on fractal size distribution and Brune (1970) model
Subevent Source Time Function	Brune (1970)	Brune (1970)	Functional form from dynamic models	Brune (1970)
Rupture Velocity	Secant rupture velocity with randomness	Secant rupture velocity with random subevent initiation points	Secant rupture velocity correlated with slip amplitude	Secant rupture velocity with random subevent initiation points
Local site and soil nonlinearity	DESRA2[b]	NOAHW[a]	NOAHW[a]	DESRA2[b]

Note: Local site and soil nonlinearity for each model was based on early works by (a) Bonilla et al. (1998), Hartzell et al. (2004), and (b) Lee et al. (1978) respectively.

Each of the models listed in Table 1 was used to generate ground motions at a series of earthquake recording stations for three earthquakes, including 17 stations for the 1999 Izmit earthquake in Turkey, 42 stations for the 1994 Northridge earthquake in California, USA, and 83 stations for the 1989 Loma Prieta earthquake in California, USA. Table 2 lists the basic properties of these earthquake events. The availability of historically recorded ground motions at these stations enabled a comparison between the generated and recorded motions. A total of 142 biaxial synthetic ground motion records were generated from each model. The vertical components were not considered in this study since horizontal components contribute to the majority of the lateral responses of civil engineering structures, which in turn leads to the majority of the damage.

Table 2 Earthquakes investigated in this study

Earthquake	Northridge	Loma Prieta	Izmit
	1994	1898	1999
Moment Magnitude	6.7	6.9	7.5
Recording stations	42	83	17
Strike	122	128	90
Dip	40	70	90
Rake	90	144	180
Fault Length (km)	20	40	160
Fault Width (km)	24	20	17
Depth of Hypocenter (km)	17.5	18	15.9

3. DAMAGE POTENTIAL INDICATOR

In this study, the equivalent oscillator for a building is defined as a Sdof elasto-plastic oscillator with unit mass and initial natural period equal to T from equation (1). The yielding force for the oscillator is the weight of the unit mass times Cs from equation (2). The damping ratio of 5% was used for all simulation. The benefit of using the seismic design parameters to construct equivalent oscillators is two-fold. Firstly, only minimal information related to the details of the building is required. Secondly, these parameters are relatively easy to estimate for existing and new buildings. An equivalent oscillator can be constructed as long as the building's structural type, height, and design ground motion information are known. Once the equivalent oscillator for the building type of interest was obtained, numerical integration was performed using the synthetic and recorded ground motions to find key Sdof oscillator responses. Adopting a format similar to the concrete damage index developed by Park and Ang (1985), the proposed damage potential indicator (DPI) can be written as

$$DPI = c_1 \frac{\Delta_m - \Delta_y}{(\mu - 1)\Delta_y} + c_2 \frac{E}{4F_y \mu \Delta_y} \quad \text{and} \quad 0 \le DPI \le 1 \qquad (1)$$

where Δ_m is the maximum displacement of the Sdof oscillator; Δ_y is the elastic displacement limit (yielding displacement); μ is the designated displacement ductility capacity for the structure type, defined as a ratio of a failure deformation to an elastic deformation limit. Note that although the equivalent Sdof oscillator does not incorporate ductility of the system it represents, the influence of system ductility in DPI calculation is accounted for through parameter μ; E is the total hysteresis energy dissipated by the Sdof oscillator; F_y is the yielding force for the Sdof oscillator; and c_1 and c_2 are the calibration coefficients for the DPI, which are determined (later in this paper) by comparing observed damage of a building and the DPI calculated using the corresponding equivalent Sdof oscillator.

The variability of ground motions, structural configurations, and quantification of observed damage makes it unrealistic to achieve a one-to-one mapping between a DPI and observed damage. However, it is reasonable to expect the proposed DPI to provide a consistent and strong correlation to observed structural damage. This can be achieved by calibrating the DPI coefficients (c_1 and c_2) using realistic structural damage data. In this study, the DPI calibration was focused on light-frame wood buildings through a verified damage index from an earlier study. That damage index was developed using data from tests of a full-scale, two-story light-frame wood townhouse building that took place at the University at Buffalo shake table (Filiatrault et al, 2010) as part of the NEESWood research project in 2006. The damage observed during the tests was recorded in detail following each shake and later a Park-Ang damage index model for the building and components was calibrated by Park and van de Lindt (2009). This damage index model was used in this study to generate damage indices of the townhouse building under a suite of earthquake ground motions. Then DPI for the same

suite of motions were calculated using equation (1) with varying c_1 and c_2 until maximum correlation between DPI and damage index was achieved. In the case of this wood frame building, based on the observation of the trend of correlation coefficient against varying calibration coefficients, eliminating the term associated with c_1 maximized the correlation. The DPI was then normalized by a constant so that the DPI's for all ground motion records that cause building collapse in the numerical analyses were greater than 1.0. Finally, the calibrated DPI in this study was:

$$DPI = 1.44\frac{E}{4F_y\mu\Delta_y} \quad \text{and} \quad 0 \le DPI \le 1 \qquad (2)$$

4. DPI FOR RECORDED AND SYNTHETIC GROUND MOTIONS

4.1 Delta-DPI Contour

Authors In order to identify the performance of the synthetic ground motions over a wide range of design configurations, DPI's were generated for various combinations of design base shear capacity (Cs) and natural period (Tn) over a structural "design space" (shown in Figure 1) to form a "DPI surface." It is expected that the same earthquake ground motion can have a significantly different damage potential for different design configurations. Although it would be ideal if the DPI for every point on the design space were calculated using a formula calibrated for that design configuration, this was not done here due to the lack of full-scale structural damage data (e.g. from shake table tests) for other types of building configurations. Thus Equation (2) was used to generate DPI's over the entire design space. The DPI surface was constructed for all synthetic and recorded ground motions.

Figure 1 shows the DPI surface for one of the recorded Northridge earthquake ground motions in this study. Inspection of Figure 1 shows that there is a failure plateau near the lower left corner where the design configuration is weak (low base shear capacity) and stiff (short period). The upper right corner represents strong and flexible designs (e.g. high-rise buildings), which had essentially no damage. In between, there is a band in the design space that experiences moderate damage. In this study, the projection of the DPI surface onto the Cs-Tn plane is termed the "DPI contour," as shown in Figure 1. Figure 2 shows the DPI contours for the synthetically-generated ground motions at the same site. Comparing the DPI contours for the recorded and synthetic motions, one can see that the performance of the synthetic models can be quite different depending on the location within the design space. For example, at point Tn=0.2, Cs=0.5 on the plot, the Artf model resulted in numerical failure of the structure, the Hart model produced virtually no damage, and the corresponding recorded ground motion produced moderate damage. However, because of the uncertain nature of seismic loading, the evaluation of synthetic ground motions should not be conducted based on only one ground motion, but rather should be (and will be) performed in a statistical sense using a suite of ground motions.

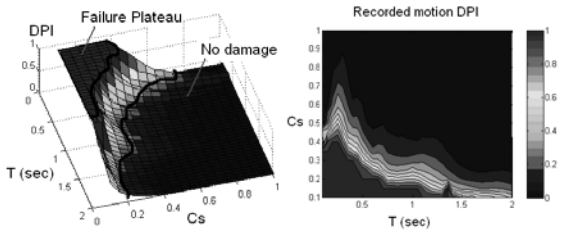

Figure 1 DPI surface and contour developed from a single recorded earthquake ground motion

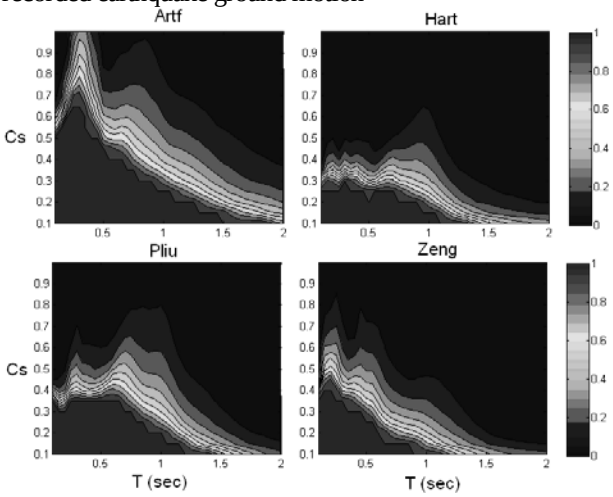

Figure 2 DPI contours for corresponding synthetic ground motion models

Using the recorded ground motions as the basis, the difference between the synthetic motion DPI and recorded motion DPI over the design space can be calculated. This value ranges from -1 to 1 and is termed herein the "Delta-DPI." Delta-DPI can be used as a measure of damage prediction accuracy for the synthetic ground motion generation models, with the damage induced by recorded ground motion as the reference point. If a model has a positive Delta-DPI, it suggests that the model would elicit more damage to the building than its recorded counterpart. On the other hand, a negative Delta-DPI indicates that the synthetic ground motion model would cause less damage to the structure than the corresponding recorded ground motion. The Delta-DPI was obtained and plotted for each of the four synthetic ground motion models in Figure 3 for one Northridge site using the data presented earlier in Figures 1 and 2.

With Delta-DPI as an indicator of a synthetic model's ability to induce damage to a building that is comparable to recorded ground motions, the effectiveness of the model may be assessed through a statistical evaluation of Delta-DPI for all sites investigated in this study. The mean and standard deviation of Delta-DPI for all 284 ground motion records is presented in Figures 4 and 5. The point P on the design space corresponds to the light-frame wood building used to calibrate DPI in this study.

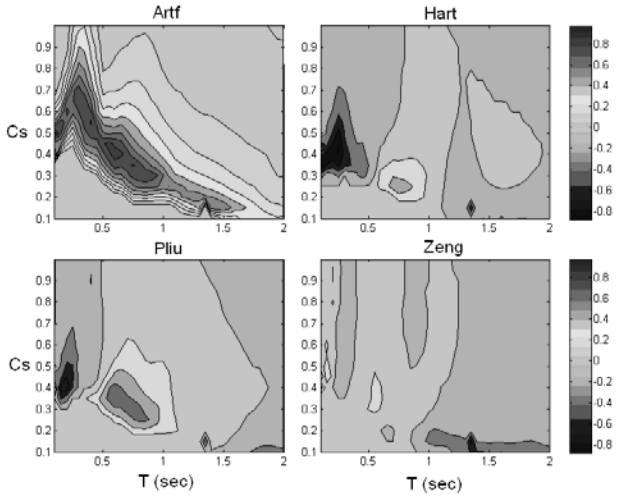

Figure 3 Delta-DPI contours for synthetic ground motion models

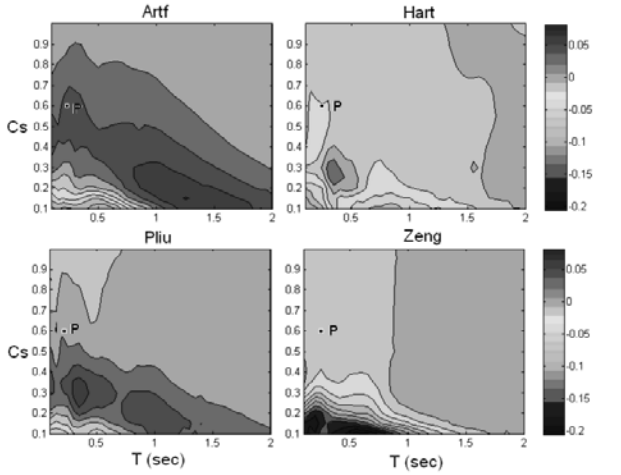

Figure 4 Mean of Delta-DPI for synthetic ground motion models (Point P represents NEESWood Benchmark building)

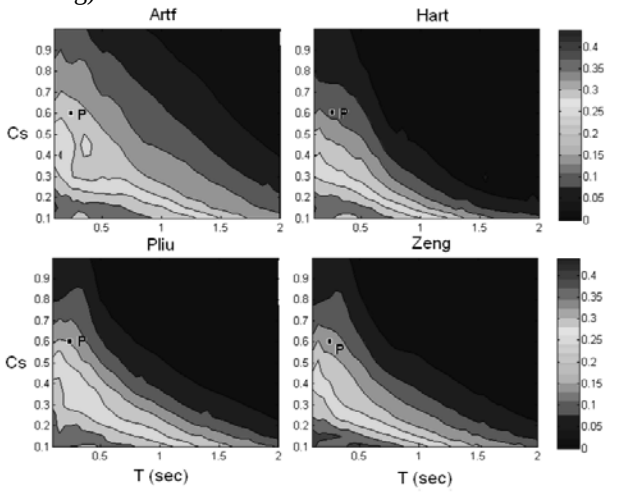

Figure 5 Standard Deviation of Delta-DPI for synthetic ground motion models (Point P represents NEESWood Benchmark building)

One can see from the Figures 7 and 8 that, on average, all the synthetic ground motions have Delta-DPI's that were fairly close to zero for most design combinations. Over-prediction was seen in limited regions of the design space for the Artf and Pliu models. The Zeng model was more likely than the other models to under-estimate damage for weak structural configurations. The variation, i.e. standard deviation, of Delta-DPI showed a constantly increasing trend as the design configuration moved towards weak and stiff (small Cs and natural period values) systems. For very weak buildings, the dispersion is close to 0.5. This indicates the building is so sensitive to the differences between ground motions that the induced damage can be quite different if the synthetic ground motion does not exactly match the actual ground motion. This is in fact not unexpected for these structural systems. Thus, it may be very difficult to use individual synthetic ground motion to reliably replicate damage to such structures from recorded ground motion.

4.2 Sensitivity to Wood Building Damage

Since the DPI used here was well calibrated for wood frame buildings, the performance of the synthetic ground motions for this building type was investigated in more detail. The purpose was to find out the accuracy of each synthetic generation model in reproducing recorded ground motion damage. Thus the Delta-DPI value for each ground motion was plotted against site or motion characteristics to identify impact of these characteristics to synthetic motion damage reproducing accuracy. Keep in mind that negative Delta-DPI indicates under-predicting real damage, positive values indicate over-predicting, and accurate damage prediction yields Delta-DPI equals to zero.

The relationship between Delta-DPI and source distance is shown in Figure 6 with scatter plots for the four synthetic ground motion models. One can see from the figure that model accuracy and distance are closely related. For ground motion sites over 30 km from the source, there is no difference between the DPI for the synthetic and recorded ground motions. For ground motions closer to the source, there is no clear trend of any specific model over- or under-predicting damage.

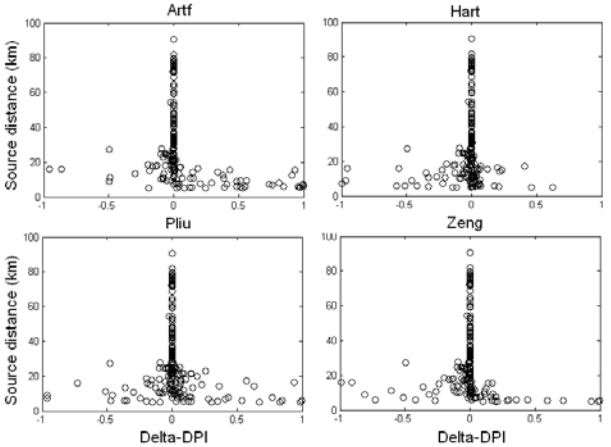

Figure 6 Relationship between Delta-DPI and source distance

Each ground motion site was assumed to be of a certain NEHRP site class as designated by the shear-wave velocity in the top 30 meters during the simulations of synthetic

ground motions. Overall, there are five site classes, namely B through E. In the scatter plots of site class versus Delta-DPI shown in Figure 7, each site class was assigned a number, with B equal to 2 and E equal to 5. The site class boundaries such as BC or DE were assigned numbers in between, i.e. 2.5 or 4.5.

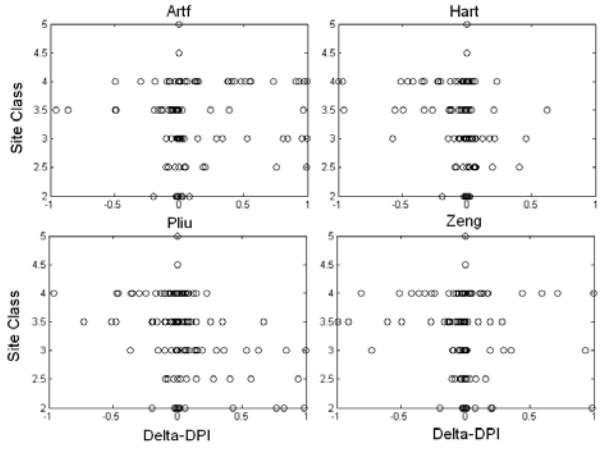

Figure 7 Relationship between Delta-DPI and site class

One can see from Figure 7 that some of the synthetic ground motion models perform differently across site conditions. The Hart and Pliu models in particular seem to show a higher possibility of over-predicting damage for site classes BC and C (2.5 and 3), but appear to under-predict for site classes CD and D (3.5 and 4). All of the models perform quite well for site class B. Although Figure 13 does not show significant dispersion in Delta-DPI for site classes DE and E, the number of such sites is too small to formulate a reliable conclusion.

A similar comparison was conducted for the level of spectral acceleration (Sa) at the building period (0.2 seconds, 5% damping). Note that the Sa values used here are from the recorded ground motions. Figure 8 shows the relationship between the site Sa and Delta-DPI. It can be seen that the stronger the ground motion, the more difficult it is to accurately replicate damage using the synthetic ground motions. It is interesting to see that all of the synthetic models over-predict damage when Sa is between 0.5 and 1.0 g. As the spectral acceleration increases above 1.0g, almost all of the models under-predict damage.

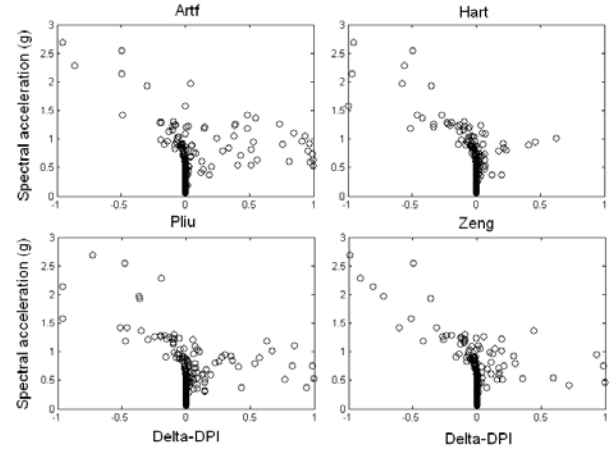

Figure 8 Relationship between Delta-DPI and Sa level

Another investigation related to the spectral acceleration parameter was conducted in this study by focusing on the ground motion sites at which the synthetic models accurately replicated (synthetic ground motion Sa within 15% of the recorded Sa value) the recorded Sa at the building period (0.2 sec). Only the ground motions with a Sa value greater than 0.5 g were considered here in order to eliminate the cases that would not cause any damage. By looking at Delta-DPI for the cases having Sa values close to those of the recorded ground motions, one can evaluate if matching the spectral acceleration at the building period will be sufficient produce synthetic ground motions with similar damage potential to recorded motions, albeit reasoning this with a single case. Figure 9 shows the CDF of the Delta-DPI for each model at the sites that have records generated with Sa values that were within 15% of the recorded motions. One can see that for most sites considered, the Delta-DPI for all models were close to zero, indicating good damage prediction accuracy especially for the Hart and Pliu models. However, some ground motions generated with model Artf and Zeng did not reproduce damage with reasonable accuracy even when the Sa at building period was matched quite well (within 15%) with their recorded counterparts. The reason for this difference was not investigated here due to the scope of the study.

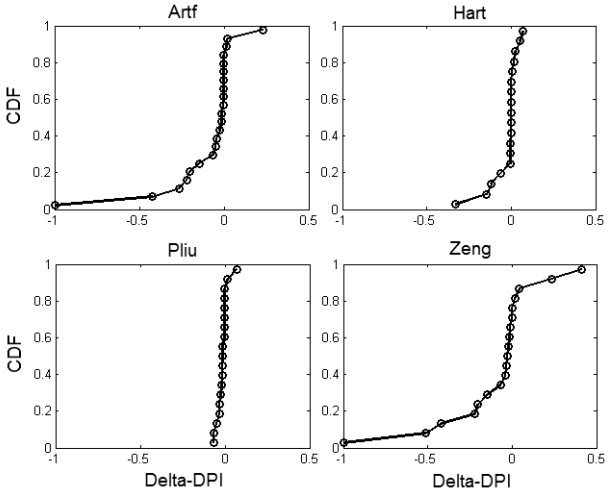

Figure 9 Distribution of Delta-DPI for synthetic motions with accurate Sa value at building period

3. CONCLUSIONS

Synthetic ground motions generated using four different models for three historical earthquakes were compared in this study based on their potential to induce damage in buildings. A damage potential indicator (DPI) that combines ground motion and building category characteristics was proposed and calibrated using damage observations from a shake table test of a full-scale wood frame structure. The proposed DPI utilizes structural parameters that are from widely adopted seismic design and evaluation standards, making the DPI a suitable candidate for general ground motion damage potential evaluation for various types of buildings. The DPI contours presented here provide a

comprehensive measure of damage potential for ground motions over a wide range of building types. Although the calibration of the proposed DPI to observed damage was limited to wood frame structures in this study, more representative DPI contours could be generated by following the same procedure using damage data for other structure types. Based on the DPI contours presented in this study, the following conclusions can be drawn related to the ability of the synthetic ground motion models to imitate the damage potential of their recorded counterparts:

Damage prediction using the synthetic ground motions is more accurate for buildings designed for significant lateral strength demands that thereby experience less ductility demand. Synthetic ground motions did not reliably predict damage to weak buildings; i.e. a high level of dispersion in the prediction was observed for such buildings.

For the three earthquake events simulated in this study, the performance of the four synthetic ground motion models was similar in that they all accurately predicted the damage potential for the majority of the sites, as compared to the recorded ground motions. However, the ability of each model to accurately predict damage at a particular site differs from model to model, especially for sites with higher ground motion intensities. At some sites (the overlapping sites in Groups A and C), the difficulty in predicting the damage potential is common to all the synthetic ground motion models investigated here, and appears to be related to the complexity and variability of ground motion close to faults.

Site-to-source distance is an important factor in the performance of the synthetic ground motions. Primarily due to ground motion attenuation and an escape from near-fault complexities, all of the models accurately predicted the damage potential for sites with distances greater than 30km. Site class seems to affect synthetic motion performance as well. More variability in synthetic motion accuracy was found for site classes C to E. This may be caused by the one-dimensional shear wave velocity models used in generating the synthetic motions, which may not account for distinct wave propagation effects at those sites, such as enclosed sedimentary basins. For all the synthetic models investigated in this study, the damage potential for sites with recorded spectral acceleration smaller than 0.5g was generally well predicted. The damage potential for sites in the approximate range of 0.5g<Sa<1.25g was over-predicted by the synthetic models and sites with Sa greater than 1.25g were typically under-predicted. Finally, matching synthetic motion spectral acceleration at the target building period with recorded ground motion appears to help achieve more accurate damage predictions for the synthetic motions. However, matching of Sa at the building period should not be used as the only procedure to achieve accurate damage prediction because some synthetic motions can produce significantly different damage even with a closely matched Sa to the recorded motions.

None of the synthetic ground motion models investigated in this study replicated the damage potential of the recorded ground motion completely. However, depending on the structure type and seismic design level of interest, some models did appear to perform better than others in certain circumstances. The proposed procedure provided another way to evaluate the effectiveness of synthetic ground motion models once details for their application was provided.

SEISMIC DESIGN OF HIGHWAY BRIDGES IN CALIFORNIA

Lian Duan

Senior Bridge Engineer, California Department of Transportation, Sacramento, California, USA
lian_duan@dot.ca.gov

Abstract: This paper presents an overview of the *Seismic Design Criteria* (SDC) and the *Guide Specifications for Seismic Design of Steel Bridges* (Guides) developed by California Department of Transportation (Caltrans). Caltrans SDC and Guides are based on required seismic performance criteria, displacement-based approach and capacity design concept. All ordinary standard bridges designed in accordance with SDC and Guides are expected to remain standing but may suffer significant damage requiring closure during the design earthquake. Important and nonstandard bridges are designed in accordance with project-specific design criteria. Structural components are classified as *Ductile* and *Capacity-protected*. Inelastic deformations are generally expected in substructure components which are identified and detailed for ductile response. Inelastic behavior in the form of controlled flexural damage may be permitted in some of the steel superstructure components such as end cross frames, shear keys and bearings to prevent damage in other parts of structures. Capacity-protected components are designed to resist the force demands determined from the overstrength capacity of ductile components connected. Details such as seat width, bearing assemblies, beam-joints and connections, reinforcement confinements, end cross frames, limiting slenderness ratios, are properly designed to ensure continuity of load path during earthquake and to ensure the design objectives are achieved.

1. INTRODUCTION

Prior to the 1989 Loma Prieta earthquake, highway bridges in California were typically designed using a single-level force-based design approach based on a "no-collapse" design philosophy. Seismic loads were determined based on a set of soil conditions and a suite of four site-based standard Acceleration Response Spectra (ARS). Structures were analyzed using the three-dimensional elastic dynamic multi-modal response spectrum method. Structural components were designed by using a reduction *Z*-factor to reduce seismic forces for ductility and risk. Minimum transverse reinforcement confinements were required.

Since 1989, the design criteria specified in California Department of Transportation (Caltrans) Bridge Design Specifications (Caltrans, 1990) and several design manuals (Caltrans, 2010a and 2010b) have been updated continuously to reflect recent research findings and development in the field of seismic bridge design. Caltrans has been shifting toward a displacement-based design approach. ATC (1996) published the improved seismic design criteria recommendations for California bridges in 1996. Caltrans published the performance and displacement-based Seismic Design Criteria (SDC), which focuses mainly on concrete bridges in 1999 (Caltrans 1999a), with the current version 1.6 (Caltrans, 2010c). The Caltrans Guide Specifications for Seismic Design of Steel Bridge (Caltrans 2001) was published in 2001. Significant advances in earthquake engineering have been made during the last 20 years.

This paper first presents seismic bridge design philosophies and concepts in general, and then presents effective details for seismic design of highway bridges used in Caltrans practice.

2. SEISMIC PERFORMANCE AND DESIGN PHOLISOPHY

Caltrans seismic performance criteria (Caltrans 2010a) shown in Table 1 includes bridge category, post earthquake damage and service levels for two seismic hazard levels.

A bridge is classified as "**Important**" when it meets one of the following:

- Required to provide post earthquake life safety; such as access to emergency facilities.
- Time for restoration of functionality after closure would create a major economic impact.
- Formally designated as critical by a local emergency plan.

A bridge is classified as "**Ordinary**" when it is not classified as an important bridge.

For Standard "Ordinary" bridges, the displacement-based one-level safety-evaluation design ("no-collapsed" design) is only required in the Caltrans SDC (Caltrans, 2010c). For non-standard "Ordinary" bridges featuring irregular geometry and framing (multi-level, variable width, bifurcating, or highly horizontally curved

superstructures, different structure types, outriggers, unbalanced mass and/or stiffness, high skew) and unusual geologic conditions (soft soil, moderate to high liquefaction potential and proximity to an earthquake fault), project specific criteria need to be developed and approved to address their non-standard features.

For "Important" bridges, the performance-based project-specific criteria are required to be developed. The performance-based criteria usually require two-level design. The first level of design is to ensure the performance (service) of a bridge in earthquake events that have relatively small magnitude but may occur several times during the life of the bridge. The second level of design is to achieve the performance (no collapse) of a bridge under the severe earthquakes that have only a small probability of occurring during the useful life of the bridge. The performance-based criteria shall include guidelines for development of site-specific ground motion estimates, capacity design to preclude brittle failure modes, rational procedures for joint shear design in concrete and the definition of limit states for various performance objectives. Several criteria (Caltrans 1997, 1999b, IAI 1995) have been developed and implemented for the design and retrofitting of important bridges by California bridge engineers.

Table 1 Caltrans Seismic Performance Criteria

Bridge Category	Seismic Hazard Evaluation Level	Post Earthquake Damage Level	Post Earthquake Service Level
Important	Functional	*Minimum*	*Immediate*
	Safety	*Repairable*	*Limited*
Ordinary	Safety	*Significant*	*No Collapse*

Functional Level Evaluation: A project specific hazard level will be developed in consultation with the Seismic Safety Peer Review Panel as defined in MTD 20-16. Ordinary Bridges are not designed for Functional Evaluation Seismic Hazards.

Safety Level Evaluation: For Ordinary Bridges, this is the "Design Earthquake" as defined below. For Important Bridges, the safety evaluation ground motion has a return period of approximately 1000-2000 years.

Design Earthquake is the collection of seismic hazards at the bridge site used in the design of bridges. The Design Earthquake" consists of the Design Spectrum as design in the SDC Version 1.5 Appendix B and may include other seismic hazards such as in liquefaction, lateral spreading, surface faulting and tsunami.

Damage Levels:

- *Minimal:* Essentially elastic performance.
- *Repairable:* Damage that can be repaired with a minimum risk of losing functionality.

Significant: A minimum risk of collapse, but damage that could require closure to repair.

Service Levels:

- *Immediate:* Full access to normal traffic is available almost immediately following the earthquake.
- *Limited:* Limited access (e.g. reduced lanes, light emergency traffic) is possible with days of the earthquake. Full service is restorable within months.
- *No Collapse:* There may be no access following the earthquake.

3. SEISMIC LOADS

For Ordinary Bridges, Safety-Evaluation ground motion is presented by the Design Response Spectrum, the envelope of a deterministic and probabilistic spectrum Figure 1 shows a set of the horizontal Design Response Spectrum. When the bridge site peak rock acceleration is 0.6g or greater, an equivalent static vertical uniform load equal to 25% of the dead load shall be applied upward and downward to the superstructure to estimate the effects of vertical acceleration.

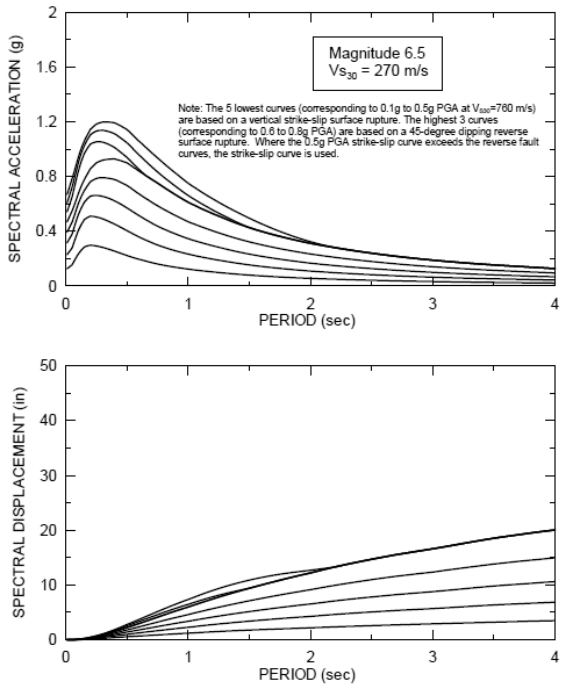

Figure 1. Spectral Accelration and Displacement for V_{30} = 270 m/s (M = 6.5)

For structures within 25 km from an active fault, the spectral ordinates of the appropriate standard Response Spectrum curves shall be modified by a near-fault adjustment factor as shown in Figure 2.

4. GENERAL SEISMIC PROVISIONS

For Ordinary bridges, structural members are identified as either ductile or capacity-protected members. A ductile member is a member that is intentionally well designed to deform inelastically for several cycles without significant degradation of strength or stiffness under the design earthquake. On the other hand, a capacity-protected member is a member that is expected to behave essentially elastic. The preferable ductile members on most bridges shall be limited to pre-determined locations within the bridge that can be easily inspected and repaired following an earthquake and may include columns, pier walls, backwalls, wingwalls,

seismic isolation and damping devices, bearings, shear keys and steel end diaphragms.

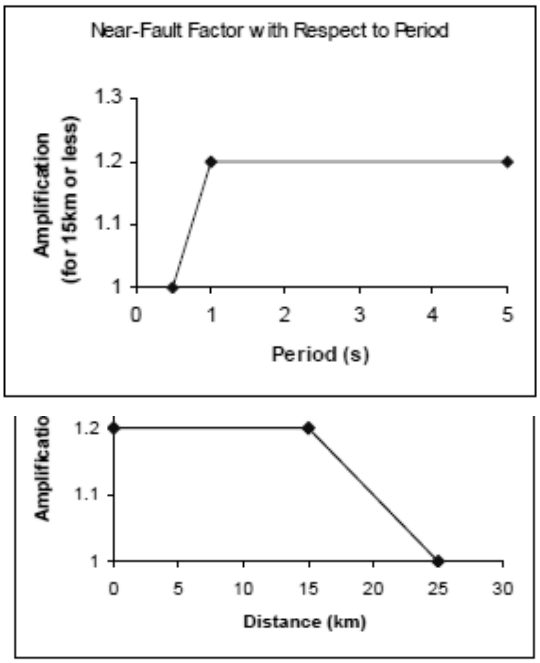

Figure 2. Near-Fault Adjustment Factor

The displacement-based design approach is used to ensure that the structural system and its individual members have enough displacement capacities to withstand the deformation imposed by the design earthquake. The capacity design concept is used to ensure all other elements not explicitly designed as ductile or sacrificial to be capacity protected such that they remain essentially elastic. This procedure has been used widely in seismic bridge design in California since 1994. Figure 3 shows the design flowchart for the ordinary standard bridges.

4.1 Global Displacement

The displacements of the global bridge system and the frame shall satisfy the following requirement:

$$\Delta_D \leq \Delta_C \quad (1)$$

where Δ_D is displacement demand determined by the global analysis, the stand alone analysis, or the larger of the two if both types of analyses are necessary; Δ_C is displacement capacity when any plastic hinge capacity reaches its ultimate capacity.

4.2 Local Displacement Ductility Capacity

To ensure the dependable ductile behavior of all columns regardless of seismic demand, a minimum local displacement ductility capacity of $\mu_c = \Delta_c/\Delta_Y \geq 3$ is required, and target local ductility of $\mu_c \geq 4$ is recommended. The local displacement ductility capacity shall be calculated for an equivalent member that approximates a fixed base cantilever element.

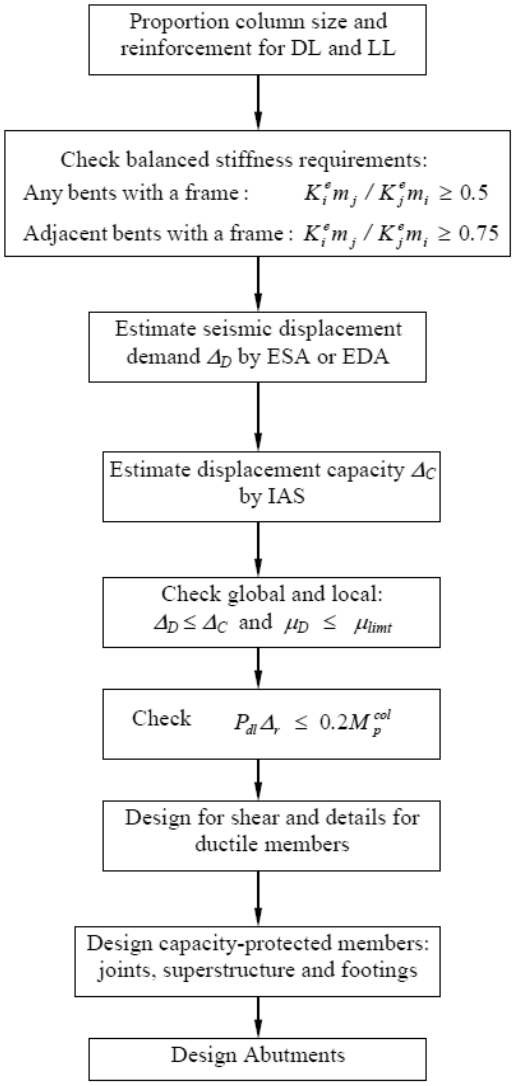

Figure 3. Caltrans Seismic Design Procedure for Ordinary Standard Bridges

4.3 Target Displacement Ductility Demand

The engineers are encouraged to limit displacement ductility demands, defined as $\mu_D = \Delta_D/\Delta_Y$ to the following limits which were calibrated to laboratory tests:

- Single Column Bents supported on fixed foundation $\mu_D \leq 4$
- Multi-Column Bents supported on fixed or pinned footings $\mu_D \leq 5$
- Pier Walls (weak direction) supported on fixed or pinned footings $\mu_D \leq 5$
- Pier walls (strong direction) supported on fixed or pinned footings $\mu_D \leq 1$

4.4 Force
